HIV infection/AIDS is a global pandemic, with cases reported from virtually every country. The current estimate of the number of cases of HIV infection among adults

worldwide is approximately 33 million, two-thirds of whom are in sub-Saharan Africa; 47% of cases are women. In addition, an estimated 1.3 million children under 15 are living with HIV/AIDS. The global distribution of these cases is illustrated in Fig. 309-9. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), in 1999 alone there were an estimated 5.4 million new cases of infection worldwide (more than 15,000 new infections each day) and 2.8 million death from AIDS, making it the fourth leading cause of mortality worldwide. The estimated number of AIDS-related deaths worldwide through the year 2000 is illustrated inFig. 309-10. The HIV epidemic has occurred in "waves" in different regions of the world, each wave having somewhat different characteristics depending on the demographics of the country and region in question and the timing of the introduction of HIV into the population. As noted above, different subtypes, or clades, of HIV-1 are prevalent in different regions of the world (see above andFig. 309-7), increasing the difficulty in the development of vaccines and perhaps accounting for different degrees of virulence. It is unlikely that a single vaccine will be applicable to all regions of the world. In this regard, in addition to HIV-1 subtype B, the predominant subtype in the United States, HIV-1 subtypes A, AE, AG, C, D, and O have been detected in individuals in the United States, as might be expected given the degree of international travel that occurs.

Table 309-3 provides the statistics and demographic features of HIV/AIDS in different regions of the world. Although the epidemic was first recognized in the United States and shortly thereafter in western Europe, it very likely began in sub-Saharan Africa (see above), which has been particularly devastated by the epidemic, with the prevalance of infection in many cities in the double digits. According to the United Nations Population Division, by the year 2015 life expectancy in the nine countries in Africa with the highest HIV prevalence rates will fall, on average, 17 years. In certain sub-Saharan African countries such as Zimbabwe and Botswana, available seroprevalence data indicate >25% of the adult population aged 15 to 49 is HIV-infected. In addition, among high-risk individuals (e.g., commercial sex workers, patients attendingSTDclinics) who live in urban areas of sub-Saharan Africa, seroprevalence is now>50% in many countries. The epidemic in Asian countries, particularly India and Thailand, has lagged temporally behind that in Africa; however, the number of new cases in this region is accelerating rapidly, and the magnitude of the epidemic is projected to exceed that of sub-Saharan Africa in the early part of the twenty-first century. The estimated number of cases in China is still relatively small; however, the potential exists for a major expansion of the epidemic in that nation of over 1 billion people.

The major mode of transmission of HIV worldwide is unquestionably heterosexual sex; this is particularly true and has been so since the begining of the epidemic in developing countries, where the numbers of infected men and women are approximately equal. The epidemic in most developed countries was first introduced among homosexual men and, to a greater or lesser degree (depending on the individual country), amongIDUs. In this regard, the total numbers of AIDS cases in those countries still reflect a high proportion of cases among these high-risk groups. However, in most developed countries, including the United States (see below), there has been a gradual shift such that among new cases of AIDS, there is a greater prevalence among heterosexuals and IDUs than among homosexual men.

AIDS IN THE UNITED STATES

AIDS has had and will continue to have an extraordinary public health impact in the United States. As of January 1, 2000, >724,600 cumulative cases of AIDS had been reported in adults and adolescents in the United States (Table 309-4) and approximately 425,000 AIDS-related deaths had been reported. It is the fifth leading cause of death among Americans aged 25 to 44 (Fig. 309-11), having dropped from first within the past few years. The death rate from AIDS declined 42% from 1996 to 1997 and 18% from 1997 to 1998. This trend is due to several factors including the improved prophylaxis and treatment of opportunistic infections, the growing experience among health professions in caring for HIV-infected individuals, improved access to health care, and the decrease in infections due to saturational effects and prevention efforts. However, the most influential factor clearly has been the increased use of potent antiretroviral drugs, generally administered in a combination of three or four agents, usually including a protease inhibitor (see below). When one looks at the totality of data collected from the beginning of the epidemic, approximately one-half of cases are among men who have had sex with men. However, over the past few years, the numbers of newly reported cases of AIDS among other groups, includingIDUs and heterosexuals, have surpassed the numbers of newly reported cases among men who have had sex with men. The proportion of new cases of AIDS per year attributed to heterosexual contact has increased dramatically over the past 15 years in the United States (Fig. 309-8). Women are increasingly affected; the proportion of AIDS cases in the United States reported among adult and adolescent females has increased from <5% to 24% from 1985 to 1998 (Fig. 309-8). Most cases of transmission by injection drug use and heterosexual contact are reported from the northeast and southeast regions of the country, particularly among minorities. HIV infection and AIDS have disproportionately affected minority populations in the United States. The rates of AIDS cases per 100,000 population reported among adults and adolescents in 1999 were 84.2 for African Americans, 34.6 for Hispanics, 9.0 for whites, 11.3 for American Indians/Alaska Natives, and 4.3 for Asian/Pacific Islanders (Fig. 309-12).

As of January 1, 2000, 8718 cases of AIDS in children <13 years old had been reported, and approximately 60% of these children have died (Table 309-5). Approximately 90% of these children were born to mothers who were HIV-infected or who were at risk for HIV infection and, in approximately 60% of those cases, the mother was either anIDU or the heterosexual partner of an IDU. About 42% of women with AIDS have become infected through injection drug use, compared to 22% of men with AIDS; 40% of women have become infected by heterosexual contact, compared to 4% of men with AIDS. Only 1% of AIDS cases are among hemophiliacs, and 1% are among recipients of blood transfusions, blood products, or transplanted tissue. The relative contribution of the latter groups will gradually decrease, even though individuals infected previously through this mode of transmission will continue to develop AIDS. The risk of additional infections via this mode of transmission in the United States is extremely small (see above). In recent years, the incidence of AIDS has decreased considerably, with ~46,000 new cases in 1999 compared to ~60,000 in 1996. This trend likely reflects both reduced infection rates since the mid-1980s; more widespread use of prophylactic therapies, which delay the onset of AIDS; and the use of highly effective antiretroviral therapy early in the course of HIV infection (see below). Also, the demography of newly infected individuals has changed considerably since the mid-1980s (see below).

HIV PREVALENCE AND INCIDENCE IN THE UNITED STATES

It is estimated that between 650,000 and 900,000 adults and adolescents in the United States are living with HIV infection, including 120,000 to 160,000 women. This estimate results in an overall nationwide prevalence of HIV infection of approximately 0.3%. Prevalence is highest among young adults in their late twenties and thirties and among minorities. An estimated 3% of black men and 1% of black women in their thirties are living with HIV infection. The number of new infections per year is estimated to be approximately 40,000, and this number has remained stable for at least 9 years. The estimated proportion of HIV infections has declined among white males, especially those >30, while the proportion of new HIV infections appears to have increased among women and minorities. Among newly infected persons in the United States, ~70% are men and ~30% are women (Fig. 309-13). Of these newly infected individuals, half are <25 years. Of new infections among men, the CDC estimates that ~60% were infected through homosexual sex, 25% through injection drug use, and 15% through heterosexual sex. Of new infections among women, ~75% were infected through heterosexual sex and 25% through injection drug use.

HIV infection and AIDS are widespread in the United States; although the epidemic on the whole is plateauing, it is spreading rapidly among certain populations, stabilizing in others, and decreasing in others. Similar to otherSTDs, HIV infection will not spread homogeneously throughout the population of the United States. However, it is clear that anyone who practices high-risk behavior is at risk for HIV infection. In addition, the alarming increase in infections and AIDS cases among heterosexuals (particularly sexual partners ofIDUs, women, and adolescents) as well as the spread in certain inner city areas (particularly among underserved minority populations with inadequate access to health care) testifies to the fact that the epidemic of HIV infection in the United States is a public health problem of major proportions.

PATHOPHYSIOLOGY AND PATHOGENESIS

The hallmark of HIV disease is a profound immunodeficiency resulting primarily from a progressive quantitative and qualitative deficiency of the subset of T lymphocytes referred to as *helper T cells*, or *inducer T cells*. This subset of T cells is defined phenotypically by the presence on its surface of the CD4 molecule (Chap. 305), which serves as the primary cellular receptor for HIV. A co-receptor must also be present together with CD4 for efficient fusion and entry of HIV-1 into its target cells (Figs. 309-3 and309-4). HIV uses two major co-receptors for fusion and entry; these co-receptors are also the primary receptors for certain chemoattractive cytokines termed *chemokines* and belong to the seven-transmembrane-domain G protein-coupled family of receptors. CCR5 and CXCR4 are the major co-receptors used by HIV (see above and below). Although a number of mechanisms responsible for cytopathicity and immune dysfunction of CD4+ T cells have been demonstrated in vitro, particularly direct infection and destruction of these cells by HIV (see below), it remains unclear which mechanisms or combination of mechanisms are primarily responsible for their progressive depletion and functional impairment in vivo. When the number of CD4+ T cells declines below a certain level (see below), the patient is at high risk of developing a variety of opportunistic diseases, particularly the infections and neoplasms that are AIDS-defining illnesses. Some features of AIDS, such asKS and neurologic abnormalities (see below),

cannot be explained completely by the immunosuppressive effects of HIV, since these complications may occur prior to the development of severe immunologic impairment.

The combination of viral pathogenic and immunopathogenic events that occurs during the course of HIV disease from the moment of initial (primary) infection through the development of advanced-stage disease is complex and varied. It is important to appreciate that the pathogenic mechanisms of HIV disease are multifactorial and multiphasic and are different at different stages of the disease. Therefore, it is essential to consider the typical clinical course of an untreated HIV-infected individual in order to more fully appreciate these pathogenic events (Fig. 309-14).

PRIMARY HIV INFECTION, INITIAL VIREMIA, AND DISSEMINATION OF VIRUS

The events associated with primary HIV infection are likely critical determinants of the subsequent course of HIV disease. In particular, the dissemination of virus to lymphoid organs is a major factor in the establishment of a chronic and persisent infection (see below). The initial infection of susceptible cells may vary somewhat with the route of infection. Virus that enters directly into the bloodstream via infected blood or blood products (i.e., transfusions, use of contaminated needles for injecting drugs, sharp-object injuries, maternal-to-fetal transmission either intrapartum or perinatally, or sexual intercourse where there is enough trauma to cause bleeding) is likely cleared from the circulation to the spleen and other lymphoid organs, where it replicates to a critical level and then leads to a burst of viremia that disseminates virus throughout the body. It is uncertain which cell in the blood or lymphoid tissue is the first to actually become infected; however, studies in animal models suggest that dendritic lineage cells may be the initial cells infected. Depending on their stage of maturation, dendritic cells can either be directly infected with virus and pass virus on to CD4+ T cells or physically bring the virus into contact with CD4+ T cells without themselves becoming infected. Studies in the monkey model of mucosal exposure toSIVstrongly suggest that the initial cell to become infected at the site of exposure is the Langerhans cell, which is a dendritic lineage cell, and that this cell passes the virus on to CD4+ T cells in the draining lymph nodes. This mechanism likely operates in humans when HIV enters "locally" (as opposed to directly into the blood), via the vagina, rectum, or urethra during intercourse or via the upper gastrointestinal tract from swallowed infected semen, vaginal fluid, or breast milk. Certainly, CD4+ T cells and to a lesser extent cells of monocyte lineage are the major ultimate targets of HIV infection. In primary HIV infection, virus replication in CD4+ T cells intensifies prior to the initiation of an HIV-specific immune response (see below), leading to a burst of viremia (Fig. 309-14) and then to a rapid dissemination of virus to other lymphoid organs, the brain, and other tissues. Individuals who experience the "acute HIV syndrome," which occurs to varying degrees in approximately 50% of individuals with primary infection, have high levels of viremia that last for several weeks (see below). The acute mononucleosis-like symptoms are well correlated with the presence of viremia. Virtually all patients appear to develop some degree of viremia during primary infection, which contributes to virus dissemination, even though they remain asymptomatic or do not recall experiencing symptoms. Careful examination of lymph nodes from more than one site in patients with established HIV infection who did not report symptoms of a primary infection strongly indicate that wide dissemination to lymphoid tissue occurs in most patients. A more detailed description of the role of lymphoid tissue in the immunopathogenesis of HIV

disease is given below. It appears that the initial level of plasma viremia in primary HIV infection does not necessarily determine the rate of disease progression; however, the set point of the level of steady-state plasma viremia after approximately 1 year does seem to correlate with the rapidity of disease progression (see below).

ESTABLISHMENT OF CHRONIC AND PERSISTENT INFECTION

Persistent Virus Replication HIV infection is relatively unique among human viral infections. Despite the robust cellular and humoral immune responses that are mounted following primary infection (see below), once infection has been established the virus is virtually never cleared completely from the body. Rather, a chronic infection develops that persists with varying degrees of virus replication for a median of approximately 10 years before the patient becomes clinically ill (see below). It is this establishment of a chronic, persistent infection that is the hallmark of HIV disease. Throughout the often protracted course of chronic infection, virus replication can almost invariably be detected in untreated patients, both by highly sensitive assays for plasma viremia as well as by demonstration of virus replication in lymphoid tissue. In human viral infections, with very few exceptions, if the host survives, the virus is completely cleared from the body and a state of immunity against subsequent infection develops. HIV infection very rarely kills the host during primary infection. Certain viruses, such asHSV(Chap. 182), are not completely cleared from the body after infection, but instead enter a latent state; in these cases, clinical latency is accompanied by microbiologic latency. This is not the case with HIV infection, in which some degree of virus replication invariably occurs during the period of clinical latency (see below). Chronicity associated with persistent virus replication can also be seen in certain cases of hepatitis B and C infections (Chap. 297); however, in these infections the immune system is not a target of the virus. As mentioned above, HIV usually does not abruptly kill the host; rather it generally succeeds in escaping from a rather vigorous immune response and establishing a state of chronic infection with varying degrees of persistently active virus replication.

Evasion of Immune System Control Clearly, HIV successfully evades elimination by the immune system in order to establish chronicity. The mechanisms whereby this occurs are not completely clear; however, several have been proposed as playing a role in this phenomenon. HIV has an extraordinary ability to mutate, but this mechanism probably acts mainly after the establishment of chronic infection and contributes to the maintenance of chronicity. Since the transmitted virus and the virus that initially becomes established as a chronic infection are relatively homogeneous, the initial escape from immune system control likely involves mechanisms other than viral mutation. Molecular analysis of clonotypes has demonstrated that clones of CD8+ cytolytic T lymphocytes (CTLs) that expand greatly during primary HIV infection and likely represent the high-affinity clones that would be expected to be most efficient in eliminating virus-infected cells are no longer detectable after their initial burst of expansion. The marked diminution of frequency or disappearance of these HIV-specific cells cannot be explained by mutations in the viral epitope to which they are directed, since virus-sequencing studies indicate that the initial viral epitope is still present when the clones are no longer detected. Furthermore, other, less expanded clones of CD8+ T cells that recognize the same viral epitope persist and likely account for the partial control of virus replication. It is thought that the initially expanded clones may have been deleted owing to the overwhelming exposure to viral antigens during the initial burst of

viremia, similar to the exhaustion of CD8+ CTLs that has been reported in the murine model of lymphocytic choriomeningitis virus (LCMV) infection. To compound this phenomenon, virus replication and thus saturation of antigen-presenting cells with viral antigen take place in the lymphoid tissue (see below), which is also the site of generation of HIV-specific CTLs.

Another potential mechanism of HIV escape is related to the fact that, during primary HIV infection and the transition to established chronic infection, both activated HIV-specificCTLs and CTL precursors are preferentially and paradoxically segregated in the peripheral blood, where very little active virus replication takes place, rather than in the lymphoid tissue, which is the main site of virus replication and spread, and the major source of plasma viremia. Finally, the escape of HIV from elimination during primary infection allows the formation of a large pool of latently infected cells that cannot be eliminated by virus-specific CTLs (see below). Thus, despite a potent immune response and the marked downregulation of virus replication following primary HIV infection, HIV succeeds in establishing a state of chronic infection with a variable degree of persistent virus replication. In most cases, during this period the patient makes the clinical transition from acute primary infection to a relatively prolonged state of clinical latency (see below).

Reservoir of Latency Infected Cells It has been clearly demonstrated that there exists in virtually all HIV-infected individuals a pool of latently infected, resting CD4+ T cells, and that this pool of cells likely serves as at least one component of the persistent reservoir of virus. Such cells manifest postintegration latency in that the HIV provirus integrates into the genome of the cell and can remain in this state until an activation signal drives the expression of HIV transcripts and ultimately replication-competent virus. This form of latency is to be distinguished from preintegration latency, in which HIV enters a resting CD4+ T cell and, in the absence of an activation signal, only a limited degree of reverse transcription of the HIV genome occurs. This period of preintegration latency may last hours to days, and if no activation signal is delivered to the cell, the proviral DNA loses its capacity to initiate a productive infection. If these cells do become activated, reverse transcription proceeds to completion and the virus continues along its replication cycle (see above and Fig. 309-15). The pool of cells that are in the postintegration state of latency are established early during the course of primary HIV infection. Despite the suppression of plasma viremia to below detectable levels (<50 copies of HIV RNA per milliliter) by potent combinations of several antiretroviral drugs for as long as 3 years, this pool of latently infected cells persists and can give rise to replication-competent virus. This persistent pool of latently infected cells is a major obstacle to any goal of eradication of virus from infected individuals.

Viral Dynamics It was originally thought that very little virus replication occurred during clinical latency. However, studies of lymphoid tissue usingPCRanalysis for HIV RNA and in situ hybridization for individual virus-expressing cells clearly demonstrated that HIV replication occurs throughout the course of HIV infection, even during clinical latency when it is very difficult to culture virus from unfractionated peripheral blood mononuclear cells. The availability of sensitive PCR techniques led to the demonstration that some degree of plasma viremia is present in virtually all untreated patients at all stages of HIV disease. Subsequently, the dynamics of viral production and turnover were quantified using mathematical modeling in the setting of the administration of reverse transcriptase

and protease inhibitors to HIV-infected individuals in clinical studies. Treatment with these drugs resulted in a precipitous decline in the level of plasma viremia, which typically fell by 99% within 2 weeks. The number of CD4+ T cells in the blood increased concurrently, which implies that the killing of CD4+ T cells is linked directly to the levels of replicating virus. However, it is generally agreed that a significant component of the early rise in CD4+ T cell numbers following the initiation of therapy is due to the redistribution of cells into the peripheral blood from other body compartments. It was determined on the basis of the emergence of resistant mutants during therapy that 93 to 99% of the circulating virus originated from recently infected, rapidly turning over CD4+ T cells and that approximately 1 to 7% of circulating virus originated from longer-lived cells, likely monocyte/macrophages. A negligible amount of circulating virus originated from the pool of latently infected cells (see above) (Fig. 309-16). It was also determined that the half-life of a circulating virion was approximately 30 min and that of productively infected cells was 1 day. Given the relatively steady level of plasma viremia and of infected cells, it appears that extremely large amounts of virus (approximately 10_{10} to 10_{11}virions) are produced and cleared from the circulation each day. In addition, data suggest that the minimum duration of the HIV-1 replication cycle in vivo averages 1.5 days. Other studies have demonstrated that the decrease in plasma viremia that results from antiretroviral therapy correlates closely with a decrease in virus replication in lymph nodes, further confirming that lymphoid tissue is the main site of HIV replication and the main source of plasma viremia. Using a mathematical formula that assumed a two-phase decay of virus-infected cells, it was originally estimated that virus could be eradicated within 2.3 to 3.1 years from an HIV-infected individual who was receiving antiretroviral therapy that successfully suppressed all virus replication. However, recent data taking into account the pool of latently infected cells (see above) indicate that there is a third, much longer phase of decay that results in a projected time to viral eradication ranging from 10 to 60 years. Concomitant with this finding was the realization that even the most potent combinations of antiretroviral drugs did not completely suppress virus replication, as indicated by the detection of variable degress of cell-associated HIV RNA by sensitive PCR assays in most patients despite the absence of detectable plasma virema. Therefore, it is highly unlikely that virus will be eradicated from HIV-infected individuals with the currently available antiretoviral drugs despite the favorable clinical outcomes that have resulted from such therapy (see below).

The level of steady-state viremia, called the viral *set point*, at approximately 1 year has important prognostic implications for the progression of HIV disease. It has been demonstrated that HIV-infected individuals who have a low set point at 6 months to 1 year progress to AIDS much more slowly than individuals whose set point is very high at that time (Fig. 309-17). Levels of viremia generally increase as disease progresses. Measurement of the level of viremia is playing an increasingly important role in guiding therapeutic decisions in HIV-infected individuals (see below).

Immunopathogenic Events during Clinical Latency With few exceptions, the level of CD4+ T cells in the blood decreases gradually and progressively in HIV-infected individuals. The slope of this decline, together with the level of plasma viremia (see above), predict well the pattern of the clinical course and the development of advanced disease. Most patients are entirely asymptomatic while this progressive decline is taking place (see below) and are often described as being in a state of *clinical latency*. However, clinical latency does not mean disease latency, since progression is generally

relentless during this period. Furthermore, clinical latency should not be confused with microbiologic latency. Although there are cells present in an infected individual that are latently infected and do not express detectable viral RNA, there is virtually always some degree of ongoing virus replication, even during the early stages of HIV disease.

ADVANCED HIV DISEASE

In untreated patients or in patients in whom therapy has not adequately controlled virus replication (see below), after a variable period, usually measured in years, the CD4+ T cell count falls below a critical level (<200 cells per microliter), and the patient becomes highly susceptible to opportunistic disease (Fig. 309-14). For this reason, theCDC case definition of AIDS was modified to include all HIV-infected individuals with CD4+ T cell counts below this level (Table 309-1). Patients may experience constitutional signs and symptoms or may develop an opportunistic disease abruptly without any prior symptoms, although the latter scenario is unusual. The depletion of CD4+ T cells continues to be progressive and unrelenting in this phase. It is not uncommon for CD4+ T cell counts to drop as low as 10/uL or even to zero, yet the patients may survive for months or even for >1 year. This situation has become increasingly common as patients are treated more aggressively and are given prophylaxis against the common life-threatening opportunistic infections (see below). In addition, control of plasma viremia by antiretroviral therapy, even in individuals with extremely low CD4+ T cell counts, has increased survival in these patients despite the fact that their CD4+ T cell counts may not significantly increase as a result of therapy. Ultimately, patients who progress to this severest form of immunodeficiency usually succumb to opportunistic infections or neoplasms (see below).

LONG-TERM SURVIVORS AND LONG-TERM NONPROGRESSORS

The median time from primary HIV infection to the development of AIDS in untreated individuals is approximately 10 years. Treatment with effective combinations of antiretroviral drugs has clearly extended this period; the full extent of this benefit has yet to be realized. The definitions of *long-term survivor* and *long-term nonprogressor* continue to evolve as more data are collected from prospective cohort studies. Predictions from one study that antedated the availability of effective antiretroviral therapy estimated that approximately 13% of homosexual/bisexual men who were infected at an early age may remain free of clinical AIDS for >20 years. Currently, individuals are considered to be long-term survivors if they remain alive for 10 to 15 years after initial infection. In most such individuals the disease has progressed, in that they have significant immunodeficiency, and many have experienced opportunistic diseases. Some of these individuals have CD4+ T cell counts that have decreased to £200/uL but have remained stable at that level for years. The mechanisms of this stabilization are not entirely clear but may relate to the beneficial effects of antiretroviral therapy and prophylaxis against opportunistic infections. In addition, a number of viral and/or host determinants likely contribute to the long-term survival of these individuals. In some individuals, the virus may either have been less virulent initially or may have mutated to a less virulent form under the influence of antiretroviral therapy. Quantitative and qualitative aspects of the HIV-specific immune response, as well as recognized and unrecognized genetic factors (see below), may also contribute to the long-term survival of these individuals.

Fewer than 5% of HIV-infected individuals are characterized as long-term nonprogressors. All long-term nonprogressors are long-term survivors; however, the reverse is not true. Individuals who have been infected with HIV for a long period (10 years), whose CD4+ T cell counts are in the normal range and have remained stable over years, and who have not received antiretroviral therapy are considered to be long-term nonprogressors. These patients are characterized by a low viral burden (low number of HIV-infected cells), low levels of plasma viremia, generally normal immune function according to commonly measured parameters (skin tests, in vitro lymphocyte responses to various mitogens and antigens), and normal-appearing lymphoid tissue architecture as determined on lymph node biopsy. In general, long-term nonprogressors manifest robust HIV-specific immune responses, both humoral (neutralizing antibodies) and cell-mediated (HIV-specificCTLs). However, this may also be true of some individuals early in the course of disease who ultimately progress to advanced disease. Although viremia is consistently very low in long-term nonprogressors, many have persistent viremia as determined by sensitivePCRassays. No qualitative abnormalities in the virus have been detected in most of these patients. However, a small subset of patients do have defective virus; in particular, in one cohort of five long-term nonprogressors, the virus had a defect in the *nef* gene. In another report, a blood donor in Australia who was HIV-infected and a group of seven individuals who were infected by blood or blood products from that donor remained free of HIV-related disease and maintained normal and stable CD4+ T cell counts for several years after infection. Sequence analysis of viruses isolated from the donor and recipients revealed similar deletions in the *nef* gene and the region of overlap of *nef* and the U3 region of the HIV long terminal repeat (Fig. 309-5). However, several of these individuals have now begun to show indications of progressive immunodeficiency, and thus they can no longer be considered nonprogressors. The precise role of host factors in long-term nonprogression remains unclear. There is no obvious and consistent genetic determinant for nonprogression. However, several genetic mutations have been demonstrated to result in a delay in the progression of HIV disease. These include heterozygosity for the *CCR5*-D32 deletion, heterozygosity for the *CCR2*-64I mutation, homozygosity for the *SDF1*-3¢A mutation, and heterozygosity for the *RANTES-28G* mutation (see "Genetic Factors in HIV Pathogenesis," below). Since CCR5 is the major co-receptor for R5 or macrophage-tropic strains of HIV and since individuals who are homozygous for the *CCR5*-D32 deletion are, with rare exceptions, protected against HIV infection, the potential mechanism for slow progression in heterozygotes is clear. In addition, certain single nucleotide polymorphisms in the *CCR5* promoter have been shown to be associated with slower progression of disease. The reason for the slowing of progression of HIV disease in individuals who are heterozygous for the *CCR2*-64I mutation is less clear; however, it has been demonstrated that CXCR4 can dimerize with the CCR2V64I mutant but not with wild-type CCR2. This dimerization may reduce the amount of CXCR4 on the cell surface and as a result inhibit infection with X4 viruses. Homozygosity for the *SDF1*-3¢A mutation may upregulate the *SDF1* gene enabling SDF-1, which is the natural ligand for CXCR4, to compete more effectively with X4 or T cell tropic virus for the CXCR4 coreceptor. The *RANTES-28G* mutation increases RANTES expression, which is the natural ligand for CCR5 and may thus inhibit infection with R5 viruses. Finally, maximal HLA heterozygosity of class I loci (A, B, and C) has been shown to be associated with delayed progression of HIV disease. Although long-term nonprogressors have robust HIV-specific immune responses as well

as competent CD8+ T cell suppressors of HIV replication, it is unclear whether these factors are directly responsible for the state of nonprogression. A substantial proportion of HIV-infected individuals manifest comparable immune responses early in the course of their disease and still experience disease progression. Long-term nonprogressors likely represent a heterogeneous group. The lack of disease progression may be explained in some by a defect in the virus; in others by any of a variety of host factors, including recognized and as yet unrecognized genetic factors; and in others by a combination of both.

ROLE OF LYMPHOID ORGANS IN HIV PATHOGENESIS

Lymphoid tissues are the major anatomic sites for the establishment and propagation of HIV infection (see above). For practical reasons, most studies on the pathogenesis of HIV infection have focused on peripheral blood mononuclear cells. However, lymphocytes in the peripheral blood represent only approximately 2% of the total body lymphocyte pool and so may not always accurately reflect the status of the entire immune system; most of the body's lymphocytes reside in lymphoid organs, such as the lymph nodes, spleen, and gut-associated lymphoid tissue. Furthermore, virus replication occurs mainly in lymphoid tissue and not in blood; the level of plasma viremia reflects virus production in lymphoid tissue. Finally, since HIV disease is an infectious disease of the immune system, it is critical to appreciate the pathogenic events that occur in the lymphoid tissue in HIV infection.

Some patients experience progressive generalized lymphadenopathy (see below) early in the course of the infection; others experience varying degrees of transient lymphadenopathy. Lymphadenopathy reflects the cellular activation and immune response to the virus in the lymphoid tissue, which is generally characterized by follicular or germinal-center hyperplasia. Lymph node involvement is a common denominator of virtually all patients with HIV infection, even those without easily detectable lymphadenopathy.

Simultaneous examination of lymph node and peripheral blood in the same patients during various stages of HIV disease, including the early asymptomatic stage (when CD4+ T cell counts generally are >500/uL), the intermediate stage (when counts are usually 200 to 500/uL) and the advanced stage (when counts are<200/uL) has led to substantial insight into the pathogenesis of HIV disease. Using a combination ofPCRtechniques for HIV DNA and RNA in tissue and RNA in plasma, in situ hybridization for HIV RNA, and light and electron microscopy, the following picture has emerged. In most untreated patients, early in the course of infection when the viral set point has been reached and prior to significant immunodeficiency (CD4+ T cell counts >500/uL), levels of plasma viremia are variable but generally low; the viral burden (number of infected cells) in the peripheral blood is usually extremely low, and expression of HIV in these cells is minimal or undetectable. Remarkably, at this time copious amounts of extracellular virions are trapped on the processes of the follicular dendritic cells (FDCs) in the germinal centers of the lymph nodes (Fig. 309-18*A*). In situ hybridization reveals expression of virus in individual cells of the paracortical area and, to a lesser extent, the germinal center (Fig. 309-18*B*). The number of cells expressing virus is low early in the course of disease and increases as disease progresses. Examination of lymph nodes during primary HIV infection in humans (see above) and

SIVinfection in macaques indicates that during the transition from primary infection to established chronic infection, germinal centers form and virus is trapped. This trapping, together with the generation of a vigorous HIV-specific immune response, likely contributes to the rapid decrease in plasma viremia seen in most patients following the initial burst of viremia associated with primary infection. A considerable amount of virus can be trapped during the period of high viremia associated with primary infection. The persistence of trapped virus after chronic infection likely reflects a steady state whereby trapped virus turns over and is replaced by fresh virions, which are produced persistently, albeit usually at low levels during the early, clinically latent stage of disease.

During early-stage HIV disease, the architecture of the germinal centers is generally preserved and may even be hyperplastic owing to in situ proliferation of cells (mostly B lymphocytes) and recruitment to the lymph nodes of a number of cell types (B cells, CD4+ and CD8+ T cells). Electron microscopy demonstrates a fine network ofFDCswith many long, finger-like processes that envelop virtually every lymphocyte in the germinal center (Fig. 309-18*C*). Extracellular virions can be seen attached to the processes, yet the FDCs appear to be relatively healthy. The trapping of antigen is a physiologically normal function for the FDCs, which present antigen to B cells and contribute to the generation of B cell memory. However, in the case of HIV, the trapped virions serve as a persistent source of cellular activation, resulting in the secretion of proinflammatory cytokines such as interleukin (IL) 1b, tumor necrosis factor (TNF)a, and IL-6, which can upregulate virus replication in infected cells (see below). Furthermore, although trapped virus is coated by neutralizing antibodies, it has been demonstrated that these virions remain infectious for CD4+ T cells while attached to the processes of the FDCs. CD4+ T cells that migrate into the germinal center to provide help to B cells in the generation of an HIV-specific immune response thus are susceptible to infection by these trapped virions. Thus, in HIV infection, a normal physiologic function of the immune system, which contributes to the clearance of virus as well as to the generation of a specific immune response, can also have deleterious consequences. It is difficult to demonstrate infection of the FDCs at this point, or even in advanced disease; however, rare examples of virus budding off FDCs have been reported.

As the disease progresses, the architecture of the germinal centers begins to show disruption, and the trapping efficiency of the lymph node diminishes. Electron microscopy reveals swollen organelles, and theFDCsbegin to undergo cell death. The mechanisms of FDC death remain unclear; there is no indication by electron microscopy of copious virus replication or budding of virions off the cell in great quantities. At this stage, the level of plasma viremia generally increases. In addition, both the relative number of infected cells in the blood and the expression of virus from these cells increases, approaching the levels in the lymph nodes. As the disease progresses to an advanced stage, there is complete disruption of the architecture of the germinal centers, accompanied by dissolution of the FDC network and massive dropout of FDCs (Fig. 309-18*D*). The trapping function of the lymph nodes is completely lost, and virus freely spills out into the circulation. SimultaneousPCRanalysis of lymph node and peripheral blood mononuclear cells indicates that the relative number of infected cells in the blood and their expression of virus begin to equal the levels in the lymph nodes at this stage. Advanced disease is accompanied by high levels of plasma viremia, which represent a true increase in virus replication, due in part to a further diminution of immune control of

virus replication (see below) as well as to the loss of the mechanical trapping function of the lymph nodes. At this point, the lymph nodes are "burnt out." This destruction of lymphoid tissue compounds the immunodeficiency of HIV disease and contributes to the inability to mount adequate immune responses against opportunistic pathogens. The events from primary infection to the ultimate destruction of the immune system are illustrated inFig. 309-19.

ROLE OF CELLULAR ACTIVATION IN HIV PATHOGENESIS

The immune system is normally in a state of homeostasis, awaiting perturbation by foreign antigenic stimuli. Activation of the immune system is an essential component of an appropriate immune response to a foreign antigen. Once the immune response deals with and clears the antigen, the system returns to relative quiescence (Chap. 305). In HIV infection, however, the immune system is chronically activated owing to the chronicity of infection and the persistence of virus replication (see above). This activated state is reflected by hyperactivation of B cells leading to hypergammaglobulinemia; spontaneous lymphocyte proliferation; activation of monocytes; expression of activation markers on CD4+ and CD8+ T cells; lymph node hyperplasia, particularly early in the course of disease (see above); increased secretion of proinflammatory cytokines (see below); elevated levels of neopterin,b_2-microglobulin, acid-labile interferon, and solubleIL-2 receptors; and autoimmune phenomena (see below). Even in the absence of direct infection of a target cell, HIV envelope proteins can interact with cellular receptors (CD4 molecules and chemokine receptors) to deliver potent activation signals resulting in calcium flux, the phosphorylation of certain proteins involved in signal transduction, co-localization of cytoplasmic proteins including those involved in cell trafficking, secretion of certain cytokines, immune dysfunction, and under certain circumstances, apoptosis (see below).

Persistent immune activation may have several deleterious consequences. From a virologic standpoint, although quiescent CD4+ T cells can be infected with HIV, reverse transcription, integration, and virus spread are much more efficient in activated cells. Furthermore, cellular activation induces expression of virus in cells latently infected with HIV (see above). From an immunologic standpoint, chronic exposure of the immune system to a particular antigen over an extended period may ultimately lead to an inability to sustain an adequate immune response to the antigen. Furthermore, the ability of the immune system to respond to a broad spectrum of antigens may be compromised if immune-competent cells are maintained in a state of chronic activation. In addition, activation of the immune system may favor the elimination of cells via programmed cell death (apoptosis) (see below) as well as the secretion of certain cytokines that can induce HIV expression (see below).

Role of Apoptosis *Apoptosis* is a form of programmed cell death that is a normal mechanism for the elimination of effete cells in organogenesis as well as in the cellular proliferation that occurs during a normal immune response (Chap. 305). Apoptosis is strictly dependent on cellular activation. It has been hypothesized that, in HIV infection, sequential activation signals delivered to CD4+ T cells induce apoptosis. Cross-linking of the CD4 molecule by gp120 or gp120/anti-gp120 complexes delivers the first of two signals required for apoptosis. The second signal supposedly leading to cell death is delivered via the T cell receptor by antigen. According to this hypothesis, direct infection

of CD4+ T cells is not required for apoptosis to occur, although it has been demonstrated that alterations in tyrosine kinase activity of HIV-infected cells may induce the cell to undergo apoptosis. HIV can trigger both Fas-dependent and Fas-independent pathways of apoptosis. Mechanisms involved in this process include upregulation of Fas and Fas ligand, upregulation of caspase-1 and caspase-8, downregulation of the anti-apoptotic Bcl-2 protein, and activation of cyclin-dependent kinases. Certain viral gene products have been associated with enhanced susceptibility to apoptosis including envelope, Nef, and Vpu. A number of studies, including those examining lymphoid tissue, have demonstrated that the rate of apoptosis is elevated in HIV infection and that apoptosis is seen in "bystander" cells such as CD8+ T cells and B cells as well as in CD4+ T cells. Macrophages have been shown to mediate apoptosis of CD8+ T cells by a mechanism involving gp120-induced upregulation of Fas ligand expression on macrophages and enhanced secretion of macrophage-derivedTNF-a. The intensity of apoptosis correlates with the general state of activation of the immune system and not with the stage of disease or with viral burden. The potential role of apoptosis in the pathogenesis of HIV disease is underscored by results from animal studies that show an increased frequency of apoptosis in CD4+ T cells in primates infected with pathogenic strains ofSIV but not in primates infected with nonpathogenic strains of SIV. It is likely that apoptosis of immune-competent cells contributes to the immune abnormalities in HIV disease; however, this is probably a nonspecific mechanism that merely reflects the aberrant state of immune activation.

Autoimmune Phenomena The autoimmune phenomena that are common in HIV-infected individuals reflect, at least in part, chronic immune system activation as well as molecular mimickry by viral components. Although these phenomena usually occur in the absence of autoimmune disease, a wide spectrum of clinical manifestations that may be associated with autoimmunity have been described (see below). Autoimmune phenomena include antibodies to lymphocytes and, less commonly, to platelets and neutrophils. Antiplatelet antibodies have some clinical relevance, in that they may contribute to the thrombocytopenia of HIV disease (see below). Antibodies to nuclear and cytoplasmic components of cells have been reported, as have antibodies to cardiolipin; CD4 molecules; CD43 molecules, C1q-A; variable regions of the T cell receptor a,b, and g chains; Fas; denatured collagen; andIL-2. In addition, autoantibodies to a range of serum proteins, including albumin, immunoglobulin, and thyroglobulin, have been reported. There is antigenic cross-reactivity between HIV viral proteins (gp120 and gp41) andMHCclass II determinants, and anti-MHC class II antibodies have been reported in HIV infection. These antibodies could potentially lead to the elimination of MHC class II-bearing cells via antibody-dependent cellular cytotoxicity (ADCC) (Chap. 305). In addition, regions of homology exist between HIV envelope glycoproteins and IL-2 as well as MHC class I molecules.

Cofactors Contributing to HIV Pathogenesis Both endogenous and exogenous factors can contribute to HIV pathogenesis by a number of mechanisms; paramount among these is the upregulation of virus expression, a process intimately connected with cellular activation. The main endogenous factors that regulate HIV expression are cytokines (see below). Among exogenous factors, other microbes likely have important effects on HIV replication and HIV pathogenesis. They can thus be considered real or potential *cofactors* in the pathogenesis of HIV disease. Co-infection or simultaneous cotransfection of cells with HIV and other viruses or viral genes has demonstrated that

certain viruses, such asHSV type 1, cytomegalovirus (CMV), human herpesvirus (HHV) 6, Epstein-Barr virus (EBV), hepatitis B virus (HBV), adenovirus, pseudorabies virus, andHTLV-I can upregulate HIV expression. Other microbes, such as *Mycoplasma* have been reported to contribute to the induction of HIV expression. *Mycobacterium tuberculosis* is a common opportunistic infection in HIV-infected individuals (see below and Chap. 169). In addition to the fact that HIV-infected individuals are more likely to develop activeTB after exposure, it has been demonstrated that active TB can accelerate the course of HIV infection. It has also been shown that levels of plasma viremia are greatly elevated in HIV-infected individuals with active TB, compared to pre-TB levels and levels of viremia after successful treatment of the active TB. In vitro studies demonstrated that virus replication was markedly enhanced in lymphocytes of HIV-infected individuals who were skin test-positive for purified protein derivative (PPD) when PPD antigen was added to culture, resulting in cellular activation. Confirmatory evidence that antigen-induced activation was a major contributor to the accelerated viremia in HIV-infected individuals with active TB was provided by studies in which HIV-infected individuals were immunized with common recall antigens such as tetanus toxoid, influenza, or pneumococcal polysaccharide. Under these circumstances, a transient elevation of plasma viremia accompanied the cellular activation induced by the immunization. A greater degree of induction of virus was seen in those individuals with early stage as opposed to advanced stage HIV disease, and the degree of virus induction correlated with the level of immune system activation.

THE CYTOKINE NETWORK IN HIV PATHOGENESIS

Cytokine Regulation of HIV Expression The immune system is homeostatically regulated by a complex network of immunoregulatory cytokines, which are pleiotropic and redundant and operate in an autocrine and paracrine manner. They are expressed continuously, even during periods of apparent quiescence of the immune system. On perturbation of the immune system by antigenic challenge, the expression of cytokines increases to varying degrees (Chap. 305). Cytokines that are important components of this immunoregulatory network have been demonstrated to play a major role in the regulation of HIV expression in vitro. A number of in vitro model systems of chronically infected monocyte or T cell lines, primary cultures of peripheral blood or lymph node mononuclear cells from HIV-infected individuals, and acutely infected primary cell cultures have been used to demonstrate the role of cytokines in the regulation of HIV expression. Potent modulation of HIV expression has been demonstrated either by manipulating endogenous cytokines or by adding exogenous cytokines to culture. Cytokines that induce HIV expression in one or more of these systems includeIL-1, IL-2, IL-3, IL-6, IL-12,TNF-a, and TNF-b, macrophage colony stimulating factor (M-CSF), and granulocyte-macrophage colony stimulating factor (GM-CSF). Among these cytokines, the most consistent and potent inducers of HIV expression are the *proinflammatory cytokines* TNF-a, IL-1b, and IL-6.IFN-aand -b suppress HIV replication, whereas transforming growth factor (TGF) b, IL-4, IL-10, and IFN-g can either induce or suppress HIV expression, depending on the system involved. The *CC-chemokines* RANTES, macrophage inflammatory protein (MIP) 1a, and MIP-1b(Chap. 305) inhibit infection by and spread of R5 (macrophage-tropic) HIV-1 strains, while *stromal cell-derived factor* (SDF) 1 inhibits infection by and spread of X4 (T cell-tropic) strains (see below). Several of these cytokines act synergistically in regulating HIV infection and replication, and others function in an autocrine and paracrine manner, similar to their physiologic

function in the regulation of the immune system. Blocking of endogenous HIV-inducing cytokines or addition of inhibitors of HIV suppressor cytokines in cultures of peripheral blood and lymph node mononuclear cells from HIV-infected individuals has demonstrated that HIV replication is controlled tightly by endogenous cytokines acting in an autocrine and paracrine manner. Indeed, the net level of virus replication in an HIV-infected individual at least in part reflects a balance between inductive and suppressive host factors, mediated mainly by cytokines. An example of this endogenous regulation is the case of IL-10, which inhibits HIV replication in acutely infected monocyte/macrophages by blocking the secretion of the HIV-inducing cytokines TNF-a and IL-6. In addition, IL-4, IL-13, and TGF-b inhibit HIV expression in chronically infected monocytic cell lines stimulated by lipopolysaccharide and GM-CSF by increasing the ratio of expression of endogenous IL-1 receptor antagonist to IL-1b.

The molecular mechanisms of HIV regulation are best understood forTNF-a, which activates NF-kB proteins that function as transcriptional activators of HIV expression. The HIV-inducing effect ofIL-1bis thought to occur at the level of viral transcription in an NF-kB-independent manner. IL-6,GM-CSF, andIFN-gregulate HIV expression mainly by posttranscriptional mechanisms. Elevated levels of TNF-a and IL-6 have been demonstrated in plasma and cerebrospinal fluid (CSF), and increased expression of TNF-a, IL-1b, IFN-g, and IL-6 has been demonstrated in the lymph nodes of HIV-infected individuals. The mechanisms whereby the CC-chemokines RANTES,MIP-1a, and MIP-1b inhibit infection of R5 strains of HIV very likely involve blocking of the binding of the virus to its co-receptor, the CC-chemokine receptor CCR5 (see above and below). Of note is the fact that CC-chemokines that inhibit infection by R5 strains of virus actually enhance infection by X4 strains of virus by inducing intracellular signal transduction through the CCR5 and CD4 molecules. In addition, products of bacterial pathogens as well as of certain viruses including HIV-1 itself can induce the expression of CXCR4 and thus potentially favor infection with X4 strains of virus that utilize this co-receptor.

Dysregulation of Cytokines HIV-infected individuals show an imbalance in the T cell limbs of the immune response, which are defined by the patterns of cytokine secretion. T helper (T_H)1 cells are characterized by secretion ofIL-2 andIFN-gand favor cell-mediated immune responses, whereas T_H2 cells are characterized by secretion of IL-4, IL-5, and IL-10 and favor humoral immune responses (Chap. 305). Since several cell types in addition to CD4+ T cells secrete these cytokines, it is more accurate to refer to immune responses that reflect one or the other cytokine pattern as *T_H1 or T_H2 type responses*. HIV-infected individuals show a decrease in T_H1 type responses relative to T_H2 type cytokine patterns. They manifest a progressive loss in expression of the IL-2 receptor and in the ability to produce the immunoregulatory cytokines IL-2 and IL-12; these cytokines are critical for effective cell-mediated immune responses in that they stimulate proliferation and lytic activity ofCTLs and natural killer (NK) cells. Furthermore, IL-12 is important for the stimulation of T_H1 type cytokines such as IL-2 and IFN-g that favor the development of cell-mediated immune responses. T_H1 type cytokines such as IL-2, IL-12,TNF-a, and IFN-g upregulate CCR5 expression, while T_H2 type cytokines such as IL-4 and IL-10 upregulate CXCR4 expression and downregulate CCR5 expression. It has also been demonstrated that in vitro apoptosis can be inhibited in T cells from HIV-infected donors by antibodies to IL-4 and IL-10 and enhanced by antibodies to IL-12. Although it has been proposed that a clear-cut switch from a T_H1

type to a T_H2 type of cytokine pattern is a critical step in the pathogenesis of HIV disease, no sharp dichotomy between these two types of cytokine patterns that is directly related to progression of disease has been corroborated. Cytokine dysregulation in HIV infection is complex and cannot be neatly classified in terms of the polarity of T_H1 and T_H2 responses.

CELLULAR TARGETS OF HIV

Although the CD4+ T lymphocytes and CD4+ cells of monocyte lineage are the principal targets of HIV, virtually any cell that expresses the CD4 molecule together with co-receptor molecules (see above and below) can potentially be infected with HIV. Circulating dendritic cells have been reported to express low levels of CD4, and depending on their stage of maturation, these cells can be infected with HIV (see below). Epidermal Langerhans cells express CD4 and have been infected by HIV in vivo. In vitro, HIV has been reported also to infect a wide range of cells and cell lines that express low levels of CD4, no detectable CD4, or only CD4 mRNA; among these areFDCs; megakaryocytes; eosinophils; astrocytes; oligodendrocytes; microglial cells; CD8+ T cells; B cells;NKcells; renal epithelial cells; cervical cells; rectal and bowel mucosal cells such as enterochromaffin, goblet, and columnar epithelial cells; trophoblastic cells; and cells from a variety of organs, such as liver, lung, heart, salivary gland, eye, prostate, testis, and adrenal gland. Since the only cells that have been shown unequivocally to be infected with HIV and to support replication of the virus are CD4+ T lymphocytes and cells of monocyte/macrophage lineage, the relevance of the in vitro infection of these other cell types is questionable.

Of potentially important clinical relevance is the demonstration that thymic precursor cells, which were assumed to be negative for CD3, CD4, and CD8 molecules, actually do express low levels of CD4 and can be infected with HIV in vitro. In addition, human thymic epithelial cells transplanted into an immunodeficient mouse can be infected with HIV by direct inoculation of virus into the thymus. Since these cells may play a role in the normal regeneration of CD4+ T cells, it is possible that their infection and depletion contribute, at least in part, to the impaired ability of the CD4+ T cell pool to completely reconstitute itself in certain infected individuals in whom antiretroviral therapy has suppressed viral replication to below detectable levels (<50 copies of HIV RNA per milliliter; see below). In addition, CD34+ monocyte precursor cells have been shown to be infected in vivo in patients with advanced HIV disease. It is likely that these cells express low levels of CD4, and therefore it is not essential to invoke CD4-independent mechanisms to explain the infection.

ROLE OF CO-RECEPTORS IN CELL TROPISM OF HIV

Different strains of HIV-1 utilize two major co-receptors along with CD4 to bind to, fuse with, and enter target cells; these co-receptors are CCR5 and CXCR4, which are receptors for certain chemokines and belong to the seven-transmembrane-domain G protein-coupled family of receptors (see above). Strains of HIV that utilize CCR5 as a co-receptor are referred to as *R5 viruses*. These viruses were formerly classified as *macrophage tropic viruses* since they readily infect macrophages but not T cell lines. Strains of HIV that utilize CXCR4 are referred to as *X4 viruses*. These viruses are also referred to as *T cell-tropic viruses* since they readily infect T cell lines but not

macrophages. In actuality, X4 viruses enter macrophages but do not proceed efficiently along the replication cycle unless an appropriate signal is delivered to the cell. Many virus strains are *dual tropic* in that they utilize both CCR5 and CXCR4; these are referred to as *R5X4 viruses*. Other terminology that has been associated with R5 versus X4 viruses is *non-syncytium-inducing viruses* versus *syncytium-inducing viruses*, respectively, based on the observation that R5 viruses generally do not form syncytia in culture with certain T cell lines, whereas X4 viruses readily form syncytia. In reality, under certain conditions both R5 and X4 viruses are capable of forming syncytia in culture.

The natural chemokine ligands for the major HIV co-receptors can readily block entry of HIV. For example, the CC-chemokines RANTES,MIP-1a, and MIP-1b, which are the natural ligands for CCR5, block entry of R5 viruses, whereasSDF-1, the natural ligand for CXCR4, blocks entry of X4 viruses. The mechanism of inhibition of viral entry is a steric inhibition of binding that is not dependent on signal transduction (Fig. 309-20).

The transmitting virus is almost invariably an R5 virus that predominates during the early stages of HIV disease. In approximately 40% of HIV-infected individuals, there is a transition to a predominantly X4 virus that is associated with a relatively rapid progression of disease. However, at least 60% of infected individuals progress in their disease while maintaining predominance of an R5 virus. Other chemokine receptor family members may function as coreceptors for HIV andSIVentry, but to a much lesser extent than do CCR5 and CXCR4; these include CCR3, BOB/GPR15, Bonzo/STRL33/TYMSTR, CCR2, CCR8, CX_3CR1(V28), and GPR1.

The basis for the tropism of different envelope glycoproteins for either CCR5 or CXCR4 relates to the ability of the HIV envelope, particularly the third variable region (V3 loop) of gp120, to interact with these co-receptors. In this regard, binding of gp120 to CD4 induces a conformational change in gp120 that increases its affinity for CCR5. It appears that the interaction of gp120 with CXCR4 is less dependent on the conformational change induced in gp120 by CD4. In fact, there are X4 strains of HIV that bind to CXCR4 in the absence of surface-bound or soluble CD4. Finally, R5 viruses are more efficient in infecting monocyte/macrophages and microglial cells of the brain (see "Neuropathogenesis," below).

ABNORMALITIES OF MONONUCLEAR CELLS

CD4+ T Cells The range of T cell abnormalities in advanced HIV infection is broad. The defects are both quantitative and qualitative and involve virtually every limb of the immune system (see below), indicating the critical dependence of the integrity of the immune system on the inducer/helper function of CD4+ T cells. Virtually all of the immune defects in advanced HIV disease can ultimately be explained by the quantitative depletion of CD4+ T cells. However, T cell dysfunction (see below) can be demonstrated in patients early in the course of infection, even when the CD4+ T cell count is in the low-normal range. The degree and spectrum of dysfunctions increase as the disease progresses. One of the first abnormalities to be detected is a defect in response to remote recall antigens, such as tetanus toxoid and influenza, at a time when mononuclear cells can still respond normally to mitogenic stimulation. Defects in responses to soluble antigens are followed in time by the loss of T cell proliferative

responses to alloantigens, and subsequently to mitogens. Essentially every T cell function has been reported to be abnormal at some stage of HIV infection. These abnormalities include defective T cell cloning and colony-forming efficiencies, impaired expression ofIL-2 receptors, defective IL-2 production, and decreasedIFN-gproduction in response to antigens. The proportion of CD4+ T cells that express CD28, which is a major co-stimulatory molecule necessary for the normal activation of T cells, is reduced during HIV infection. Cells lacking expression of CD28 do not respond to activation signals and may express markers of terminal activation including HLA-DR, CD38, and CD45RO. CD4+ T cells from HIV-infected individuals express abnormally low levels of CD40 ligand, which may explain the dysregulation of B cell function observed in HIV disease.

It is difficult to explain completely the profound immunodeficiency noted in HIV-infected individuals solely on the basis of direct infection and quantitative depletion of CD4+ T cells. This is particularly apparent during the early stages of HIV disease, when CD4+ T cell numbers may be only marginally decreased. Certainly, at the stage of advanced disease when the CD4+ T cell count is in the range of 0 to 50/uL, quantitative depletion alone can explain the immune defects. However, it is likely that CD4+ T cell dysfunction results from a combination of depletion of cells due to direct infection and a number of virus-related but indirect effects on the cell (Table 309-6).

Single-cell killing and the formation of syncytia between infected and uninfected cells have been demonstrated clearly in vitro, although the precise mechanisms of cell death in vivo have not been determined. Cytopathicity in an infected cell in vitro may result from a number of mechanisms, including copious budding of virions from the cell surface with resulting disruption of the integrity of the cell membrane; interference with cellular RNA processing or the accumulation of high levels of heterodisperse RNA molecules; disruption of cellular protein synthesis owing to high levels of viral RNA; accumulation of high levels of unintegrated viral DNA in the cell cytoplasm; induction of aberrant patterns of protein tyrosine phosphorylation; and the interaction between HIV gp120 and CD4 intracellularly. Strain differences in single-cell killing are determined largely by gp120 sequences, which supports the importance of the viral envelope in this process. *Syncytia formation* involves fusion of the cell membrane of an infected cell with the cell membranes of variable numbers of uninfected CD4+ cells. Although cell fusion has not been shown to be an important pathogenic process in vivo, a direct relationship between the presence of syncytia and the degree of cytopathic effect has been demonstrated in vitro, and a correlation has been reported between the presence of virus isolates that readily induce syncytia in vitro and a more aggressive clinical course in the patient. Efficient syncytia formation depends on the leukocyte adhesion molecule LFA-1 (Chap. 305) on human CD4+ T cells acutely infected with HIV in vitro.

Humoral and cellular immune responses to HIV may contribute to protective immunity by eliminating virus and virus-infected cells (see below). However, since the main targets of HIV infection are immune-competent cells, these responses may contribute to immune-cell depletion and immunologic dysfunction by eliminating both infected cells and "innocent bystander" cells. Soluble viral proteins, particularly gp120, can bind with high affinity to the CD4 molecules on uninfected T cells and monocytes; in addition, virus and/or viral proteins can bind to dendritic cells orFDCs. HIV-specific antibody can recognize these bound molecules and potentially collaborate in the elimination of the

cells byADCC.

Nonpolymorphic determinants ofMHCclass I products share a degree of homology with gp120 and gp41 proteins of HIV. Such similarities may lead to the generation of autoantibodies to self-MHC determinants. In fact, anti-HLA-DR antibodies have been demonstrated in the sera of HIV-infected individuals (see "Autoimmune Phenomena," above). These antibodies could contribute to the elimination of HLA-DR-expressing cells byADCC; in addition, it has been suggested that these antibodies may inhibit certain T cell functions that involve HLA-DR molecules.

HIV envelope glycoproteins gp120 and gp160 manifest high-affinity binding to CD4 as well as to various chemokine receptors (see above). Intracellular signals transduced by gp120 have been associated with a number of immunopathogenic processes including anergy, apoptosis, and abnormalities of cell trafficking. The molecular mechanisms responsible for these abnormalities include dysregulation of the T cell receptor-phosphoinositide pathway, p56lck activation, phosphorylation of focal adhesion kinase, activation of the MAP kinase and ras signaling pathways, and downregulation of the co-stimulatory molecules CD40 ligand and CD80.

Finally, the inexorable decline in CD4+ T cell counts that occurs in most HIV-infected individuals may result in part from the inability of the immune system to regenerate the CD4+ T cell pool rapidly enough to compensate for both HIV-mediated destruction of cells and natural attrition of cells. At least two major mechanisms may contribute to the failure of the CD4+ T cell pool to reconstitute itself adequately over the course of HIV infection. The first is the destruction of lymphoid precursor cells, including thymic and bone marrow progenitor cells (see above); the other is the gradual disruption of the lymphoid tissue microenvironment, which is essential for efficient regeneration of immune-competent cells (see above).

CD8+ T Cells The level of CD8+ T cells varies throughout the course of disease. Following the resolution of acute primary infection, CD8+ T cells generally rebound to higher than normal levels and may remain that way throughout the clinically latent stage of disease. This CD8+ T lymphocytosis may in part reflect the expansion of clones of HIV-specific CD8+CTLs. During the late stages of HIV infection, there may be a significant reduction in the numbers of CD8+ T cells. HIV-specific CD8+ CTLs have been demonstrated in HIV-infected individuals early in the course of disease (see below). As the disease progresses, this functional capability decreases and may be lost entirely. The cause of this loss of cytolytic activity is unclear. However, it has been demonstrated that, as disease progresses, CD8+ T cells assume an abnormal phenotype characterized by expression of activation markers such as HLA-DR with an absence of expression of theIL-2 receptor (CD25) and a loss of clonogenic potential. It has been reported that the phenotype of CD8+ T cells in HIV-infected individuals may be of prognostic significance. Those individuals whose CD8+ T cells developed a phenotype of HLA-DR+/CD38- following seroconversion had stabilization of their CD4+ T cell counts, whereas those whose CD8+ T cells developed a phenotype of HLA-DR+/CD38+ had a more aggressive course and a poorer prognosis. In addition to the defects in HIV-specific CTLs, functional defects in otherMHC-restricted CTLs, such as those directed against influenza andCMV, have been demonstrated. Since the integrity of CD8+ T cell function depends in part on adequate inductive signals from

CD4+ T cells, the defect in CD8+ CTLs is likely compounded by the quantitative loss of CD4+ T cells.

B Cells B cells from HIV-infected individuals manifest abnormal activation, which is reflected by spontaneous proliferation and immunoglobulin secretion and by increased spontaneous secretion ofTNF-aandIL-6. The enhanced spontaneous in vitro transformation of B cells withEBV is probably due to defective T cell immune surveillance and has as its in vivo counterpart an increase in the incidence of EBV-related B cell lymphomas. Untransformed B cells cannot be infected with HIV. However, HIV or its products can activate B cells directly; portions of the HIV gp41 envelope protein have been reported to induce polyclonal B cell activation. In addition, it has been reported that products of the VH_3genes on the surface of B cells can serve as a receptor for HIV. It is likely that in vivo activation of B cells by virus products accounts at least in part for the spontaneous activation of these cells noted ex vivo. B cells from HIV-infected individuals express abnormally low levels of HLA-DR on their surface and fail to upregulate CD70 normally following stimulation with activated T cells; this latter defect is associated with impaired CD70-dependent immunoglobulin synthesis. In advanced HIV disease, B cells fail to proliferate and differentiate in response to ligation of the B cell antigen receptor and CD40, suggesting a defect in signal transduction. In vivo, this activated state manifests itself by hypergammaglobulinemia and by the presence of circulating immune complexes and autoantibodies (see above). HIV-infected individuals respond poorly to primary and secondary immunizations with protein and polysaccharide antigens. These B cell defects are likely responsible in part for the increase in certain bacterial infections seen in advanced HIV disease in adults, as well as for the important role of bacterial infections in the morbidity and mortality of HIV-infected children, who cannot mount an adequate humoral response to common bacterial pathogens. The absolute number of circulating B cells may be depressed in primary HIV infection; however, this phenomenon is usually transient and likely reflects in part a redistribution of cells out of the circulation and into the lymphoid tissue. In certain patients, the number of circulating B cells decreases in advanced-stage disease.

Monocyte/Macrophages Circulating monocytes are generally normal in number in HIV-infected individuals. Monocytes express the CD4 molecule and several co-receptors for HIV on their surface, including CCR5, CXCR4, and CCR3, and thus are targets of HIV infection. Of note is the fact that the degree of cytopathicity of HIV for cells of the monocyte lineage is low, and HIV can replicate extensively in cells of the monocyte lineage with little cytopathic effect. Hence, monocyte-lineage cells may play a role in the dissemination of HIV in the body and can serve as reservoirs of HIV infection, thus representing an obstacle to the eradication of HIV by antiretroviral drugs. In vivo infection of circulating monocytes is difficult to demonstrate; however, infection of tissue macrophages and macrophage-lineage cells in the brain (infiltrating macrophages or resident microglial cells) and lung (pulmonary alveolar macrophages) can be demonstrated easily. Infection of monocyte precursors in the bone marrow may directly or indirectly be responsible for certain of the hematologic abnormalities in HIV-infected individuals. A number of abnormalities of circulating monocytes have been reported in HIV-infected individuals, including decreased secretion ofIL-1 and IL-12; increased secretion of IL-10; defects in antigen presentation and induction of T cell responses due to decreasedMHCclass II expression; and abnormalities of Fc receptor function, C3 receptor-mediated clearance, oxidative burst responses, and certain cytotoxic functions

such asADCC, possibly related to low levels of expression of Fc and complement receptors. The mechanisms of the monocyte defects are uncertain but almost certainly cannot be even partly explained by direct infection with HIV. Exposure of monocytes to viral proteins such as gp120 and Tat, as well as to certain cytokines, can cause abnormal activation, and this may play a role in cellular dysfunction (see above).

Dendritic and Langerhans Cells There has been considerable disagreement regarding the HIV infectibility and hence the depletion as well as the dysfunction of circulating dendritic cells. Depending on their state of maturation, dendritic cells express varying levels of CD4 as well as several chemokine receptors. In this regard, it appears that the ability of a dendritic cell to become infected depends in part on its state of maturation. Mature dendritic cells have been demonstrated to be infectable by both R5 and X4 isolates of HIV-1. Immature tissue dendritic cells have been less well studied in their native state. Certain groups have reported infection and dysfunction of dendritic cells from HIV-infected individuals, particularly a decreased ability to present antigen to T cells, and other groups have found little if any HIV infection or functional abnormalities. In this regard, there is general agreement regarding the ability of skin and mucous membrane Langerhans cells to be infected (see above). These latter cells likely play an important role in the initiation and propagation of HIV infection (see above). Even in those dendritic cells in which infection occurs, the efficiency of infection and level of productivity of infection is quite low compared to CD4+ T cells.

Natural Killer Cells The role ofNK cells is to provide immunosurveillance against virus-infected cells, certain tumor cells, and allogeneic cells (Chap. 305). Functional abnormalities in NK cells have been observed throughout the course of HIV disease, and the severity of these abnormalities increases as disease progresses. Most studies report that NK cells are normal in number and phenotype in HIV-infected individuals; however, a numerical decrease in the CD16+/CD56+ subpopulation of NK cells has been reported together with an increase in activation markers. The abnormality in NK cell function is thought to result from a defect in postbinding lysis. However, the lytic machinery does not appear to be impaired, since NK cells from HIV-infected individuals mediateADCCnormally. The addition of eitherIL-2, IL-12, IL-15, orIFN-ato cultures improves the defective in vitro NK cell function of HIV-infected individuals. Enhanced expression of cytolytic inhibitory receptors in HIV-infected individuals may contribute to the abnormalities in NK function. Furthermore, selective HIV-mediated downregulation of HLA-A and -B, but not HLA-C and -D molecules may inhibit NK-mediated killing of HIV-infected target cells. Finally, NK cells serve as important sources of HIV-inhibitory CC-chemokines. NK cells isolated from HIV-infected individuals constitutively produce high levels ofMIP-1a, MIP-1b, and RANTES. In addition, high levels of these chemokines are seen when NK cells are stimulated with IL-2 or IL-15 or when CD16 is cross-linked or during the process of lytic killing of target cells.

GENETIC FACTORS IN HIV PATHOGENESIS

Several reports have describedMHCalleles and other host factors that may influence the pathogenesis and course of HIV disease. These include associations with certain HIV-related manifestations, such asKS and diffuse lymphadenopathy, or with the type of clinical course, such as long-term survival or rapid progression (Table 309-7). A number of mechanisms have been proposed whereby MHC-encoded molecules might

predispose an individual either to rapid progression or to nonprogression to AIDS. These proposed mechanisms include the ability to present certain immunodominant HIV T helper orCTLepitopes, leading to a relatively protective immune response against HIV and hence to slow progression of disease. In contrast, certain MHC class I or class II alleles might predispose an individual to an immunopathogenic response against viral epitopes in certain tissues, such as the central nervous system (CNS) or lungs, or against certain HIV-infected cell types, such as macrophages or dendritic cells/Langerhans cells. In addition, certain rare MHC class I and class II alleles might facilitate rapid recognition of HIV-infected cells from the infecting partner in primary HIV infection and promote rejection of these cells by alloreactive responses. Similarly, common MHC alleles could lead to less effective removal of HIV-infected allogeneic cells. It has been clearly demonstrated that maximal *HLA* heterozygosity for class I loci (A, B, and C) is associated with a delayed onset of AIDS among HIV-infected individuals, whereas homozygosity for these loci was associated with a more rapid progression to AIDS and death. This observation is likely due to the fact that individuals heterozygous at *HLA* loci are able to present a greater variety of antigenic peptides to cytotoxic T lymphocytes than are homozygotes resulting in a more effective immune response against a number of pathogens including HIV. Of particular note is the fact that the HLA class I alleles B*35 and Cw*04 were consistently associated with rapid development of AIDS. Other data have indicated that transporter associated with antigen-presenting (TAP) genes play a role in determining the outcome of HIV infection. HLA profiles that reflect certain combinations of MHC-encoded TAP and class I and class II genes are strongly associated with different rates of progression to AIDS.

Rare individuals have been reported who had had repetitive sexual exposure to HIV in high-risk situations but remained uninfected. The peripheral blood mononuclear cells of two such individuals were found to be highly resistant to infection in vitro with R5 strains of HIV-1, but they were readily infected with X4 strains. Genetic analysis revealed that these two individuals inherited a homozygous defect in the gene that codes for CCR5, the cellular co-receptor for R5 strains of HIV-1. The defective *CCR5* allele contained a 32-bp deletion corresponding to the second extracellular loop of the receptor. The encoded protein was severely truncated, and the receptor was nonfunctional, explaining the refractoriness to infection with R5 strains of HIV-1. Population studies revealed that approximately 1% of the Caucasian population of western European ancestry possessed the homozygous defect. Up to 20% of this group had the heterozygous defect. Of note, cohort studies of hundreds of DNA samples originating from western and central Africa and Japan did not reveal a single mutant allele, suggesting that the allele is either absent or extremely rare in Africa and Japan. In a cohort of 1400 HIV-1-infected Caucasian individuals, no subject homozygous for the mutation was found, strongly supporting the concept that the homozygous defect confers protection against infection. This finding is particularly compelling in light of the fact that transmitting viruses are strongly biased towards R5 strains of HIV-1 (see above). Furthermore, there was a higher frequency of individuals heterozygous for the genetic defect among HIV-infected patients who were long-term nonprogressors compared to HIV-infected individuals who progressed more rapidly (see above). Of note, several individuals have been identified who were homozygous for the *CCR5* D32 defect who in fact did become infected with HIV. These individuals were found to have an X4 strain of HIV that was associated in some cases with an accelerated course of disease. Slow progression of HIV disease is also seen in individuals who are heterozygous for the

CCR2V64I mutation; this is felt to be due to dimerization of CXCR4 with the mutated CCR2V64I resulting in a decreased expression of CXCR4 on the cell surface. Individuals who are homozygous for the *SDF1*-3¢A mutation manifest slow progression, likely due to the upregulation ofSDF-1 and resulting inhibition of binding of X4 viruses to mononuclear cells. Delayed progression of disease is also seen in those individuals who have any of a number of single nucleotide polymorphisms in the *CCR5* promoter. In addition, individuals who carry a certain allele (IL-10-5¢592A) of theIL-10 promoter are at increased risk of infection and, once infected, progress more rapidly than homozygotes for the alternative genotype. The mechanism of this effect is felt to be a downregulation of the inhibitory cytokine IL-10 resulting in facilitation of HIV replication. Finally, individuals with a mutation of the *RANTES* gene (*RANTES-28G*) manifest a delay in disease progression due likely to the increased expression of RANTES and resulting inhibition of infection with R5 viruses (Table 309-7).

NEUROPATHOGENESIS

HIV-infected individuals can experience a variety of neurologic abnormalities due either to opportunistic infections and neoplasms (see below) or to direct effects of HIV or its products. With regard to the latter, HIV has been demonstrated in the brain andCSF of infected individuals with and without neuropsychiatric abnormalities. The main cell types that are infected in the brain in vivo are those of the monocyte/macrophage lineage, including monocytes that have migrated to the brain from the peripheral blood as well as resident microglial cells. HIV entry into brain is felt to be due, at least in part, to the ability of virus-infected and immune-activated macrophages to induce adhesion molecules such as E-selectin and vascular cell adhesion molecule-1 (VCAM-1) on brain endothelium. Other studies have demonstrated that HIV gp120 enhances the expression of intercellular adhesion molecule-1 (ICAM-1) in glial cells; this effect may facilitate entry of HIV-infected cells into theCNS and may promote syncytia formation. Virus isolates from the brain are preferentially R5 strains as opposed to X4 strains (see above); in this regard, HIV-infected individuals who are heterozygous for *CCR5D32* appear to be relatively protected against the development of HIV encephalopathy compared to wild-type individuals. Distinct HIV envelope sequences are associated with the clinical expression of the AIDS dementia complex (see below). Although there have been reports of infrequent HIV infection of neuronal cells and astrocytes, there is no convincing evidence that brain cells other than those of monocyte/macrophage lineage can be productively infected in vivo. Nonetheless, it has been demonstrated that galactosyl ceramide may be an essential component of the HIV gp120 receptor on neural cells, and antibodies to galactosyl ceramide inhibit entry of HIV into neural cell lines in vitro.

HIV-infected individuals may manifest white matter lesions as well as neuronal loss. Given the relative absence of evidence of HIV infection of neurons either in vivo or in vitro, it is unlikely that direct infection of these cells accounts for their loss. Rather, the HIV-mediated effects on brain tissue are thought to be due to a combination of direct effects, either toxic or function-inhibitory, of gp120 on neuronal cells and effects of a variety of neurotoxins released from infiltrating monocytes, resident microglial cells, and astrocytes. In this regard, it has been demonstrated that both HIV-1 Nef and Tat can induce chemotaxis of leukocytes, including monocytes, into theCNS. Neurotoxins can be released from monocytes as a consequence of infection and/or immune activation.

Monocyte-derived neurotoxic factors have been reported to kill neurons via the *N*-methyl-D-aspartate (NMDA) receptor. In addition, HIV gp120 shed by virus-infected monocytes could cause neurotoxicity by antagonizing the function of vasoactive intestinal peptide (VIP), by elevating intracellular calcium levels, and by decreasing nerve growth factor levels in the cerebral cortex. A variety of monocyte-derived cytokines can contribute directly or indirectly to the neurotoxic effects in HIV infection; these includeTNF-a,IL-1, IL-6,TGF-b,IFN-g, platelet-activating factor, and endothelin. Certain studies have correlated levels of CC-chemokinesMIP-1a, MIP-1b, and RANTES inCSF with HIV-related encephalopathy. In addition, infection and/or activation of monocyte-lineage cells can result in increased production of eicosanoids, nitric oxide, and quinolinic acid, which may contribute to neurotoxicity. Astrocytes may play diverse roles in HIV neuropathogenesis. Reactive gliosis or astrocytosis has been demonstrated in the brains of HIV-infected individuals, and TNF-a and IL-6 have been shown to induce astrocyte proliferation. In addition, astrocyte-derived IL-6 can induce HIV expression in infected cells in vitro. Furthermore, it has been suggested that astrocytes may downregulate macrophage-produced neurotoxins. It has been reported that HIV-infected individuals with the E4 allele for apolipoprotein E (apo E) are at increased risk for AIDS encephalopathy and peripheral neuropathy. The likelihood that HIV or its products are involved in neuropathogenesis is supported by the observation that neuropsychiatric abnormalities may undergo remarkable and rapid improvement upon the initiation of antiretroviral therapy, particularly in HIV-infected children.

PATHOGENESIS OF KAPOSI'S SARCOMA

KSis an opportunistic disease in HIV-infected individuals. Unlike opportunistic infections, its occurrence is not strictly related to the level of depression of CD4+ T cell counts (see below). There are at least four distinct epidemiologic forms of Kaposi's sarcoma: (1) the classic form that occurs in older men of predominantly Mediterranean or eastern European Jewish backgrounds with no recognized contributing factors; (2) the equatorial African form that occurs in all ages, also without any recognized precipitating factors; (3) the form associated with organ transplantation and its attendent iatrogenic immunosuppressed state; and (4) the form associated with HIV-1 infection. The pathogenesis of KS is complex and has not been fully delineated. KS does not result from a neoplastic transformation of cells in the classic sense and so is not truly a sarcoma. It is a manifestation of excessive proliferation of spindle cells that are believed to be of vascular origin and have features in common with endothelial and smooth-muscle cells. In HIV disease the development of KS is dependent on the interplay of a variety of factors including HIV-1 itself,HHV-8, immune activation, and cytokine secretion. A number of epidemiologic and virologic studies have clearly linked HHV-8, which is also referred to as *Kaposi's sarcoma-associated herpesvirus* (KSHV), to KS not only in HIV-infected individuals but also in individuals with the other forms of KS. KSHV is a g-herpesvirus related toEBV and herpesvirus saimiri. It encodes a homologue to human IL-6 and in addition to KS has been implicated in the pathogenesis of body cavity lymphoma, multiple myeloma, and monoclonal gammopathy of undetermined significance. Sequences of HHV-8 are found universally in the lesions of KS, and patients with KS are virtually all seropositive for HHV-8. HHV-8 DNA sequences can be found in the B cells of 30 to 50% of patients with KS and 7% of patients with AIDS without clinically apparent KS.

Between 1 and 2% of eligible blood donors are positive for antibodies toHHV-8, while the prevalence of HHV-8 seropositivity in HIV-infected men is 30 to 35%. The prevalence in HIV-infected women is approximately 4%. This finding is reflective of the lower incidence ofKS in women. It has been debated whether HHV-8 is actually the transforming agent in KS; the bulk of the cells in the tumor lesions of KS are not neoplastic cells. However, a recent study has demonstrated that endothelial cells can be transformed in vitro by HHV-8. Despite the complexity of the pathogenic events associated with the development of KS in HIV-infected individuals, it is generally felt that HHV-8 is indeed the etiologic agent of this disease. The initiation and/or propagation of KS requires an activated state and is mediated, at least in part, by cytokines. A number of factors, includingTNF-a,IL-1b, IL-6,GM-CSF, basic fibroblast growth factor, and oncostatin M, function in an autocrine and paracrine manner to sustain the growth and chemotaxis of the KS spindle cells. It has been suggested that the HIV Tat protein plays a major role in the pathogenesis of KS. In this regard, it has been demonstrated thatIFN-gcan induce endothelial cells to proliferate and to invade the extracellular matrix in response to HIV Tat. This occurs as a result of the upregulation by IFN-g of the expression and activity of the receptors for Tat, which are the integrins$a_5b_1$anda_vb_3. In addition, the HIV-1 Tat protein has been shown to act synergistically with basic fibroblast growth factor in the induction of lesions resembling KS lesions in mice. Glucocorticoids have been shown to have a stimulatory effect, and human chorionic gonadotrophin an inhibitory effect, on KS spindle cells, suggesting that modulation of the balance of autocrine factors may have therapeutic potential in KS.

IMMUNE RESPONSE TO HIV

As detailed above and below, following the initial burst of viremia during primary infection, HIV-infected individuals mount a robust immune response that usually substantially curtails the levels of plasma viremia and likely contributes to delaying the ultimate development of clinically apparent disease for a median of 10 years. This immune response contains elements of both humoral and cell-mediated immunity (Table 309-8;Fig. 309-21). It is directed against multiple antigenic determinants of the HIV virion as well as against viral proteins expressed on the surface of infected cells. Ironically, those CD4+ T cells with T cell receptors specific for HIV are theoretically those CD4+ T cells most likely to bind to infected cells and themselves be infected and destroyed. Thus, an early consequence of HIV infection may be interference with the generation of an effective immune response through the elimination of HIV-specific CD4+ T lymphocytes.

Although a great deal of investigation has been directed toward delineating and better understanding the components of this immune response, it remains unclear which of these phenomena are most important in delaying progression of infection and which, if any, play a role in the pathogenesis of HIV disease.

HUMORAL IMMUNE RESPONSE

Antibodies to HIV usually appear within 6 weeks and almost invariably within 12 weeks of primary infection (Fig. 309-22); rare exceptions are individuals who have defects in the ability to produce HIV-specific antibodies. Detection of these antibodies forms the basis of most diagnostic screening tests for HIV infection. The appearance of

HIV-binding antibodies detected byELISAand western blot assays occurs prior to the appearance of neutralizing antibodies; the latter generally appear following the initial decreases in plasma viremia, which is more closely related to the appearance of HIV-specific CD8+ T lymphocytes. The first antibodies detected are those directed against the structural or gag proteins of HIV, p24 and p17, and the gag precursor p55. The development of antibodies to p24 is associated with a decrease in the serum levels of free p24 antigen. Antibodies to the gag proteins are followed by the appearance of antibodies to the envelope proteins (gp160, gp120, p88, and gp41) and to the products of the *pol* gene (p31, p51, and p66). In addition, one may see antibodies to the low-molecular-weight regulatory proteins encoded by the HIV genes *vpr*, *vpu*, *vif*, *rev*, *tat*, and *nef*.

While antibodies to multiple antigens of HIV are produced, the precise functional significance of these different antibodies is unclear. The best studied have been the antibodies directed towards the envelope proteins of the virus. As noted above, the envelope of HIV consists of an outer envelope glycoprotein with a molecular mass of 120 kDa and a transmembrane glycoprotein with a molecular mass of 41 kDa. These are initially synthesized as a 160-kDa precursor that is cleaved by cellular proteases. Most of the antienvelope antibodies are directed either toward an epitope in the gp41 region comprising amino acids 579 to 613 or toward a hypervariable region in the gp120 molecule, known as the *V3 loop region*, comprising amino acids 303 through 338. This V3 region is a major site for the development of mutations that lead to variants of HIV that are not well recognized by the immune system.

Antibodies directed toward the envelope proteins of HIV have been characterized both as being protective and as possibly contributing to the pathogenesis of HIV disease. Among the protective antibodies are those that function to neutralize HIV directly and prevent the spread of infection to additional cells, as well as those that participate inADCC. *Neutralizing antibodies* may be a component of primary HIV infection, and some long-term nonprogressors have been reported to have increased titers of neutralizing antibodies. Neutralizing antibodies appear to be of two forms, type-specific and group-specific. *Type-specific neutralizing antibodies* are generally directed to the V3 loop region. These antibodies neutralize only viruses of a given strain and are present in low titer in most infected individuals. *Group-specific neutralizing antibodies* are capable of neutralizing a wide variety of HIV isolates. At least two forms of group specific antibodies have been identified: those binding to amino acids 423 to 437 of gp120 and those binding to amino acids 728 to 745 of gp41. The other major class of protective antibodies are those that participate in ADCC, which is actually a form of cell-mediated immunity (Chap. 305) in whichNK cells that bear Fc receptors are armed with specific anti-HIV antibodies that bind to the NK cells via their Fc portion. These armed NK cells then bind to and destroy cells expressing HIV antigens. Antibodies to both gp120 and gp41 have been shown to participate in ADCC-mediated killing of HIV-infected cells. The levels of antienvelope antibodies capable of mediating ADCC are highest in the earlier stages of HIV infection. In vitro, IL-2 can augment ADCC-mediated killing.

In addition to playing a role in host defense, HIV-specific antibodies have also been implicated in disease pathogenesis. Antibodies directed to gp41, when present in low titer, have been shown in vitro to be capable of facilitating infection of cells through an Fc receptor-mediated mechanism known as *antibody enhancement*. Thus, the same

regions of the envelope protein of HIV that give rise to antibodies capable of mediatingADCCalso elicit the production of antibodies that can facilitate infection of cells in vitro. In addition, it has been postulated that anti-gp120 antibodies that participate in the ADCC killing of HIV-infected cells might also kill uninfected CD4+ T cells if the uninfected cells had bound free gp120, a phenomenon referred to as *bystander killing*.

CELLULAR IMMUNE RESPONSE

Given the fact that T cell-mediated immunity is known to play a major role in host defense against most viral infections (Chap. 305), it is generally thought to be an important component of the host immune response to HIV. T cell immunity can be divided into two major categories, mediated respectively by the *helper/inducer CD4+ T cells* and the *cytotoxic/immunoregulatory CD8+ T cells*.

It has been difficult to demonstrate the presence of HIV-specific CD4+ T cells in HIV-infected patients directly, particularly in those with advanced disease. This difficulty may be related to the fact that these cells, with their high affinity for binding to HIV-infected cells, may be among the first to be infected and destroyed during HIV infection. CD4+ T lymphocytes with reactivity to the p24 antigen of HIV have been reported to be present in a subset of long-term nonprogressors and in a subset of patients in whom therapy was initiated shortly following infection. While a reverse correlation exists between the presence of these cells and levels of plasma HIV viremia, it is unclear whether or not there is a causal relationship between these parameters. Through the use of computer modeling, several regions of the HIV-1 envelope molecule have been identified that are structurally analogous to other known T cell epitopes by virtue of having structures known as *amphipathic helices*. Peptides from these envelope regions have been used to identify the presence of CD4+ T cells specific for these regions in the peripheral blood of HIV-infected individuals. Other studies have demonstrated that peripheral blood T cells of some healthy, HIV-negative individuals also react to the envelope proteins of HIV. It is unclear whether or not this represents the presence of a degree of protective immunity in these individuals.

MHCclass I-restricted, HIV-specific CD8+ T cells have been identified in the peripheral blood of patients with HIV-1 infection. These cells include cytotoxic T cells (CTLs) and T cells that can be induced by HIV antigens to express cytokines such asIFN-g. CTLs have been identified in the peripheral blood of patients within weeks of HIV infection. These CD8+ T lymphocytes, through their HIV-specific antigen receptors, bind to and cause the lytic destruction of target cells bearing identical MHC class I molecules associated with HIV antigens. Two types of CTL activity can be demonstrated in the peripheral blood or lymph node mononuclear cells of HIV-infected individuals. The first type directly lyses appropriate target cells in culture without prior in vitro stimulation (*spontaneous CTL activity*). The other type of CTL activity reflects the *precursor frequency of CTLs* (CTLp); this type of CTL activity can be demonstrated by stimulation of CD8+ T cells in vitro with a mitogen such as phytohemagglutinin or anti-CD3 antibody. Following primary HIV infection, the qualitative nature of the HIV-specific CTL response is an important predictor of eventual clinical outcome. Patients who mount a broad CD8+ CTL response generally have a more favorable clinical course than do patients who mount a more restricted CTL response. These data are consistent with studies in theSIVmodel where deletion of CD8+ T cells leads to a more accelerated

clinical course.

In addition toCTLs, CD8+ T cells capable of being induced by HIV antigens to express cytokines such asIFN-galso appear in the setting of HIV-1 infection. It is not clear whether these are the same or different effector pools compared to those cells mediating cytotoxicity; in addition, the relative roles of each in host defense against HIV are not fully understood. It does appear that these CD8+ T cells are driven to in vivo expansion by HIV antigen. There is a direct correlation between levels of CD8+ T cells capable of producing IFN-g in response to HIV antigens and plasma levels of HIV-1 RNA. Thus, while these cells are clearly induced by HIV-1 infection, their overall ability to control infection remains unclear. Multiple HIV antigens, including Gag, Env, Pol, Tat, Rev, and Nef, can elicit CD8+ T cell responses.

At least three other forms of cell-mediated immunity to HIV have been described: CD8+ T cell-mediated suppression of HIV replication,ADCC, and NKcell activity. *CD8+ T cell-mediated suppression of HIV replication* refers to the ability of CD8+ T cells from an HIV-infected patients to inhibit the replication of HIV in tissue culture in a noncytolytic manner. There is no requirement for HLA compatibility between the CD8+ T cells and the HIV-infected cells. This effector mechanism is thus nonspecific and appears to be mediated by soluble factor(s) including the CC-chemokines RANTES,MIP-1aand MIP-1b (see above). These chemokines are potent suppressors of HIV replication and operate at least in part via blockade of the co-receptor (CCR5) on peripheral blood mononuclear cells for R5 or macrophage-tropic strains of HIV (see above). *ADCC*, as described above in relation to humoral immunity, involves the killing of HIV-expressing cells by NK cells armed with specific antibodies directed against HIV antigens. Finally, *NK cells* alone have been shown to be capable of killing HIV-infected target cells in tissue culture. This primitive cytotoxic mechanism of host defense is directed toward nonspecific surveillance for neoplastic transformation and viral infection through recognition of altered class IMHCmolecules.

DIAGNOSIS AND LABORATORY MONITORING OF HIV INFECTION

The establishment of HIV as the causative agent of AIDS and related syndromes early in 1984 was followed by the rapid development of sensitive screening tests for HIV infection. By March, 1985, blood donors in the United States were routinely screened for antibodies to HIV. In June 1996, blood banks in the United States added the p24 antigen capture assay to the screening process to help identify the rare infected individuals who were donating blood in the time (up to 3 months) between infection and the development of antibodies. The development of sensitive assays for monitoring levels of plasma viremia ushered in a new era of being able to monitor the progression of HIV disease more closely. Utilization of these tests, coupled with the measurement of levels of CD4+ T lymphocytes in peripheral blood, is essential in the management of patients with HIV infection.

DIAGNOSIS OF HIV INFECTION

The diagnosis of HIV infection depends upon the demonstration of antibodies to HIV and/or the direct detection of HIV or one of its components. As noted above, antibodies to HIV generally appear in the circulation 2 to 12 weeks following infection.

The standard screening test for HIV infection is theELISA, also referred to as an enzyme immunoassay (EIA). This solid-phase assay is an extremely good screening test with a sensitivity of>99.5%. Most diagnostic laboratories use a commercial EIA kit that contains antigens from both HIV-1 and HIV-2 and thus are able to detect either. These kits use both natural and recombinant antigens and are continuously updated to increase their sensitivity to newly discovered species, such as group O viruses (Fig. 309-6). EIA tests are generally scored as positive (highly reactive), negative (nonreactive), or indeterminate (partially reactive). While the EIA is an extremely sensitive test, it is not optimal with regard to specificity. This is particularly true in studies of low-risk individuals, such as volunteer blood donors. In this latter population, only 10% of EIA-positive individuals are subsequently confirmed to have HIV infection. Among the factors associated with false-positive EIA tests are antibodies to class II antigens, autoantibodies, hepatic disease, recent influenza vaccination, and acute viral infections. For these reasons, anyone suspected of having HIV infection based upon a positive or inconclusive EIA result must have the result confirmed with a more specific assay.

The most commonly used confirmatory test is the western blot (Fig. 309-23). This assay takes advantage of the fact that multiple HIV antigens of different, well-characterized molecular weights elicit the production of specific antibodies. These antigens can be separated on the basis of molecular weight, and antibodies to each component can be detected as discrete bands on the western blot. A negative western blot is one in which no bands are present at molecular weights corresponding to HIV gene products. In a patient with a positive or indeterminateEIA and a negative western blot, one can conclude with certainty that the EIA reactivity was a false positive. On the other hand, a western blot demonstrating antibodies to products of all three of the major genes of HIV (*gag*, *pol*, and *env*) is conclusive evidence of infection with HIV. Criteria established by the U.S. Food & Drug Administration (FDA) in 1993 for a positive western blot state that a result is considered positive if antibodies exist to two of the three HIV proteins: p24, gp41, and gp120/160. Using these criteria, approximately 10% of all blood donors deemed positive for HIV-1 infection lacked an antibody band to the *pol* gene product p31. Some 50% of these blood donors were subsequently found to be false positives. Thus, the absence of the p31 band should increase the suspicion that one may be dealing with a false-positive test result. In this setting it is prudent to obtain additional confirmation with an RNA-based test and/or a follow-up western blot. By definition, western blot patterns of reactivity that do not fall into the positive or negative categories are considered "indeterminate." There are two possible explanations for an indeterminate western blot result. The most likely explanation in a low-risk individual is that the patient being tested has antibodies that cross-react with one of the proteins of HIV. The most common patterns of cross-reactivity are antibodies that react with p24 and/or p55. The least likely explanation in this setting is that the individual is infected with HIV and is in the process of mounting a classic antibody response. In either instance, the western blot should be repeated in 1 month to determine whether or not the indeterminate pattern is a pattern in evolution. In addition, one may attempt to confirm a diagnosis of HIV infection with the p24 antigen capture assay or one of the tests for HIV RNA (discussed below). While the western blot is an excellent confirmatory test for HIV infection in patients with a positive or indeterminate EIA, it is a poor screening test. Among individuals with a negative EIA andPCR for HIV, 20 to 30% may

show one or more bands on western blot. While these bands are usually faint and represent cross-reactivity, their presence creates a situation in which other diagnostic modalities [such as DNA PCR, RNA PCR, the (b)DNA assay, or p24 antigen capture] must be employed to ensure that the bands do not indicate early HIV infection.

A guideline for the use of these serologic tests in attempting to make a diagnosis of HIV infection is depicted in Fig. 309-24. In patients in whom HIV infection is suspected, the appropriate initial test is theEIA. If the result is negative, unless there is strong reason to suspect early HIV infection (as in a patient exposed within the previous 3 months), the diagnosis is ruled out and retesting should be performed only as clinically indicated. If the EIA is indeterminate or positive, the test should be repeated. If the repeat is negative on two occasions, one can assume that the initial positive reading was due to a technical error in the performance of the assay and that the patient is negative. If the repeat is indeterminate or positive, one should proceed to the HIV-1 western blot. If the western blot is positive, the diagnosis is HIV-1 infection. If the western blot is negative, the EIA can be assumed to have been a false positive for HIV-1 and the diagnosis of HIV-1 infection is ruled out. It would be prudent at this point to perform specific serologic testing for HIV-2 following the same type of algorithm. If the western blot for HIV-1 is indeterminate, it should be repeated in 4-6 weeks; in addition, one may proceed to a p24 antigen capture assay, HIV-1 RNA assay, or HIV-1 DNAPCR and specific serologic testing for HIV-2. If the p24 and HIV RNA assays are negative and there is no progression in the western blot, a diagnosis of HIV-1 is ruled out. If either the p24 or HIV-1 RNA assay is positive and/or the HIV-1 western blot shows progression, a tentative diagnosis of HIV-1 infection can be made and later confirmed with a follow-up western blot demonstrating a positive pattern.

As mentioned above, a variety of laboratory tests are available for the direct detection of HIV or its components (Table 309-9;Fig. 309-25). These tests may be of considerable help in making a diagnosis of HIV infection when the western blot results are indeterminate. In addition, the tests detecting levels of HIV RNA can be used to determine prognosis and to assess the response to antiretroviral therapies. The simplest of the direct detection tests is the *p24 antigen capture assay*. This is anEIA-type assay in which the solid phase consists of antibodies to the p24 antigen of HIV. It detects the viral protein p24 in the blood of HIV-infected individuals where it exists either as free antigen or complexed to anti-p24 antibodies. Overall, approximately 30% of individuals with untreated HIV infection have detectable levels of free p24 antigen. This increases to about 50% when samples are treated with a weak acid to dissociate antigen-antibody complexes. Throughout the course of HIV infection, an equilibrium exists between p24 antigen and anti-p24 antibodies. During the first few weeks of infection, before an immune response develops, there is a brisk rise in p24 antigen levels (Fig. 309-22). After the development of anti-p24 antibodies, these levels decline. Late in the course of infection, when circulating levels of virus are high, p24 antigen levels also increase, particularly when detected by techniques involving dissociation of antigen-antibody complexes. This assay has its greatest use as a screening test for HIV infection in patients suspected of having the acute HIV syndrome, as high levels of p24 antigen are present prior to the development of antibodies. In addition, it is currently routinely used along with the HIV EIA assay to screen blood donors in the United States for evidence of HIV infection. Its utility as an assay is decreasing with the increased use of the reverse transcriptase PCR (RT-PCR) and

bDNA technique for direct detection of HIV RNA.

The ability to measure and monitor levels of HIV RNA in the plasma of patients with HIV infection has been of extraordinary value in furthering our understanding of the pathogenesis of HIV infection and in providing a diagnostic tool in settings where measurements of anti-HIV antibodies may be misleading, such as in acute infection and neonatal infection. Two assays are predominantly used for this purpose. They are the*RT-PCR*(Amplicor) and the *bDNA* (Quantiplex). It should be pointed out that the only test approved by theFDA at this time for the measurement of HIV RNA levels is the RT-PCR test. While this approval is limited to the use of the test for determining prognosis, it is the general consensus that this test as well as the bDNA test are also of value for monitoring the effects of therapy and in making a diagnosis of HIV infection. In addition to these two commercially available tests, the *DNA PCR* is also employed by research laboratories for making a diagnosis of HIV infection by amplifying HIV proviral DNA from peripheral blood mononuclear cells. The commercially available RNA detection tests have a sensitivity of 40 to 50 copies of HIV RNA per milliliter of plasma, while the DNA PCR tests can detect proviral DNA at a frequency of one copy per 10,000 to 100,000 cells. Thus, these tests are extremely sensitive. One frequent consequence of a high degree of sensitivity is some loss of specificity, and false-positive results have been reported with each of these techniques. For this reason, a positiveEIA with a confirmatory western blot remains the "gold standard" for a diagnosis of HIV infection, and the interpretation of other test results must be done with this in mind.

In theRT-PCRtechnique, following DNAase treatment, a cDNA copy is made of all RNA species present in plasma. Insofar as HIV is an RNA virus, this will result in the production of DNA copies of the HIV genome in amounts proportional to the amount of HIV RNA present in plasma. This proviral DNA is then amplified and characterized using standardPCRtechniques, employing primer pairs that can distinguish genomic cDNA from messenger cDNA. The bDNA assay involves the use of a solid-phase nucleic acid capture system and signal amplification through successive nucleic acid hybridizations to detect small quantities of HIV RNA. Both tests can achieve a tenfold increase in sensitivity to 40 to 50 copies of HIV RNA per milliliter with a preconcentration step in which plasma undergoes ultracentrifugation to pellet the viral particles. In addition to being a diagnostic and prognostic tool, RT-PCR is also useful for amplifying defined areas of the HIV genome for sequence analysis and has become an important technique for studies of sequence diversity and microbial resistance to antiretroviral agents. In patients with a positive or indeterminateEIA test and an indeterminate western blot, and in patients in whom serologic testing may be unreliable (such as patients with hypogammaglobulinemia or advanced HIV disease), these tests provide valuable tools for making a diagnosis of HIV infection. They should only be used for diagnosis when standard serologic testing has failed to provide a definitive result.

LABORATORY MONITORING OF PATIENTS WITH HIV INFECTION

The epidemic of HIV infection and AIDS has provided the clinician with new challenges for integrating clinical and laboratory data to effect optimal patient management. The close relationship between clinical manifestations of HIV infection and CD4+ T cell count has made measurement of the latter a routine part of the evaluation of HIV-infected individuals. Determinations of CD4+ T cell counts and measurements of the levels of

HIV RNA in serum or plasma provide a powerful set of tools for determining prognosis and monitoring response to therapy. While the CD4+ T cell count provides information on the current immunologic status of the patient, the HIV RNA level predicts what will happen to the CD4+ T cell count in the near future, and hence provides an important piece of prognostic information.

CD4+ T Cell Counts The CD4+ T cell count is the laboratory test generally accepted as the best indicator of the immediate state of immunologic competence of the patient with HIV infection. This measurement, which is the product of the percent of CD4+ T cells (determined by flow cytometry) and the total lymphocyte count [determined by the white blood cell count (WBC) and the differential count] has been shown to correlate very well with the level of immunologic competence. Patients with CD4+ T cell counts <200/uL are at high risk of infection with *P. carinii*, while patients with CD4+ T cell counts<50/uL are at high risk of infection withCMV and mycobacteria of the *M. avium complex* (MAC) (Fig. 309-26). Patients with HIV infection should have CD4+ T cell measurements performed at the time of diagnosis and every 3 to 6 months thereafter. More frequent measurements should be made if a declining trend is noted. According to most guidelines, a CD4 T cell count<500/uL is an indication for consideration of initiating antiretroviral therapy, and a decline in CD4+ T cell count of>25% is an indication for considering a change in therapy. Once the CD4+ T cell count is <200/uL, patients should be placed on a regimen for *P. carinii* prophylaxis, and once the count is <50/uL, primary prophylaxis for MAC infection is indicated. As with any laboratory measurement, one may wish to obtain two determinations prior to any significant changes in patient management based upon CD4+ T cell count alone.

HIV RNA Determinations Facilitated by highly sensitive techniques for the precise quantitation of small amounts of nucleic acids, the measurement of serum or plasma levels of HIV RNA has become an essential component in the monitoring of patients with HIV infection. As discussed under diagnosis of HIV infection, the two most commonly used techniques are theRT-PCRassay and the bDNA assay. Both assays generate data in the form of number of copies of HIV RNA per milliliter of serum or plasma and, by employing a 1:10 concentration step with ultracentrifugation, can detect as few as 40 to 50 copies of HIV RNA per milliliter of plasma. Although earlier versions of the bDNA assay generated values that were approximately 50% of those of the RT-PCR assay, the more recent versions (version 3 or higher) provide numbers essentially identical to those of the RT-PCR test (Fig. 309-25). While it is common practice to describe levels of HIV RNA below these cut-offs as "undetectable," this is a term that should be avoided as it is imprecise and leaves the false impression that the level of virus is 0. By utilizing more sensitive, nestedPCRtechniques and by studying tissue levels of virus as well as plasma levels, HIV RNA can be detected in virtually every patient with HIV infection. Measurements of changes in HIV RNA levels over time have been of great value in delineating the relationship between levels of virus and rates of disease progression (Fig. 309-17), the rates of viral turnover, the relationship between immune system activation and viral replication, and the time to development of drug resistance. HIV RNA measurements are greatly influenced by the state of activation of the immune system and may fluctuate greatly in the setting of secondary infections or immunization. For these reasons, decisions based upon HIV RNA levels should never be made on a single determination. Measurements of plasma HIV RNA levels should be made at the time of HIV diagnosis and every 3 to 4 months thereafter

in the untreated patient. In general, most guidelines suggest that therapy be initiated in patients with>20,000 copies of HIV RNA per milliliter (see below). Following the initiation of therapy or any change in therapy, plasma HIV RNA levels should be monitored approximately every 4 weeks until the effectiveness of the therapeutic regimen is determined by the development of a new steady-state level of HIV RNA. In most instances of effective therapy this will be <50 copies per milliliter. This level of virus is generally achieved within 6 months of the initiation of effective treatment. During therapy, levels of HIV RNA should be monitored every 3 to 4 months to evaluate the continuing effectiveness of therapy.

HIV Resistance Testing The availability of multiple antiretroviral drugs as treatment options has generated a great deal of interest in the potential for measuring the sensitivity of an individual's HIV virus(es) to different antiretroviral agents. HIV resistance testing can be done through either genotypic or phenotypic measurements. In the genotypic assays, sequence analyses of the HIV genomes obtained from patients are compared to sequences of viruses with known antiretroviral resistance profiles. In the phenotypic assays, the in vivo growth of viral isolates obtained from the patient are compared to the growth of reference strains of the virus in the presence or absence of different antiretroviral drugs. A modification of this phenotypic approach utilizes a comparison of the enzymatic activities of the reverse transcriptase or protease genes obtained by molecular cloning of patients' isolates to the enzymatic activities of genes obtained from reference strains of HIV in the presence or absence of different drugs targeted to these genes. These tests are quite good in identifying those antiretroviral agents that have been utilized in the past in a given patient. Their clinical value in identifying which antiretroviral regimen is best for an individual patient is still under investigation.

Other Tests A variety of other laboratory tests have been studied as potential markers of HIV disease activity. Among these are quantitative culture of replication-competent HIV from plasma, peripheral blood mononuclear cells, or resting CD4+ T cells; circulating levels ofb_2-microglobulin, solubleIL-2 receptor, IgA, acid-labile endogenous interferon, orTNF-a; and the presence or absence of activation markers such as CD38 or HLA-DR on CD8+ T cells. While these measurements have value as markers of disease activity and help to increase our understanding of the pathogenesis of HIV disease, they do not currently play a major role in the monitoring of patients with HIV infection.

CLINICAL MANIFESTATIONS

The clinical consequences of HIV infection encompass a spectrum ranging from an acute syndrome associated with primary infection to a prolonged asymptomatic state to advanced disease. It is best to regard HIV disease as beginning at the time of primary infection and progressing through various stages. As mentioned above, active virus replication and progressive immunologic impairment occur throughout the course of HIV infection in most patients. With the exception of long-term nonprogressors (see above), HIV disease in untreated patients inexorably progresses even during the clinically latent stage.

THE ACUTE HIV SYNDROME

It is estimated that 50 to 70% of individuals with HIV infection experience an acute clinical syndrome approximately 3 to 6 weeks after primary infection (Fig. 309-27). Varying degrees of clinical severity have been reported, and although it has been suggested that symptomatic seroconversion leading to the seeking of medical attention indicates an increased risk for an accelerated course of disease, this has not been shown definitively. In fact, there does not appear to be a correlation between the level of the initial burst of viremia in acute HIV infection and the subsequent course of disease. The typical clinical findings are listed inTable 309-10; they occur along with a burst of plasma viremia. The syndrome is typical of an acute viral syndrome and has been likened to acute infectious mononucleosis. Symptoms usually persist for 1 to several weeks and gradually subside as an immune response to HIV develops and the levels of plasma viremia decrease. Opportunistic infections have been reported during this stage of infection, reflecting the immunodeficiency that results from reduced numbers of CD4+ T cells and likely also from the dysfunction of CD4+ T cells owing to cross-linking of the CD4 molecule on the cell surface by viral envelope proteins (see "Mechanisms of CD4+ T Lymphocyte Depletion and Dysfunction," above) associated with the extremely high levels of plasma viremia. A number of immunologic abnormalities accompany the acute HIV syndrome, including multiphasic perturbations of the numbers of circulating lymphocyte subsets. The number of total lymphocytes and T cell subsets (CD4+ and CD8+) are initially reduced. An inversion of the CD4+/CD8+ T cell ratio occurs later because of a rise in the number of CD8+ T cells. In fact, there may be a selective and transient expansion of CD8+ T cell subsets, as determined by T cell receptor analysis (see above). The total circulating CD8+ T cell count may remain elevated or return to normal; however, CD4+ T cell levels usually remain somewhat depressed, although there may be a slight rebound towards normal. Lymphadenopathy occurs in approximately 70% of individuals with primary HIV infection. Most patients recover spontaneously from this syndrome and many are left with only a mildly depressed CD4+ T cell count that remains stable for a variable period before beginning its progressive decline (see below); in some individuals, the CD4+ T cell count returns to the normal range. Approximately 10% of patients manifest a fulminant course of immunologic and clinical deterioration after primary infection, even after the disappearance of symptoms. In most patients, primary infection with or without the acute syndrome is followed by a prolonged period of clinical latency.

THE ASYMPTOMATIC STAGE -- CLINICAL LATENCY

Although the length of time from initial infection to the development of clinical disease varies greatly, the median time for untreated patients is approximately 10 years. As emphasized above, HIV disease with active virus replication is ongoing and progressive during this asymptomatic period. The rate of disease progression is directly correlated with HIV RNA levels. Patients with high levels of HIV RNA in plasma progress to symptomatic disease faster than do patients with low levels of HIV RNA (Fig. 309-17). Some patients referred to as long-term nonprogressors show little if any decline in CD4+ T cell counts over extended periods of time. These patients generally have extremely low levels of HIV RNA. Certain other patients remain entirely asymptomatic despite the fact that their CD4+ T cell counts show a steady progressive decline to extremely low levels. In these patients, the appearance of an opportunistic disease may be the first manifestation of HIV infection. During the asymptomatic period of HIV

infection, the average rate of CD4+ T cell decline is approximately 50/uL per year. When the CD4+ T cell count falls to <200/uL, the resulting state of immunodeficiency is severe enough to place the patient at high risk for opportunistic infection and neoplasms, and hence for clinically apparent disease.

SYMPTOMATIC DISEASE

Symptoms of HIV disease can appear at any time during the course of HIV infection. Generally speaking, the spectrum of illness that one observes changes as the CD4+ T cell count declines. The more severe and life-threatening complications of HIV infection occur in patients with CD4+ T cells counts <200/uL. A diagnosis of AIDS is made in anyone with HIV infection and a CD4+ T cell count<200/uL and in anyone with HIV infection who develops one of the HIV-associated diseases considered to be indicative of a severe defect in cell-mediated immunity (category C,Table 309-2). While the causative agents of the secondary infections are characteristically opportunistic organisms such as *P. carinii*, atypical mycobacteria,CMV, and other organisms that do not ordinarily cause disease in the absence of a compromised immune system, they also include common bacterial and mycobacterial pathogens. Approximately 80% of deaths among AIDS patients are as a direct result of an infection other than HIV, with bacterial infections heading the list. Following the widespread use of combination antiretroviral therapy and implementation of guidelines for the prevention of opportunistic infections (Table 309-11), the incidence of secondary infections has decreased dramatically (Fig. 309-28). Overall, the clinical spectrum of HIV disease is constantly changing as patients live longer and new and better approaches to treatment and prophylaxis are developed. In general, it should be stressed that a key element of treatment of symptomatic complications of HIV disease, whether they are primary or secondary, is achieving good control of HIV replication through the use of combination antiretroviral therapy and instituting primary and secondary prophylaxis as indicated.

Disease of the Respiratory System Acute bronchitis and sinusitis are prevalent during all stages of HIV infection. The most severe cases tend to occur in patients with lower CD4+ T cell counts. Sinusitis presents as fever, nasal congestion, and headache. The diagnosis is made by computed tomography (CT) or magnetic resonance imaging (MRI). The maxillary sinuses are most commonly involved; however, disease is also frequently seen in the ethmoid, sphenoid, and frontal sinuses. While some patients may improve without antibiotic therapy, radiographic improvement is quicker and more pronounced in patients who have received antimicrobial therapy. It is postulated that this high incidence of sinusitis results from an increased frequency of infection with encapsulated organisms such as *H. influenzae* and *Streptococcus pneumoniae*. In patients with low CD4+ T cell counts one may see mucormycosis infections of the sinuses. In contrast to the course of this infection in other patient populations, mucormycosis of the sinuses in patients with HIV infection may progress more slowly. In this setting aggressive, frequent local debridement in addition to local and systemic amphotericin B may be needed for effective treatment.

Pulmonary disease is one of the most frequent complications of HIV infection. The most common manifestation of pulmonary disease is pneumonia. The two most common causes of pneumonia are bacteria infections and *P. carinii* infection. Other major causes of pulmonary infiltrates include mycobacterial infections, fungal infections, nonspecific

interstitial pneumonitis, KS, and lymphoma.

Pneumonia is seen with an increased frequency in patients with HIV infection. Patients with HIV infection appear to be particularly prone to infections with encapsulated organisms. *S. pneumoniae* (Chap. 138) and *H. influenzae* (Chap. 149) are responsible for most cases of bacterial pneumonia in patients with AIDS. This may be a consequence of altered B cell function and/or defects in neutrophil function that may be secondary to HIV disease (see above). Pneumococcal infection may be the earliest serious infection to occur in patients with HIV disease. This can present as pneumonia, sinusitis, and/or bacteremia. Patients with HIV infection have a sixfold increase in the incidence of pneumococcal pneumonia and a 100-fold increase in the incidence of pneumococcal bacteremia. Pneumococcal disease may be seen in patients with relatively intact immune systems. In one study, the baseline CD4+ T cell count at the time of a first episode of pneumococcal pneumonia was ~300/uL. Of interest is the fact that the inflammatory response to pneumococcal infection appears proportional to the CD4+ T cell count. Due to this high risk of pneumococcal disease, immunization with pneumococcal polysaccharide is one of the generally recommended prophylactic measures for patients with HIV infection and CD4+ T cell counts >200/uL. It is less clear if this intervention is of benefit in patients with more advanced disease and high viral loads.

P. carinii pneumonia (PCP), once the hallmark of AIDS, has dramatically declined in incidence following the development of effective prophylactic regimens and the widespread use of combination antiretroviral therapy. The risk of PCP is most common among those who have experienced a previous bout of PCP and those who have CD4+ T cell counts of <200/uL. Overall, 79% of patients with PCP have CD4+ T cell counts <100/uL and 95% of patients have CD4+ T cell counts <200/uL. Recurrent fever, night sweats, thrush, and unexplained weight loss are also associated with an increased incidence of PCP. For these reasons, it is strongly recommended that all patients with CD4+ T cell counts<200/uL (or a CD4 percentage<15) receive some form of PCP prophylaxis. At present the incidence of PCP is approaching zero in patients with known HIV infection receiving appropriate antiretroviral therapy and prophylaxis. Primary PCP is now occurring at a median CD4+ T cell count of 36/uL, while secondary PCP is occurring at a median CD4+ T cell count of 10/uL. Patients with PCP generally present with fever and a cough that is usually nonproductive or productive of only scant amounts of white sputum. They may complain of a characteristic retrosternal chest pain that is worse on inspiration and is described as sharp or burning. HIV-associated PCP may have an indolent course characterized by weeks of vague symptoms and should be included in the differential diagnosis of fever, pulmonary complaints, or unexplained weight loss in any patient with HIV infection and <200 CD4+ T cells/uL. The most common finding on chest x-ray is either a normal film, if the disease is suspected early, or a faint bilateral interstitial infiltrate. The classic finding of a dense perihilar infiltrate is unusual in patients with AIDS. In patients with PCP who have been receiving aerosolized pentamidine for prophylaxis, one may see an x-ray picture of upper lobe cavitary disease, reminiscent ofTB. Other less common findings on chest x-ray include lobar infiltrates and pleural effusions. Routine laboratory evaluation is usually of little help in the differential diagnosis of PCP. A mild leukocytosis is common, although this may not be obvious in patients with prior neutropenia. Arterial blood gases may indicate hypoxemia with a decline in Pa_{O2} and an increase in the arterial-alveolar (a - A)

gradient. Arterial blood gas measurements not only aid in making the diagnosis of PCP but also provide important information for staging the severity of the disease and directing treatment. A definitive diagnosis of PCP requires demonstration of the trophozoite or cyst form of the organism in samples obtained from induced sputum, bronchoalveolar lavage, transbronchial biopsy, or open lung biopsy.PCR has been used to detect specific DNA sequences for *P. carinii* in clinical specimens where histologic examinations have failed to make a diagnosis.

In addition to pneumonia, a number of other clinical problems have been reported in HIV-infected patients as a result of infection with *P. carinii*. Otic involvement may be seen as a primary infection, presenting as a polypoid mass involving the external auditory canal. In patients receiving aerosolized penamidine for prophylaxis againstPCP one may see a variety of extrapulmonary manifestations of *P. carinii*. These include ophthalmic lesions of the choroid, a necrotizing vasculitis that resembles Burger's disease, bone marrow hypoplasia, and intestinal obstruction. Other organs that have been involved include lymph nodes, spleen, liver, kidney, pancreas, pericardium, heart, thyroid, and adrenals. Organ infection may be associated with cystic lesions that may appear calcified onCT or ultrasound. The standard treatment for PCP or disseminated pneumocystosis is trimethoprim/sulfamethoxazole (TMP/SMZ). A high incidence of side effects, particularly skin rash and bone marrow suppression, is seen with TMP/SMZ in patients with HIV infection. Alternative treatments for mild to moderate PCP include dapsone/trimethoprim and clindamycin/primaquine. Intravenous pentamidine is the treatment of choice for severe disease in the patient unable to tolerate TMP/SMZ. For patients with a Pa_{O2}<70 mmHg or with an a - A gradient >35 mmHg, adjunct glucocorticoid therapy should be used in addition to specific antimicrobials. Overall, treatment should be for 21 days and followed by secondary prophylaxis. Prophylaxis for PCP is indicated for any HIV-infected individual who has experienced a prior bout of PCP, any patient with a CD4+ T cell count of<200/uL or a CD4 percentage<15, any patient with unexplained fever for>2 weeks, and any patient with a history of oropharyngeal candidiasis. The preferred regimen for prophylaxis is TMP/SMZ, one double-strength tablet daily. This regimen also provides protection against toxoplasmosis and some bacterial respiratory pathogens. For patients who cannot tolerate TMP/SMZ, alternatives include dapsone plus pyrimethamine plus leucovorin, aerosolized pentamidine administered by the Respirgard II nebulizer, and atovaquone. Primary prophylaxis for PCP can be discontinued in those patients treated with combination antiretroviral therapy who maintain good suppression of HIV (<500 copies per milliliter) and CD4+ T cell counts >200/uL for at least 3 to 6 months. There is as yet insufficient information to know if the same recommendation will hold for discontinuation of secondary prophylaxis.

M. tuberculosis, once thought to be on its way to extinction in the United States, experienced a resurgence associated with the HIV epidemic (Chap. 169). Worldwide, approximately one-third of all AIDS-related deaths are associated withTB. In the United States approximately 5% of AIDS patients have active TB. HIV infection increases the risk of developing active tuberculosis by a factor of 15 to 30. For the patient with untreated HIV infection and a positivePPD skin test, the rate of reactivation TB is 7 to 10% per year. Untreated TB can accelerate the course of HIV infection. Levels of plasma HIV RNA increase in the setting of active TB and decline in the setting of successful TB treatment. Active TB is most common in patients 25 to 44 years of age, in

African-Americans and Hispanics, in patients in New York City and Miami, and in patients in developing countries. In these demographic groups, 20 to 70% of the new cases of active TB are in patients with HIV infection. The epidemic of TB embedded in the epidemic of HIV infection probably represents the greatest health risk to the general public and the health care profession associated with the HIV epidemic. In contrast to infection with atypical mycobacteria such asMAC, active TB often develops relatively early in the course of HIV infection and may be an early clinical sign of HIV disease. In one study, the median CD4+ T cell count at presentation of TB was 326/uL. The clinical manifestations of TB in HIV-infected patients are quite varied and generally show different patterns as a function of the CD4+ T cell count. In patients with relatively high CD4+ T cell counts, the typical pattern of pulmonary reactivation occurs in which patients present with fever, cough, dyspnea on exertion, weight loss, night sweats, and a chest x-ray revealing cavitary apical disease of the upper lobes. In patients with lower CD4+ T cell counts, disseminated disease is more common. In these patients the chest x-ray may reveal diffuse or lower lobe bilateral reticulonodular infiltrates consistent with miliary spread, pleural effusions, and hilar and/or mediastinal adenopathy. Infection may be present in bone, brain, meninges, gastrointestinal tract, lymph nodes (particularly cervical lymph nodes), and viscera. Approximately 60 to 80% of patients have pulmonary disease, and 30 to 40% have extrapulmonary disease. Respiratory isolation and a negative-pressure room should be used for patients in whom a diagnosis of pulmonary TB is being considered. This approach is critical to limit nosocomial and community spread of infection. Culture of the organism from an involved site provides a definitive diagnosis. Blood cultures are positive in 15% of patients. In the setting of fulminant disease one cannot rely upon the accuracy of a negative PPD skin test to rule out a diagnosis of TB. TB is one of the conditions associated with HIV infection for which cure is possible. Therapy for TB is generally the same in the HIV-infected patient as in the HIV-negative patient (Chap. 169). Due to pharmacokinetic interactions, rifabutin should be substituted for rifampin in patients receiving the HIV protease inhibitors or nonnucleoside reverse transcriptase inhibitors; both drugs should be avoided in patients receiving ritonavir. Treatment is most effective in programs that involve directly observed therapy. Effective prevention of active TB can be a reality if the health care professional is aggressive in looking for evidence of latent TB by making sure that all patients with HIV infection receive a PPD skin test. Anergy testing is not of value in this setting. HIV-infected individuals with a skin test reaction of>5 mm or those who are close household contacts of persons with active TB should receive treatment with 9 months of isoniazid, or 2 months of therapy with rifampin and pyrazinamide, or 2 months of therapy with rifabutin and pyrazinamide.

Atypical mycobacterial infections are also seen with an increased frequency in patients with HIV infection. Infections with at least 12 different mycobacteria have been reported, including *M. bovis* and representatives of all four Runyon groups. The most common atypical mycobacterial infection is with *M. avium* or *M. intracellulare* species, the *M. avium* complex (MAC). Infections with MAC are seen mainly in patients in the United States and are rare in Africa. It has been suggested that prior infection with *M. tuberculosis* decreases the risk of MAC infection. MAC infections probably arise from organisms that are ubiquitous in the environment, including both soil and water. The presumed portals of entry are the respiratory and gastrointestinal tract. MAC infection is a late complication of HIV infection, occurring in patients with CD4+ T cell counts of<50/uL. The average CD4+ T cell count at the time of diagnosis is 10/uL. The most

common presentation is disseminated disease with fever, weight loss, and night sweats. At least 85% of patients with MAC infection are mycobacteremic, and large numbers of organisms can often be demonstrated on bone marrow biopsy. The chest x-ray is abnormal in approximately 25% of patients, with the most common pattern being that of a bilateral, lower lobe infiltrate suggestive of miliary spread. Alveolar or nodular infiltrates and hilar and/or mediastinal adenopathy can also occur. Other clinical findings include endobronchial lesions, abdominal pain, diarrhea, and lymphadenopathy. The diagnosis is made by the culture of blood or involved tissue. The finding of two consecutive sputum samples positive for MAC is highly suggestive of pulmonary infection. Cultures may take 2 weeks to turn positive. Therapy consists of a macrolide, usually clarithromycin, with ethambutol. Some physicians elect to add a third drug from among rifabutin, ciprofloxacin, or amikacin in patients with extensive disease. Therapy is generally for life; however, with the advent of highly active antiretroviral therapy (HAART), it may be possible to discontinue therapy in patients with sustained suppression of HIV replication and CD4+ T cell counts >100/uL for>6 months. Primary prophylaxis for MAC is indicated in patients with HIV infection and CD4+ T cell counts<50/uL. This may be discontinued in patients in whom HAART induces a sustained suppression of viral replication and increases in CD4+ T cell counts to >100/uL for 3 to 6 months.

Rhodococcus equi is a gram-positive pleomorphic acid-fast non-spore-forming bacillus that can cause pulmonary and/or disseminated infection in patients with HIV infection. Fever and cough are the most common presenting signs. Radiographically one may see cavitary lesions and consolidation. Blood cultures are often positive. Treatment is based upon antimicrobial sensitivity testing.

Fungal infections of the lung can be seen in patients with AIDS. Patients with pulmonary cryptococcal disease present with fever, cough, dyspnea, and in some cases, hemoptysis. A focal or diffuse interstitial infiltrate is seen on chest x-ray in>90% of patients. In addition, one may see lobar disease, cavitary disease, pleural effusions, and hilar or mediastinal adenopathy. Over half of patients are fungemic, and 90% of patients have concomitantCNSinfection. *Coccidioides immitis* is a mold that is endemic in the southwest United States. It can cause a reactivation pulmonary syndrome in patients with HIV infection. Most patients with this condition will have CD4+ T cell counts <250/uL. Patients present with fever, weight loss, cough, and extensive, diffuse reticulonodular infiltrates on chest x-ray. One may also see nodules, cavities, pleural effusions, and hilar adenopathy. While serologic testing is of value in the immunocompetent host, serologies are negative in 25% of HIV-infected patients with coccidioidal infection. Invasive aspergillosis is not an AIDS-defining illness and is generally not seen in patients with AIDS in the absence of neutropenia or administration of glucocorticoids. *Aspergillus* infection may have an unusual presentation in the respiratory tract of patients with AIDS where it gives the appearance of a pseudomembranous tracheobronchitis. Primary pulmonary infection of the lung may be seen with *histoplasmosis*. The most common pulmonary manifestation of histoplasmosis, however, is in the setting of disseminated disease, presumably due to reactivation. In this setting respiratory symptoms are usually minimal, with cough and dyspnea occurring in 10 to 30% of patients. The chest x-ray is abnormal in about 50% of patients, showing either a diffuse interstitial infiltrate or diffuse small nodules.

Two forms of *idiopathic interstitial pneumonia* have been identified in patients with HIV infection: lymphoid interstitial pneumonitis (LIP) and nonspecific interstitial pneumonitis (NIP). LIP, a common finding in children, is seen in about 1% of adult patients with HIV infection. This disorder is characterized by a benign infiltrate of the lung and is felt to be part of the polyclonal activation of lymphocytes seen in the context of HIV andEBVinfections. Transbronchial biopsy is diagnostic in 50% of the cases, with an open-lung biopsy required for diagnosis in the remainder of cases. This condition is generally self-limited and no specific treatment is necessary. Severe cases have been managed with brief courses of glucocorticoids. Although rarely a clinical problem since the use ofHAART, evidence of NIP may be seen in up to half of all patients with untreated HIV infection. Histologically, interstitial infiltrates of lymphocytes and plasma cells in a perivascular and peribronchial distribution are present. When symptomatic, patients present with fever and nonproductive cough occasionally accompanied by mild chest discomfort. Chest x-ray is usually normal or may reveal a faint interstitial pattern. Similar to LIP, this is a self-limited process for which no therapy is indicated.

Neoplastic diseases of the lung includingKS and lymphoma are discussed below in the section on malignancies.

Diseases of the Cardiovascular System While heart disease is a relatively common postmortem finding in HIV-infected patients (25 to 75% in autopsy series), it is less of a problem clinically. The most common clinically significant finding is a dilated cardiomyopathy associated with congestive heart failure referred to as *HIV-associated cardiomyopathy*. This generally occurs as a late complication of HIV infection and, histologically, displays elements of myocarditis. For this reason some have advocated treatment with intravenous Ig. HIV can be directly demonstrated in cardiac tissue in this setting, and there is debate over whether or not it plays a direct role in this condition. Patients present with typical findings of congestive heart failure, namely edema and shortness of breath. Patients with HIV infection may also develop cardiomyopathy as a side effect ofIFN-aor nucleoside analogue therapy, which is reversible once therapy is stopped.KS, cryptococcosis, Chagas disease, and toxoplasmosis can involve the myocardium, leading to cardiomyopathy. In one series, most patients with HIV infection and a treatable myocarditis were found to have myocarditis associated with toxoplasmosis. Most of these patients also had evidence ofCNStoxoplasmosis. Thus,MRI or double-dose contrastCT scan of the brain should be included in the workup of any patient with advanced HIV infection and cardiomyopathy.

A variety of other cardiovascular problems are found in patients with HIV infection. Pericardial effusions may be seen in the setting of advanced HIV infection. Predisposing factors includeTB, congestive heart failure, mycobacterial infection, cryptococcal infection, pulmonary infection, lymphoma, andKS. While pericarditis is quite rare, in one series 5% of patients with HIV disease had pericardial effusions that were considered to be moderate or severe. Tamponade and death have occurred in association with pericardial KS, presumably owing to acute hemorrhage. A high percentage of patients have hypertriglyceridemia and elevations in serum cholesterol, and coronary artery disease has been a relatively frequent finding at autopsy. This problem appears to becoming even more prevalent as a side effect ofHAART. While clinically significant ischemic heart disease has not been reported to be occurring with an increased frequency in this patient population, many are concerned that it is just a matter of time

before this is the case. Nonbacterial thrombotic endocarditis has been reported and should be considered in patients with unexplained embolic phenomena. Intravenous pentamidine, when given rapidly, can result in hypotension as a consequence of cardiovascular collapse.

Diseases of the Oropharynx and Gastrointestinal System Oropharyngeal and gastrointestinal diseases are common features of HIV infection. They are most frequently due to secondary infections. In addition, oral and gastrointestinal lesions may occur withKS and lymphoma.

Oral lesions, including *thrush*, *hairy leukoplakia*, and *aphthous ulcers*, are particularly common in patients with untreated HIV infection. Thrush, due to *Candida* infection, and oral hairy leukoplakia, presumed due toEBV, are usually indicative of fairly advanced immunologic decline; they generally occur in patients with CD4+ T cell counts of <300/uL. In one study, 59% of patients with oral candidiasis went on to develop AIDS in the next year. Thrush appears as a white, cheesy exudate, often on an erythematous mucosa in the posterior oropharynx (seePlate IID-43). While most commonly seen on the soft palate, early lesions are often found along the gingival border. The diagnosis is made by direct examination of a scraping for pseudohyphal elements. Culturing is of no diagnostic value, as most patients with HIV infection will have a positive throat culture for *Candida* even in the absence of thrush. Oral hairy leukoplakia presents as white, frondlike lesions, generally along the lateral borders of the tongue and sometimes on the adjacent buccal mucosa (seePlate IID-42). Despite its name, oral hairy leukoplakia is not considered a premalignant condition. Lesions are associated with florid replication of EBV. While usually more disconcerting as a sign of HIV-associated immunodeficiency than a clinical problem in need of treatment, severe cases have been reported to respond to topical podophyllin or systemic therapy with acyclovir. Aphthous ulcers of the posterior oropharynx are also seen with regularity in patients with HIV infection. These lesions are of unknown etiology and can be quite painful and interfere with swallowing. Topical anesthetics provide immediate symptomatic relief of short duration. The fact that thalidomide is an effective treatment for this condition suggests that the pathogenesis may involve the action of tissue-destructive cytokines. Palatal, glossal, or gingival ulcers may also result from cryptococcal disease or histoplasmosis.

Esophagitis (Fig. 309-29) may present with odynophagia and retrosternal pain. Upper endoscopy is generally required to make an accurate diagnosis. Esophagitis may be due to *Candida*,CMV, orHSV. While CMV tends to be associated with a single large ulcer, HSV infection is more often associated with multiple small ulcers. The esophagus may also be the site ofKS and lymphoma. Like the oral mucosa, the esophageal mucosa may have large, painful ulcers of unclear etiology that may respond to thalidomide. While achlorhydria is a common problem in patients with HIV infection, other gastric problems are generally rare. Among the conditions involving the stomach are KS and lymphoma. Infections of the small and large intestine leading to diarrhea, abdominal pain, and occasionally fever are among the most significant gastrointestinal problems in the HIV-infected patients. They include infections with bacteria, protozoa, and viruses.

Bacteria and fungi may be responsible for secondary infections of the gastrointestinal tract. Infections with enteric pathogens such as *Salmonella*, *Shigella*, and

Campylobacter are more common in homosexual men and are often more severe and more apt to relapse in patients with HIV infection. Patients with untreated HIV have approximately a 20-fold increased risk of infection with *S. typhimurium*. They may present with a variety of nonspecific symptoms including fever, anorexia, fatigue, and malaise of several weeks' duration. Diarrhea is common but may be absent. Diagnosis is made by culture of blood and stool. Long-term therapy with ciprofloxacin is the recommended treatment. HIV-infected patients also have an increased incidence of *S. typhi* infection in areas of the world where typhoid is a problem. *Shigella* spp., particularly *S. flexneri*, can cause severe intestinal disease in HIV-infected individuals. Up to 50% of patients will develop bacteremia. *Campylobacter* infections occur with an increased frequency in patients with HIV infection. While *C. jejuni* is the strain most frequently isolated, infections with many other strains have been reported. Patients usually present with crampy abdominal pain, fever, and bloody diarrhea. Infection may present as proctitis. Stool examination reveals the presence of fecal leukocytes. Systemic infection can occur, with up to 10% of infected patients exhibiting bacteremia. Most strains are sensitive to erythromycin. Abdominal pain and diarrhea may be seen withMACinfection.

Fungal infections may also be a cause of diarrhea in patients with HIV infection. Histoplasmosis, coccidioidomycosis, and penicilliosis have all been identified as a cause of fever and diarrhea in patients with HIV infection. Peritonitis has been seen with *C. immitis*.

Cryptosporidia, microsporidia, and *Isospora belli* (Chap. 218) are the most common opportunistic protozoa that infect the gastrointestinal tract and cause diarrhea in HIV-infected patients. Cryptosporidial infection may present in a variety of ways, ranging from a self-limited or intermittent diarrheal illness in patients in the early stages of HIV infection to a severe, life-threatening diarrhea in severely immunodeficient individuals. In patients with untreated HIV infection and CD4+ T cell counts of <300/uL, the incidence of cryptosporidiosis is approximately 1% per year. In 75% of cases the diarrhea is accompanied by crampy abdominal pain, and 25% of patients have nausea and/or vomiting. Cryptosporidia may also cause biliary tract disease in the HIV-infected patient, leading to cholecystitis with or without accompanying cholangitis. The diagnosis of cryptosporidial diarrhea is made by stool examination. The diarrhea is noninflammatory, and the characteristic finding is the presence of oocysts that stain with acid-fast dyes. Therapy is predominantly supportive, and marked improvements have been reported in the setting of effective antiretroviral therapy. Treatment with up to 2000 mg/d of nitazoxanide (NTZ) is associated with improvement in symptoms or a decrease in shedding of organisms in about half of patients. Its overall role in the management of this condition remains unclear. Patients can minimize their risk of developing cryptosporidiosis by avoiding contact with human and animal feces and by not drinking untreated water from lakes or rivers.

Microsporidia are small, unicellular, obligate intracellular parasites that reside in the cytoplasm of enteric cells (Chap. 218). The main species causing disease in humans is *Enterocytozoon bieneusi*. The clinical manifestations are similar to those described for Cryptosporidia and include abdominal pain and diarrhea. The small size of the organism may make it difficult to detect; however, with the use of chromotrope-based stains, organisms can be identified in stool samples by light microscopy. Definitive diagnosis

generally depends on electron microscopic examination of a stool specimen, intestinal aspirate, or intestinal biopsy specimen. In contrast to cryptosporidia, microsporidia have been noted in a variety of extraintestinal locations, including the eye, muscle, and liver, and have been associated with conjunctivitis and hepatitis. Albendazole, 400 mg bid, has been reported to be of benefit in some patients.

I. belli is a coccidian parasite (Chap. 218) most commonly found as a cause of diarrhea in patients from the Caribbean and Africa. Its cysts appear in the stool as large, acid-fast structures that can be differentiated from those of cryptosporidia on the basis of size, shape, and number of sporocysts. The clinical syndromes of *Isospora* infection are identical to those caused by cryptosporidia. The important distinction is that infection with *Isospora* is generally relatively easy to treat withTMP/SMZ. While relapses are common, a thrice-weekly regimen, similar to that used to provide prophylaxis againstPCP, appears adequate to prevent recurrence.

CMVcolitis was once seen in 5 to 10% of patients with AIDS. It is much less common with the advent ofHAART. CMV colitis presents as diarrhea, abdominal pain, weight loss, and anorexia. The diarrhea is usually nonbloody, and the diagnosis is achieved through endoscopy and biopsy. Multiple mucosal ulcerations are seen at endoscopy, and biopsies reveal characteristic intranuclear inclusion bodies. Bacteremia may result as a consequence of thinning of the bowel wall. Treatment is with either ganciclovir or foscarnet for 3 to 6 weeks. Relapses are common, and maintenance therapy is typically necessary in patients whose HIV infection is poorly controlled. Patients with CMV disease of the gastrointestinal tract should be carefully monitored for evidence of retinitis.

In addition to disease caused by specific secondary infections, patients with HIV infection may also experience a chronic diarrheal syndrome for which no etiologic agent other than HIV can be identified. This entity is referred to as *AIDS enteropathy* or *HIV enteropathy*. It is most likely a direct result of HIV infection in the gastrointestinal tract. Histologic examination of the small bowel in these patients reveals low-grade mucosal atrophy with a decrease in mitotic figures, suggesting a hyporegenerative state. Patients often have decreased or absent small-bowel lactase and malabsorption with accompanying weight loss.

The initial evaluation of a patient with HIV infection and diarrhea should include a set of stool examinations, including culture, examination for ova and parasites, and examination for *Clostridium difficile* toxin. Approximately 50% of the time this workup will demonstrate infection with pathogenic bacteria, mycobacteria, or protozoa. If the initial stool examinations are negative, additional evaluation, including upper and/or lower endoscopy with biopsy, will yield a diagnosis of microsporidial or mycobacterial infection of the small intestine ~30% of the time. In patients for whom this diagnostic evaluation is nonrevealing, a presumptive diagnosis of HIV enteropathy can be made if the diarrhea has persisted for >1 month. An algorithm for the evaluation of diarrhea in patients with HIV infection is given inFig. 309-30.

Rectal lesions are common in HIV-infected patients, particularly the perirectal ulcers and erosions due to the reactivation ofHSV(Fig. 309-31). These may appear quite atypical, as denuded skin without vesicles, and they respond well to treatment with acyclovir,

famciclovir, or foscarnet. Other rectal lesions encountered in the patients with HIV infection include condylomata acuminata,KS, and intraepithelial neoplasia.

Hepatobiliary Disease Diseases of the hepatobiliary system are a major problem in patients with HIV infection. It has been estimated that approximately one-third of the deaths of patients with HIV infection are in some way related to liver disease. While this is predominantly a reflection of the problems encountered in the setting of co-infection with hepatitis B or C, it is also a reflection of the hepatic injury, predominantly in the form of hepatic steatosis, that can be seen in the context of nucleoside analogue antiretroviral therapy.

Over 95% of HIV-infected individuals have evidence of infection withHBV; 5-40% of patients are co-infected with hepatitis C virus (HCV); and co-infection with hepatitis D, E, and/or G viruses is common. HIV infection has a significant impact on the course of hepatitis virus infection. It is associated with approximately a threefold increase in the development of persistent hepatitis B surface antigenemia. Patients infected with both HBV and HIV have decreased evidence of inflammatory liver disease. The presumption that this is due to the immunosuppressive effects of HIV infection is supported by the observations that this situation can be reversed, and one may see the development of more severe hepatitis following the initiation of effective antiretroviral therapy.IFN-ais less successful as a treatment of HBV in patients with HIV co-infection, and lamivudine is the treatment of choice. It is important to remember that lamivudine is also a potent antiretroviral agent in the setting of combination antiretroviral therapy. It should not be used as a single agent in patients with HIV infection, even if it is only being used to treat HBV, in order to avoid the rapid development of lamivudine-resistant quasispecies of HIV. In contrast to the situation with HBV, HCV infection is more severe in the patient with HIV infection. In the setting of HIV and HCV co-infection, levels of HCV are approximately tenfold higher than in the HIV-negative patient with HCV infection. The incidence of HCV-associated liver failure appears to be higher by a similar factor in patients with HIV infection. Hepatitis A virus infection is not seen with an increased frequency in patients with HIV infection. It is recommended that all patients with HIV infection who have not experienced natural infection be immunized with hepatitis A and/or hepatitis B vaccines.

A variety of other infections may also involve the liver. Granulomatous hepatitis may be seen as a consequence of mycobacterial or fungal infections, particularlyMACinfection. Hepatic masses may be seen in the context ofTB, peliosis hepatis, or fungal infection. Among the fungal opportunistic infection *C. immitis* and *Histoplasma capsulatum* are those most likely to involve the liver. Biliary tract disease in the form of papillary stenosis or sclerosing cholangitis has been reported in the context of cryptosporidiosis,CMVinfection, andKS.

Many of the drugs used to treat HIV infection are metabolized by the liver and can cause liver injury. Nucleoside analogues work by inhibiting DNA synthesis. This can result in toxicity to mitochondria, which can lead to disturbances in oxidative metabolism. This may be manifest as hepatic steatosis and, in severe cases, lactic acidosis and fulminant liver failure. It is important to be aware of this condition and to watch for it in patients with HIV infection receiving nucleoside analogues. It is reversible if diagnosed early and the offending agent(s) discontinued. Indinavir may cause mild to

moderate elevations in serum bilirubin in 10 to 15% of patients in a syndrome similar to Gilbert's syndrome.

Pancreatic injury is most commonly a consequence of drug toxicity, notably that secondary to pentamidine or dideoxynucleosides. While up to half of patients in some series have biochemical evidence of pancreatic injury, <5% of patients show any clinical evidence of pancreatitis that is not linked to a drug toxicity.

Diseases of the Kidney and Genitourinary Tract Diseases of the kidney or genitourinary tract may be a direct consequence of HIV infection, due to an opportunistic infection or neoplasm, or related to drug toxicity. *HIV-associated nephropathy* was first described inIDUs and was initially thought to be IDU nephropathy in patients with HIV infection; it is now recognized as a true direct complication of HIV infection. HIV-associated nephropathy can be an early manifestation of HIV infection and is also seen in children. Over 90% of reported cases have been in African-American or Hispanic individuals; the disease is not only more prevalent in these populations but also more severe. Proteinuria is the hallmark of this disorder. Overall, microalbuminuria is seen in ~20% of untreated HIV-infected patients; significant proteinuria is seen in closer to 2%. Edema and hypertension are rare. Ultrasound examination reveals enlarged, hyperechogenic kidneys. A definitive diagnosis is obtained through renal biopsy. Histologically, focal segmental glomerulosclerosis is present in 80%, and mesangial proliferation in 10 to 15% of cases. Prior to effective antiretroviral therapy, this disease was characterized by relatively rapid progression to end-stage renal disease. Treatment with prednisone, 60 mg/d, has been reported to be of benefit in some cases. The incidence of this disease in patients receiving adequate antiretroviral therapy has not been well defined; however, the impression is that it has decreased in frequency. It is the leading cause of end-stage renal disease in patients with HIV infection.

Among the drugs commonly associated with renal damage in patients with HIV disease are pentamidine, amphotericin, adefovir, cidofovir, and foscarnet.TMP/SMZmay compete for tubular secretion with creatinine and cause an increase in the serum creatinine level. Sulfadiazine may crystallize in the kidney and result in an easily reversible form of renal shutdown. One of the most common drug-induced renal complications is indinavir-associated renal calculi. This condition is seen in ~10% of patients receiving this HIV protease inhibitor. It may present with a variety of manifestations, ranging from asymptomatic hematuria to renal colic. Adequate hydration is the mainstay of treatment and prevention for this condition.

Genitourinary tract infections are seen with a high frequency in patients with HIV infection; they present with dysuria, hematuria, and/or pyuria and are managed in the same fashion as in patients with HIV infection. Infections with *T. pallidum*, the etiologic agent of *syphilis*, play an important role in the HIV epidemic (Chap. 172). In HIV-negative individuals, genital syphilitic ulcers as well as the ulcers of chancroid are major predisposing factors for heterosexual transmission of HIV infection. While most HIV-infected individuals with syphilis have a typical presentation, a variety of formerly rare clinical problems may be encountered in the setting of dual infection. Among them are *lues maligna*, an ulcerating lesion of the skin due to a necrotizing vasculitis; unexplained fever; nephrotic syndrome; and neurosyphilis. The most common

presentation of syphilis in the HIV-infected patient is that of *condylomata lata*, a form of secondary syphilis. Neurosyphilis may be asymptomatic or may present as acute meningitis, neuroretinitis, deafness, or stroke. The rate of neurosyphilis may be as high as 1% in patients with HIV infection. As a consequence of the immunologic abnormalities seen in the setting of HIV infection, diagnosis of syphilis through standard serologic testing may be challenging. On the one hand, a significant number of patients have false-positive Venereal Disease Research Laboratory (VDRL) tests due to polyclonal B cell activation. On the other hand, the development of a new positive VDRL may be delayed in patients with new infections, and the anti-fluorescent treponema antibody (anti-FTA) test may be negative due to immunodeficiency. Thus, dark-field examination of appropriate specimens should be performed in any patient in whom syphilis is suspected, even if the patient has a negative VDRL. Similarly, any patient with a positive serum VDRL test, neurologic findings, and an abnormal spinal fluid examination should be considered to have neurosyphilis, regardless of theCSF VDRL result. In any setting, patients treated for syphilis need to be carefully monitored to ensure adequate therapy.

Vulvovaginal candidiasis is a common problem in women with HIV infection. Symptoms include pruritus, discomfort, dyspareunia, and dysuria. Vulvar infection may present as a moribilliform rash that may extend to the thighs. Vaginal infection is usually associated with a white discharge, and plaques may be seen along an erythematous vaginal wall. Diagnosis is made by microscopic examination of the discharge for pseudohyphal elements in a 10% potassium hydroxide solution. Mild disease can be treated with topical therapy. More serious disease can be treated with fluconazole. Other causes of vaginitis include *Trichomonas* and mixed bacteria.

Diseases of the Endocrine System and Metabolic Disorders A variety of endocrine and metabolic disorders are seen in the context of HIV infection. Between 33 and 75% of patients with HIV infection receivingHAARTdevelop a syndrome often referred to as *lipodystrophy*, consisting of elevations in plasma triglycerides, total cholesterol, apolipoprotein B, and high-density lipoprotein cholesterol as well as hyperinsulinemia. Many of these patients have been noted to have a characteristic set of body habitus changes associated with fat redistribution, consisting of truncal obesity coupled with peripheral wasting (Fig. 309-32). Truncal obesity is apparent as an increase in abdominal girth related to increases in mesenteric fat, a dorsocervical fat pad ("buffalo hump") reminiscent of patients with Cushing's syndrome, and enlargement of the breasts. The peripheral wasting is particularly noticeable in the face and buttocks and by the prominence of the veins in the legs. Other related problems include insulin-requiring diabetes mellitus and avascular necrosis of the femoral head. These changes may develop at any time ranging from approximately 6 weeks to several years following the initiation of HAART. The syndrome has been reported in association with regimens containing a variety of different drugs, and while initially reported in the setting of protease inhibitor therapy, it appears similar changes can be induced by potent protease-sparing regimens. National Cholesterol Education Program (NCEP) guidelines should be followed in the management of these lipid abnormalities (Chap. 242). Due to concerns regarding drug interactions, the most commonly utilized agents in this setting are gemfibrozil and atorvostatin.

Patients with advanced HIV disease may develop hyponatremia due to the syndrome of

inappropriate antidiuretic hormone (vasopressin) secretion (SIADH) as a consequence of increased free water intake and decreased free water excretion. SIADH is usually seen in conjunction with pulmonary orCNSdisease. Low serum sodium may also be due to adrenal insufficiency; concomitant high serum potassium should alert one to this possibility. Adrenal gland disease may be due to mycobacterial infections,CMVdisease, cryptococcal disease, histoplasmosis, or ketoconazole toxicity.

Thyroid function is generally normal in patients with HIV infection although approximately 2 to 3% of patients may have elevations in thyroid stimulating hormone (TSH). In advanced HIV disease, infection of the thyroid gland may occur with opportunistic pathogens, including *P. carinii*,CMV, mycobacteria, *Toxoplasma gondii*, and *Cryptococcus neoformans*. These infections are generally associated with a nontender, diffuse enlargement of the thyroid gland. Thyroid function is usually normal. Diagnosis is made by fine-needle aspirate or open biopsy.

Advanced HIV disease is associated with *hypogonadism* in approximately 50% of men. While this is generally a complication of underlying illness, testicular dysfunction may also be a side effect of ganciclovir therapy. In some surveys, up to two-thirds of patients report decreased libido and one-third complain of impotence. Androgen replacement therapy should be considered in patients with symptomatic hypogonadism. HIV infection does not seem to have a significant effect on the menstrual cycle outside the setting of advanced disease.

Rheumatologic Diseases Immunologic and rheumatologic disorders are common in patients with HIV infection and range from excessive immediate-type hypersensitivity reactions (Chap. 310) to an increase in the incidence of reactive arthritis (Chap. 315) to conditions characterized by a diffuse infiltrative lymphocytosis. These phenomena occur in an apparent paradox to the profound immunodeficiency and immunosuppression that characterizes HIV infection. In addition, following the initiation of antiretroviral therapy, one may see a variety of exaggerated immune responses to existing opportunistic infections referred to as *immune reactivation syndromes*.

Drug allergies are the most significant allergic reactions occurring in HIV-infected patients and appear to become more common as the disease progresses. They occur in 65% of patients who receive therapy withTMP/SMZfor PCP. In general, these drug reactions are characterized by erythematous, morbilliform eruption that are pruritic, tend to coalesce, and are often associated with fever. Nonetheless, ~33% of patients can be maintained on the offending therapy, and thus these reactions are not an immediate indication to stop the drug. Anaphylaxis is extremely rare in patients with HIV infection, and patients who have a cutaneous reaction during a single course of therapy can still be considered candidates for future treatment or prophylaxis with the same agent. The one exception to this is the nucleoside analogue abacavir, where fatal hypersensitivity reactions have been reported with rechallenge. A hypersensitivity reaction to abacavir is an absolute contraindication to future therapy. For other agents, including TMP/SMZ, desensitization regimens are moderatively successful. While the mechanisms underlying these allergic-type reactions remain unknown, patients with HIV infection have been noted to have elevated IgE levels that increase as the CD4+ T cell count declines. The numerous examples of patients with multiple drug reactions suggest that a common pathway is involved.

HIV infection shares many similarities with a variety of autoimmune diseases, including a substantial polyclonal B cell activation that is associated with a high incidence of antiphospholipid antibodies, such as anticardiolipin antibodies,VDRLantibodies, and lupus-like anticoagulants. In addition, HIV-infected individuals have an increased incidence of antinuclear antibodies. Despite these serologic findings, there is no evidence that HIV-infected individuals have an increase in two of the more common autoimmune diseases, i.e., systemic lupus erythematosus and rheumatoid arthritis. In fact, it has been observed that these diseases may be somewhat ameliorated by the concomitant presence of HIV infection, suggesting that an intact CD4+ T cell limb of the immune response plays an integral role in the pathogenesis of these conditions. Similarly, there are anecdotal reports of patients with common variable immunodeficiency (Chap. 308), characterized by hypogammaglobulinemia who have had a normalization of Ig levels following the development of HIV infection, suggesting a possible role for overactive CD4+ T cell immunity in certain forms of that syndrome. The one autoimmune disease that may occur with an increased frequency in patients with HIV infection is a variant of primary Sjogren's syndrome (Chap. 314). Patients with HIV infection may develop a syndrome consisting of parotid gland enlargement, dry eyes, and dry mouth that is associated with lymphocytic infiltrates of the salivary gland and lung. In contrast to Sjogren's syndrome, in which these infiltrates are composed predominantly of CD4+ T cells, in patients with HIV infection the infiltrates are composed predominantly of CD8+ T cells. In addition, while patients with Sjogren's syndrome are mainly women who have autoantibodies to Ro and La and who frequently have HLA-DR3 or -B8,MHChaplotypes, HIV-infected individuals with this syndrome are usually African-American men who do not have anti-Ro or anti-La and who most often are HLA-DR5. This syndrome appears to be less common with the increased use of effective antiretroviral therapy. The term *diffuse infiltrative lymphocytosis syndrome* (DILS) has been proposed to describe this entity and to distinguish it from Sjogren's syndrome.

Approximately one-third of HIV-infected individuals experience arthralgias; furthermore, 5 to 10% are diagnosed as having some form of reactive arthritis, such as Reiter's syndrome or psoriatic arthritis (Chaps. 315 and324). These syndromes occur with increasing frequency as the competency of the immune system declines. This association may be related to an increase in the number of infections with organisms that may trigger a reactive arthritis with progressive immunodeficiency. Reactive arthritides in HIV-infected individuals generally respond well to standard treatment; however, therapy with methotrexate has been associated with an increase in the incidence of opportunistic infections and should be used with caution and only in severe cases.

HIV-infected individuals also experience a variety of joint problems without obvious cause that are referred to generically as *HIV- or AIDS-associated arthropathy*. This syndrome is characterized by subacute oligoarticular arthritis developing over a period of 1 to 6 weeks and lasting 6 weeks to 6 months. It generally involves the large joints, predominantly the knees and ankles, and is nonerosive with only a mild inflammatory response. X-rays of the joint are nonrevealing. Nonsteroidal anti-inflammatory drugs are only marginally helpful; however, relief has been noted with the use of intraarticular glucocorticoids. A second form of arthritis also thought to be secondary to HIV infection

is called *painful articular syndrome*. This condition, found in as many as 10% of AIDS patients, presents as an acute, severe, sharp pain in the affected joint. It affects primarily the knees, elbows, and shoulders; lasts 2 to 24 h; and may be severe enough to require narcotic analgesics. The cause of this arthropathy is unclear; however, it is thought to result from a direct effect of HIV on the joint. This condition is reminiscent of the fact that other lentiviruses, in particular the caprine arthritis-encephalitis virus, are capable of directly causing arthritis.

A variety of other immunologic or rheumatologic diseases have been reported in HIV-infected individuals, either de novo or in association with opportunistic infections or drugs. Using the criteria of widespread musculoskeletal pain of at least 3 months' duration and the presence of at least 11 of 18 possible tender points by digital palpation, 11% of an HIV-infected cohort containing 55%IDUswere diagnosed as having *fibromyalgia* (Chap. 325). While the incidence of frank arthritis was less in this population than in other studied populations that consisted predominantly of homosexual men, these data support the concept that there are musculoskeletal problems that occur as a direct result of HIV infection. In addition there have been reports of leukocytoclastic vasculitis in the setting of zidovudine therapy.CNSangiitis and polymyositis have also been reported in HIV-infected individuals. Septic arthritis is surprisingly rare, especially given the increased incidence of staphylococcal bacteremias seen in this population. When septic arthritis has been reported, it has usually been due to systemic fungal infections with *C. neoformans*, *Sporothrix schenckii*, or *H. capsulatum*, or systemic mycobacterial infection with *M. haemophilum*.

Following the initiation of effective antiretroviral therapy, a paradoxical worsening of preexisting, untreated opportunistic infections may be noted. These *immune reactivation syndromes* are particularly common in patients with underlying untreated mycobacterial infections. They appear to be related to a phenomenon similar to type IV hypersensitivity reactions and reflect the immediate improvements in immune function that occur as levels of HIV RNA drop and the immunosuppressive effects of HIV infection are controlled. In severe cases the use of immunosuppressive drugs such as glucocorticoids may be required to blunt the inflammatory component of these reactions while specific antimicrobial therapy takes effect.

Diseases of the Hematopoietic System Disorders of the hematopoietic system including lymphadenopathy, anemia, leukopenia, and/or thrombocytopenia are common throughout the course of HIV infection and may be the direct result of HIV, manifestations of secondary infections and neoplasms, or side effects of therapy (Table 309-12). Direct histologic examination and culture of lymph node or bone marrow tissue are often diagnostic. A significant percentage of bone marrow aspirates from patients with HIV infection have been reported to contain lymphoid aggregates, the precise significance of which is unknown.

Some patients, otherwise asymptomatic, may develop *persistent generalized lymphadenopathy* as an early clinical manifestation of HIV infection. This condition is defined as the presence of enlarged lymph nodes (>1 cm) in two or more extrainguinal sites for >3 months without an obvious cause. The lymphadenopathy is due to marked follicular hyperplasia in the node in response to HIV infection. The nodes are generally discrete and freely movable. This feature of HIV disease may be seen at any point in the

spectrum of immune dysfunction and is not associated with an increased likelihood of developing AIDS. Paradoxically, a loss in lymphadenopathy or a decrease in lymph node size outside the setting of antiretroviral therapy may be a prognostic marker of disease progression. In patients with CD4+ T cell counts>200/uL, the differential diagnosis of lymphadenopathy includesKS andTB. In patients with more advanced disease, lymphadenopathy may also be due to lymphoma, atypical mycobacterial infection, toxoplasmosis, systemic fungal infection, or bacillary angiomatosis. While indicated in patients with CD4+ T cell counts <200/uL, lymph node biopsy is not indicated in patients with early-stage disease unless there are signs and symptoms of systemic illness, such as fever and weight loss, or unless the nodes begin to enlarge, become fixed, or coalesce.

Anemia is the most common hematologic abnormality in HIV-infected patients. While generally mild, anemia can be quite severe and require chronic blood transfusions. Among the specific reversible causes of anemia in the setting of HIV infection are drug toxicity, systemic fungal and mycobacterial infections, nutritional deficiencies, and parvovirus B19 infections. Zidovudine has a somewhat selective ability to block erythroid maturation, an effect that precedes effects on other marrow elements. A characteristic feature of zidovudine therapy is an elevated mean corpuscular volume (MCV). Another drug used in patients with HIV infection that has a selective effect on the erythroid series is dapsone. This drug can cause a serious hemolytic anemia in patients who are deficient in glucose-6-phosphate dehydrogenase and can create a functional anemia in others through induction of methemoglobinemia. Folate levels are usually normal in HIV-infected individuals; however, vitamin B_{12}levels may be depressed as a consequence of achlorhydria or malabsorption. True autoimmune hemolytic anemia is rare, although ~20% of patients with HIV infection may have a positive direct antiglobulin test as a consequence of polyclonal B cell activation. Infection with parvovirus B19 may also cause anemia. It is important to recognize this possibility given the fact that it responds well to treatment with intravenous immunoglobulin. Erythropoietin levels in patients with HIV infection and anemia are generally less than expected given the degree of anemia. Treatment with erythropoietin at doses of 100 ug/kg three times a week may result in an increase in hemoglobulin levels. An exception to this is a subset of patients with zidovudine-associated anemia in whom erythropoietin levels may be quite high.

During the course of HIV infection, neutropenia may be seen in approximately half of patients. In most instances it is mild; however, it can be severe and can put patients at risk of spontaneous bacterial infections. This is most frequently seen in patients with severely advanced HIV disease and in patients receiving any of a number of potentially myelosuppressive therapies. In the setting of neutropenia, diseases that are not commonly seen in HIV-infected patients, such as aspergillosis or mucormycosis, may occur. The potential role of colony-stimulating factors in the management of patients with HIV infection has undergone extensive evaluation. Both granulocyte colony stimulating factor (G-CSF) andGM-CSFincrease neutrophil counts in patients with HIV infection regardless of the cause of the neutropenia. Earlier concerns about the potential of these agents to also increase levels of HIV were not confirmed in controlled clinical trials.

Thrombocytopenia may be an early consequence of HIV infection. Approximately 3% of

patients with untreated HIV infection and CD4+ T cell counts ³400/uL have platelet counts <150,000/uL. For untreated patients with CD4+ T cell counts <400/uL, this incidence increases to 10%. Thrombocytopenia is rarely a serious clinical problem in patients with HIV infection and generally responds well to antiretroviral therapy. Clinically, it resembles the thrombocytopenia seen in patients with idiopathic thrombocytopenic purpura (Chap. 116). Immune complexes containing anti-gp120 antibodies and anti-anti gp120 antibodies have been noted in the circulation and on the surface of platelets in patients with HIV infection. Patients with HIV infection have also been noted to have a platelet-specific antibody directed towards a 25-kDa component of the surface of the platelet. Other data suggest that the thrombocytopenia in patients with HIV infection may be due to a direct effect of HIV on megakaryocytes. Whatever the cause, it is very clear that the most effective medical approach to this problem has been the use of combination antiretroviral therapy. For patients with platelet counts<20,000/uL a more aggressive approach combining intravenous Ig or anti-Rh Ig for an immediate response with antiretroviral therapy for a more lasting response is appropriate. Splenectomy is a rarely needed option and is reserved for patients refractory to medical management. Because of the risk of serious infection with encapsulated organisms, all patients with HIV infection about to undergo splenectomy should be immunized with pneumococcal polysaccharide. It should be noted that, in addition to causing an increase in the platelet count, removal of the spleen will result in an increase in the peripheral blood lymphocyte count, making CD4+ T cell counts unreliable. In this setting, the clinician should rely on the CD4+ T cell percent for making diagnostic decisions with respect to the likelihood of opportunistic infections. A CD4+ T cell percent of 15 is approximately equivalent to a CD4+ T cell count of 200/uL. In patients with early HIV infection, thrombocytopenia has also been reported as a consequence of classic thrombotic thrombocytopenic purpura (Chap. 116). This clinical syndrome, consisting of fever, thrombocytopenia, hemolytic anemia, and neurologic and renal dysfunction, is a rare complication of early HIV infection. As in other settings, the appropriate management is the use of salicylates and plasma exchange. Other causes of thrombocytopenia include lymphoma, mycobacterial infections, and fungal infections.

Dermatologic Diseases Dermatologic problems occur in >90% of patients with HIV infection. From the macular, roseola-like rash seen with the acute seroconversion syndrome to extensive end-stageKS, cutaneous manifestations of HIV disease can be seen throughout the course of HIV infection. Among the more common nonneoplastic problems are seborrheic dermatitis, eosinophilic pustular folliculitus, and opportunistic infections. Extrapulmonary pneumocystosis may cause a necrotizing vasculitis. Neoplastic conditions are covered below in the section on malignant diseases.

Seborrheic dermatitis occurs in 3% of the general population and in up to 50% of patients with HIV infection. Seborrheic dermatitis increases in prevalence and severity as the CD4+ T cell count declines. In HIV-infected patients, seborrheic dermatitis may be aggravated by concomitant infection with *Pityrosporum*, a yeastlike fungus; use of topical antifungal agents has been recommended in cases refractory to standard topical treatment.

Eosinophilic pustular folliculitis is a rare dermatologic condition that is seen with increased frequency in patients with HIV infection. It presents as multiple, urticarial perifollicular papules that may coalesce into plaquelike lesions. Skin biopsy reveals an

eosinophilic infiltrate of the hair follicle, which in certain cases has been associated with the presence of a mite. Patients typically have an elevated serum IgE level and may respond to treatment with topical anthelminthics. Patients with HIV infection have also been reported to develop a severe form of *Norwegian scabies* with hyperkeratotic psoriasiform lesions.

Both *psoriasis* and *ichthyosis*, although they are not reported to be increased in frequency, may be particularly severe when they occur in patients with HIV infection. Preexisting psoriasis may become guttate in appearance and more refractory to treatment in the setting of HIV infection.

Reactivation herpes zoster (*shingles*) is seen in 10 to 20% of patients with HIV infection. This reactivation syndrome of varicella-zoster virus indicates a modest decline in immune function and may be the first indication of clinical immunodeficiency. In one series, patients who developed shingles did so an average of 5 years after HIV infection. In a cohort of patients with HIV infection and localized zoster, the subsequent rate of the development of AIDS was 1% per month. In that study, AIDS was more likely to develop if the outbreak of zoster was associated with severe pain, extensive skin involvement, or involvement of cranial or cervical dermatomes. The clinical manifestations of reactivation zoster in HIV-infected patients, although indicative of immunologic compromise, are not as severe as those seen in other immunodeficient conditions. Thus, while lesions may extend over several dermatomes (see Plate IID-37) and frank cutaneous dissemination may be seen, visceral involvement has not been reported. In contrast to patients without a known underlying immunodeficiency state, patients with HIV infection tend to have recurrences of zoster with a relapse rate of approximately 20%. Acyclovir or famciclovir is the treatment of choice. Foscarnet is of value in patients with acyclovir-resistant virus.

Infection with *herpes simplex virus* in HIV-infected individuals is associated with recurrent orolabial, genital, and perianal lesions as part of recurrent reactivation syndromes (Chap. 182). As HIV disease progresses and the CD4+ T cell count declines, these infections become more frequent and severe. Lesions often appear as beefy red, are exquisitely painful, and have a tendency to occur high in the gluteal cleft (Fig. 309-31). PerirectalHSV may be associated with proctitis and anal fissures. HSV should be high in the differential diagnosis of any HIV-infected patient with a poorly healing, painful perirectal lesion. In addition to recurrent mucosal ulcers, recurrent HSV infection in the form of *herpetic whitlow* can be a problem in patients with HIV infection, presenting with painful vesicles or extensive cutaneous erosion. Acyclovir or famciclovir is the treatment of choice in these settings.

Diffuse skin eruptions due to *Molluscum contagiosum* may be seen in patients with advanced HIV infection. These flesh-colored, umbilicated lesions may be treated with local therapy. They tend to regress with effective antiretroviral therapy. Similarly, *condyloma acuminatum* lesions may be more severe and more widely distributed in patients with low CD4+ T cell counts. Atypical mycobacterial infections may present as erythematous cutaneous nodules as may fungal infections, *Bartonella*, *Acanthamoeba*, andKS.

The skin of patients with HIV infection is often a target organ for drug reactions (Chap.

59). Although most skin reactions are mild and not necessarily an indication to discontinue therapy, patients may have particularly severe cutaneous reactions, including erythroderma and *Stevens-Johnson syndrome*, as a reaction to drugs, particularly sulfa drugs, the nonnucleoside reverse transcriptase inhibitors, abacavir, and amprenavir. Similarly, patients with HIV infection are often quite photosensitive and burn easily following exposure to sunlight or as a side effect of radiation therapy (see Chap. 60).

HIV infection and its treatment may be accompanied by cosmetic changes of the skin that are not of great clinical importance but may be troubling to patients. Yellowing of the nails and straightening of the hair, particularly in African-American patients, have been reported as a consequence of HIV infection. Zidovudine therapy has been associated with elongation of the eyelashes and the development of a bluish discoloration to the nails, again more common in African-American patients. Therapy with clofazimine may cause a yellow-orange discoloration of the skin.

Neurologic Diseases Clinical disease of the nervous system accounts for a significant degree of morbidity in a high percentage of patients with HIV infection (Table 309-13). The neurologic problems that occur in HIV-infected individuals may be either primary to the pathogenic processes of HIV infection or secondary to opportunistic infections or neoplasms (see above). Among the more frequent opportunistic diseases that involve theCNS are toxoplasmosis, cryptococcosis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Other less common problems include mycobacterial infections; syphilis; and infection withCMV,HTLV-I, or *Acanthamoeba*. Overall, secondary diseases of the CNS occur in approximately one-third of patients with AIDS. These data antedate the widespread use of combination antiretroviral therapy, and this frequency is considerably less in patients receiving effective antiretroviral drugs. Primary processes related to HIV infection of the nervous system are reminiscent of those seen with other lentiviruses, such as the Visna-Maedi virus of sheep. Neurologic problems occur throughout the course of disease and may be inflammatory, demyelinating, or degenerative in nature. While only one of these, the *AIDS dementia complex*, or *HIV encephalopathy*, is considered an AIDS-defining illness, most HIV-infected patients have some neurologic problem during the course of their disease. As noted in the section on pathogenesis, damage to the CNS may be a direct result of viral infection of the CNS macrophages or glial cells or may be secondary to the release of neurotoxins and potentially toxic cytokines such asIL-1b,TNF-a, IL-6, andTGF-b. Virtually all patients with HIV infection have some degree of nervous system involvement with the virus. This is evidenced by the fact thatCSFfindings are abnormal in approximately 90% of patients, even during the asymptomatic phase of HIV infection. CSF abnormalities include pleocytosis (50 to 65% of patients), detection of viral RNA (~75%), elevated CSF protein (35%), and evidence of intrathecal synthesis of anti-HIV antibodies (90%). It is important to point out that evidence of infection of the CNS with HIV does not imply impairment of cognitive function. The neurologic function of an HIV-infected individual should be considered normal unless clinical signs and symptoms suggest otherwise.

Aseptic meningitis may be seen in any but the very late stages of HIV infection. In the setting of acute primary infection patients may experience a syndrome of headache, photophobia, and meningismus. Rarely, an acute encephalopathy due to encephalitis

may occur. Cranial nerve involvement may be seen, predominantly cranial nerve VII but occasionally V and/or VIII.CSFfindings include a lymphocytic pleocytosis, elevated protein level, and normal glucose level. This syndrome, which cannot be clinically differentiated from other viral meningitides (Chap. 373), usually resolves spontaneously within 2 to 4 weeks; however, in some patients, signs and symptoms may become chronic. Aseptic meningitis may occur any time in the course of HIV infection; however, it is rare following the development of AIDS. This fact suggests that clinical aseptic meningitis in the context of HIV infection is an immune-mediated disease.

C. neoformans is the leading infectious cause of meningitis in patients with AIDS (Chap. 204). It is the initial AIDS-defining illness in approximately 2% of patients and generally occurs in patients with CD4+ T cell counts <100/uL. Cryptococcal meningitis is particularly common in patients with AIDS in Africa, occurring in ~20% of patients. Most patients resent with a picture of subacute meningoencephalitis with fever, nausea, vomiting, altered mental status, headache, and meningeal signs. The incidence of seizures and focal neurologic deficits is low. TheCSFprofile may be normal or may show only modest elevations inWBC or protein levels. In addition to meningitis, patients may develop cryptococcomas. Approximately one-third of patients also have pulmonary disease. Uncommon manifestations of cryptococcal infection include skin lesions that resemble *molluscum contagiosum*, lymphadenopathy, palatal and glossal ulcers, arthritis, gastroenteritis, myocarditis, and prostatitis. The prostate gland may serve as a reservoir for smoldering cryptococcal infection. The diagnosis of cryptococcal meningitis is made by identification of organisms in spinal fluid with India ink examination or by the detection of cryptococcal antigen. A biopsy may be needed to make a diagnosis ofCNScryptococcoma. Treatment is with intravenous amphotericin B, at a dose of 0.7 mg/kg daily, with flucytosine, 25 mg/kg qid for 2 weeks, followed by fluconazole, 400 mg/d orally for 8 weeks, and then fluconazole, 200 mg/d for life. Other fungi that may cause meningitis in patients with HIV infection are *C. immitis* and *H. capsulatum*. Meningoencephalitis has also been reported due to *Acanthamoeba* or *Naegleria*.

HIV encephalopathy, also called HIV-associated dementia or AIDS dementia complex, consists of a constellation of signs and symptoms ofCNSdisease that generally occurs late in the course of HIV infection and progresses slowly over months. A major feature of this entity is the development of dementia, defined as a decline in cognitive ability from a previous level. It may present as impaired ability to concentrate, increased forgetfulness, difficulty reading, or increased difficulty performing complex tasks. Initially these symptoms may be indistinguishable from findings of situational depression or fatigue. In contrast to "cortical" dementia (such as Alzheimer's disease), aphasia, apraxia, and agnosia are uncommon, leading some investigators to classify HIV encephalopathy as a "subcortical dementia" (see below). In addition to dementia, patients with HIV encephalopathy may also have motor and behavioral abnormalities. Among the motor problems are unsteady gait, poor balance, tremor, and difficulty with rapid alternating movements. Increased tone and deep tendon reflexes may be found in patients with spinal cord involvement. Late stages may be complicated by bowel and/or bladder incontinence. Behavioral problems include apathy and lack of initiative, with progression to a vegetative state in some instances. Some patients develop a state of agitation or mild mania. These changes usually occur without significant changes in level of alertness. This is in contrast to the finding of somnolence in patients with dementia due to toxic/metabolic encephalopathies.

HIV encephalopathy is the initial AIDS-defining illness in approximately 3% of patients with HIV infection and thus only rarely precedes clinical evidence of immunodeficiency. Clinically significant encephalopathy eventually develops in approximately one-fourth of patients with AIDS. As immunologic function declines, the risk and severity of HIV encephalopathy increases. Autopsy series suggest that 80 to 90% of patients with HIV infection have histologic evidence of CNSinvolvement. Several classification schemes have been developed for grading HIV encephalopathy; a commonly used clinical staging system is outlined inTable 309-14.

The precise cause of HIV encephalopathy remains unclear, although the condition is thought to be a result of direct effects of HIV on theCNS. HIV has been found in the brains of patients with HIV encephalopathy by Southern blot, in situ hybridization,PCR, and electron microscopy. Multinucleated giant cells, macrophages, and microglial cells appear to be the main cell types harboring virus in the CNS. Histologically, the major changes are seen in the subcortical areas of the brain and include pallor and gliosis, multinucleated giant cell encephalitis, and vacuolar myelopathy. Less commonly, diffuse or focal spongiform changes occur in the white matter.

There are no specific criteria for a diagnosis of HIV encephalopathy, and this syndrome must be differentiated from a number of other diseases that affect theCNS of HIV-infected patients (Table 309-13). The diagnosis of dementia depends upon demonstrating a decline in cognitive function. This can be accomplished objectively with the use of a Mini-Mental Status Examination (MMSE) (Table 309-15) in patients for whom prior scores are available. For this reason, it is advisable for all patients with a diagnosis of HIV infection to have a baseline MMSE. However, changes in MMSE scores may be absent in patients with mild HIV encephalopathy. Imaging studies of the CNS, by eitherMRI orCT, often demonstrate evidence of cerebral atrophy (Fig. 309-33). MRI may also reveal small areas of increased density on T2-weighted images. Lumbar puncture is an important element of the evaluation of patients with HIV infection and neurologic abnormalities. It is generally most helpful in ruling out or making a diagnosis of opportunistic infections. In HIV encephalopathy, patients may have the nonspecific findings of an increase inCSFcells and protein level. While HIV RNA can often be detected in the spinal fluid and HIV can be cultured from the CSF, this finding is not specific for HIV encephalopathy. There appears to be no correlation between the presence of HIV in the CSF and the presence of HIV encephalopathy. Elevated levels ofb_2-microglobulin, neopterin, and quinolinic acid (a metabolite of tryptophan reported to cause CNS injury) have been noted in the CSF of patients with HIV encephalopathy. These findings suggest that these factors as well as inflammatory cytokines may be involved in the pathogenesis of this syndrome.

Combination antiretroviral therapy is of benefit in patients with HIV encephalopathy. Improvement in neuropsychiatric test scores has been noted for both adult and pediatric patients treated with antiretrovirals. The rapid improvement in cognitive function noted with the initiation of antiretroviral therapy suggests that at least some component of this problem is quickly reversible, again supporting at least a partial role of soluble mediators in the pathogenesis. It should also be noted that these patients have an increased sensitivity to the side effects of neuroleptic drugs. The use of these drugs for symptomatic treatment is associated with an increased risk of extrapyramidal side

effects; therefore, patients with HIV encephalopathy who receive these agents must be monitored carefully.

Seizures may be a consequence of opportunistic infections, neoplasms, or HIV encephalopathy (Table 309-16). The seizure threshold is often lower than normal in these patients owing to the frequent presence of electrolyte abnormalities. Seizures are seen in 15 to 40% of patients with cerebral toxoplasmosis, 15 to 35% of patients with primaryCNSlymphoma, 8% of patients with cryptococcal meningitis, and 7 to 50% of patients with HIV encephalopathy. Seizures may also be seen in patients with CNS tuberculosis, aseptic meningitis, and progressive multifocal leukoencephalopathy. Seizures may be the presenting clinical symptom of HIV disease. In one study of 100 patients with HIV infection presenting with a first seizure, cerebral mass lesions were the most common cause, responsible for 32 of the 100 new-onset seizures. Of these 32 cases, 28 were due to toxoplasmosis and 4 to lymphoma. HIV encephalopathy accounted for an additional 24 new-onset seizures. Cryptococcal meningitis was the third most common diagnosis, responsible for 13 of the 100 seizures. In 23 cases, no cause could be found, and it is possible that these cases represent a subcategory of HIV encephalopathy. Of these 23 cases, 16 (70%) had two or more seizures, suggesting that anticonvulsant therapy is indicated in all patients with HIV infection and seizures unless a rapidly correctable cause is found. While phenytoin remains the initial treatment of choice, hypersensitivity reactions to this drug have been reported in >10% of patients with AIDS, and therefore the use of phenobarbital or valproic acid must be considered as alternatives.

Patients with HIV infection may present with *focal neurologic deficits* from a variety of causes. The most common cause are toxoplasmosis, progressive multifocal leukoencephalopathy, andCNSlymphoma. Other causes include cryptococcal infections (discussed above; alsoChap. 204), stroke, and reactivation Chagas' disease.

Toxoplasmosis has been one of the most common causes of secondaryCNSinfections in patients with AIDS, but its incidence is decreasing in the era ofHAART. It is most common in patients from the Caribbean and from France. Toxoplasmosis is generally a late complication of HIV infection and usually occurs in patients with CD4+ T cell counts <200/uL. Cerebral toxoplasmosis is thought to represent a reactivation syndrome. It is 10 times more common in patients with antibodies to the organism than in patients who are seronegative. Patients diagnosed with HIV infection should be screened for IgG antibodies to *T. gondii* during the time of their initial workup. Those who are seronegative should be counseled about ways to minimize the risk of primary infection including avoiding the consumption of undercooked meat and careful hand washing after contact with soil or changing the cat litter box. The most common clinical presentation in patients with HIV infection is fever, headache, and focal neurologic deficits. Patients may present with seizure, hemiparesis, or aphasia as a manifestation of these focal deficits or with a picture more influenced by the accompanying cerebral edema and characterized by confusion, dementia, and lethargy, which can progress to coma. The diagnosis is usually suspected on the basis ofMRIfindings of multiple lesions in multiple locations, although in come cases only a single lesion is seen. Pathologically, these lesions generally exhibit inflammation and central necrosis and, as a result, demonstrate ring enhancement on contrast MRI (Fig. 309-34) or, if MRI is unavailable or contraindicated, on double-dose contrastCT. There is usually evidence of

surrounding edema. In addition to toxoplasmosis, the differential diagnosis of single or multiple enhancing mass lesions in the HIV-infected patient includes primary CNS lymphoma (see below) and, less commonly,TB or fungal or bacterial abscesses. The definitive diagnostic procedure is brain biopsy. However, given the morbidity than can accompany this procedure, it is usually reserved for the patient who has failed 2 to 4 weeks of empirical therapy. If the patient is seronegative for *T. gondii*, the likelihood that a mass lesion is due to toxoplasmosis is <10%. In that setting, one may choose to be more aggressive and perform a brain biopsy sooner. Standard treatment is sulfadiazine and pyrimethamine with leucovorin as needed for a minimum of 4 to 6 weeks. Alternative therapeutic regimens include clindamycin in combination with pyrimethamine; atovaquone plus pyrimethamine; and azithromycin plus pyrimethamine plus rifabutin. Relapses are common, and it is recommended that patients with a history of prior toxoplasmic encephalitis receive maintenance therapy with sulfadiazine, pyrimethamine, and leucovorin. Patients with CD4+ T cell counts <100/uL and IgG antibody to *Toxoplasma* should receive primary prophylaxis for toxoplasmosis. Fortunately, the same daily regimen of a single double-strength tablet ofTMP/SMZused for *P. carinii* prophylaxis provides adequate primary protection against toxoplasmosis. It is likely that future recommendations will allow for discontinuation of prophylaxis for toxoplasmosis in the setting of effective antiretroviral therapy and increases in CD4+ T cell counts to>100/uL for 3 to 6 months.

JC virus, a human papilloma virus that is the etiologic agent of *progressive multifocal leukoencephalopathy* (PML), is an important opportunistic pathogen in patients with AIDS (Chap. 373). While approximately 70% of the general adult population have antibodies to JC virus, indicative of prior infection,<10% of healthy adults show any evidence of ongoing viral replication. PML is the only known clinical manifestation of JC virus infection. It is a late manifestation of AIDS and is seen in ~4% of patients with AIDS. The lesions of PML begin as small foci of demyelination in subcortical white matter that eventually coalesce. The cerebral hemispheres, cerebellum, and brainstem may all be involved. Patients typically have a protracted course with multifocal neurologic deficits, with or without changes in mental status. Ataxia, hemiparesis, visual field defects, aphasia, and sensory defects may occur.MRItypically reveals multiple, nonenhancing white matter lesions that may coalesce and have a predeliction for the occipital and parietal lobes. The lesions show signal hyperintensity on T2-weighted images and diminished signal on T1-weighted images. Prior to the availability of potent antiretroviral combination therapy, the majority of patients with PML died within 3 to 6 months of the onset of symptoms. There is no specific treatment for PML; however, regressions of more than 2.5 years in duration have been reported in patients with PML treated withHAARTfor their HIV disease. Factors influencing a favorable prognosis include a CD4+ T cell count >100/uL at baseline and the ability to maintain an HIV viral load of <500 copies per milliliter. Baseline viral load does not have independent predictive value of survival. Of note, PML is one of the few opportunistic infections that continue to occur with some frequency despite the widespread use of HAART.

Reactivation American trypanosomiasis may present as acute meningoencephalitis with focal neurologic signs, fever, headache, vomiting, and seizures. In South America, reactivation of *Chagas' disease* is considered to be an AIDS-defining condition and may be the initial AIDS-defining condition. Lesions appear radiographically as single or multiple hypodense areas, typically with ring enhancement and edema. They are found

predominantly in the subcortical areas, a feature that differentiates them from the deeper lesions of toxoplasmosis. *Trypanosoma cruzi* amastigotes, or trypanosomes, can be identified from biopsy specimens orCSF. Other CSF findings include elevated protein and a mild (<100 cells/uL) lymphocytic pleocytosis. Organisms can also be identified by direct examination of the blood. Treatment consists of benzimidazole (2.5 mg/kg bid) or nifurtimox (1 mg/kg tid) for at least 60 days, followed by maintenance therapy for life with either drug at a dose of 5 mg/kg three times a week.

Stroke may occur in patients with HIV infection. In contrast to the other causes of focal neurologic deficits in patients with HIV infection, the symptoms of a stroke are sudden in onset. Among the secondary infectious diseases in patients with HIV infection that may be associated with stroke are vasculitis due to cerebral varicella zoster or neurosyphilis and septic embolism in association with fungal infection. Other elements of the differential diagnosis of stroke in the patient with HIV infection include atherosclerotic cerebral vascular disease, thrombotic thrombocytopenic purpura, and cocaine or amphetamine use.

PrimaryCNSlymphoma is discussed below in the section on neoplastic diseases.

Spinal cord disease, or myelopathy, is present in approximately 20% of patients with AIDS, often as part of HIV encephalopathy. In fact, 90% of the patients with HIV-associated myelopathy have some evidence of dementia, suggesting that similar pathologic processes may be responsible for both conditions. Three main types of spinal cord disease are seen in patients with AIDS. The first of these is a vacuolar myelopathy, as discussed above under HIV encephalopathy. This condition is pathologically similar to subacute combined degeneration of the cord such as occurs with pernicious anemia. Although vitamin B_{12}deficiency can be seen in patients with AIDS, it does not appear to be responsible for the myelopathy seen in the majority of patients. Vacuolar myelopathy is characterized by a subacute onset and often presents with gait disturbances, predominantly ataxia and spasticity; it may progress to include bladder and bowel dysfunction. Physical findings include evidence of increased deep tendon reflexes and extensor plantar responses. The second form of spinal cord disease involves the dorsal columns and presents as a pure sensory ataxia. The third form is also sensory in nature and presents with paresthesias and dysesthesias of the lower extremities. In contrast to the cognitive problems seen in patients with HIV encephalopathy, these spinal cord syndromes do not respond well to antiretroviral drugs, and therapy is mainly supportive.

One important disease of the spinal cord that also involves the peripheral nerves is a *myelopathy* and *polyradiculopathy* seen in association withCMVinfection. This entity is generally seen late in the course of HIV infection and is fulminant in onset, with lower extremity and sacral paresthesias, difficulty in walking, areflexia, ascending sensory loss, and urinary retention. The clinical course is rapidly progressive over a period of weeks.CSFexamination reveals a predominantly neutrophilic pleocytosis, and CMV DNA can be detected by CSFPCR. Therapy with ganciclovir or foscarnet can lead to rapid improvement, and prompt initiation of foscarnet or ganciclovir therapy is important in minimizing the degree of permanent neurologic damage. Combination therapy with both drugs should be considered in patients who have been previously treated for CMV disease.**Other diseases involving the spinal cord in patients with HIV infection include*

HTLV-I-associated myelopathy (HAM) (Chap. 191), neurosyphilis (Chap. 172), infection with herpes simplex (Chap. 182) or varicella-zoster (Chap. 183), TB (Chap. 169), and lymphoma (Chap. 112).

Peripheral neuropathies are common in patients with HIV infection. They occur at all stages of illness and take a variety of forms. Early in the course of HIV infection, an acute inflammatory demyelinating polyneuropathy resembling Guillain-Barre syndrome may occur (Chap. 378). In other patients, a progressive or relapsing-remitting inflammatory neuropathy resembling chronic inflammatory demyelinating polyneuropathy (CIDP) has been noted. Patients commonly present with progressive weakness, areflexia, and minimal sensory changes.CSFexamination often reveals a mononuclear pleocytosis, and peripheral nerve biopsy demonstrates a perivascular infiltrate suggesting an autoimmune etiology. Plasma exchange or intravenous immunoglobulin has been tried with variable success. Because of the immunosuppressive effects of glucocorticoids, they should be reserved for severe cases of CIDP refractory to other measures. Another autoimmune peripheral neuropathy seen in patients with AIDS is mononeuritis multiplex (Chaps. 378 and317) due to a necrotizing arteritis of peripheral nerves. The most common peripheral neuropathy in patients with HIV infection is a *distal sensory polyneuropathy* that may be a direct consequence of HIV infection or a side effect of dideoxynucleoside therapy. Two-thirds of patients with AIDS may be shown by electrophysiologic studies to have some evidence of peripheral nerve disease. Presenting symptoms are usually painful burning sensations in the feet and lower extremities. Findings on examination include a stocking-type sensory loss to pinprick, temperature, and touch sensation and a loss of ankle reflexes. Motor changes are mild and are usually limited to weakness of the intrinsic foot muscles. Response of this condition to antiretrovirals has been variable, perhaps because antiretrovirals are responsible for the problem in some instances. When due to dideoxynucleoside therapy, patients with lower extremity peripheral neuropathy may complain of a sensation that they are walking on ice. Other entities in the differential diagnosis of peripheral neuropathy include diabetes mellitus, vitamin B_{12}deficiency, and side effects from metronidazole or dapsone. For distal symmetric polyneuropathy that fails to resolve following the discontinuation of dideoxynucleosides, therapy is symptomatic; gabapentin, carbamazepine, tricyclics, or analgesics may be effective for dysesthesias. Some patients may respond to combination antiretroviral therapy, and preliminary data suggest that nerve growth factor may benefit some cases.

Myopathy may complicate the course of HIV infection; causes include HIV infection itself, zidovudine, and the generalized wasting syndrome. HIV-associated myopathy may range in severity from an asymptomatic elevation in creatine kinase levels to a subacute syndrome characterized by proximal muscle weakness and myalgias. Quite pronounced elevations in creatine kinase may occur in asymptomatic patients, particularly after exercise. The clinical significance of this as an isolated laboratory finding is unclear. A variety of both inflammatory and noninflammatory pathologic processes have been noted in patients with more severe myopathy, including myofiber necrosis with inflammatory cells, nemaline rod bodies, cytoplasmic bodies, and mitochondrial abnormalities. Profound muscle wasting, often with muscle pain, may be seen after prolonged zidovudine therapy. This toxic side effect of the drug is dose-dependent and is related to its ability to interfere with the function of mitochondrial polymerases. It is reversible following discontinuation of the drug. Red ragged fibers are

a histologic hallmark of zidovudine-induced myopathy.

Ophthalmologic Disease Ophthalmologic problems occur in approximately half of patients with advanced HIV infection. The most common abnormal findings on funduscopic examination are cotton-wool spots. These are hard white spots that appear on the surface of the retina and often have an irregular edge. They represent areas of retinal ischemia secondary to microvascular disease. At times they are associated with small areas of hemorrhage and thus can be difficult to distinguish fromCMVretinitis. In contrast to CMV retinitis, however, these lesions are not associated with visual loss and tend to remain stable or improve over time.

One of the most devastating consequences of HIV infection isCMVretinitis. Patients at high risk of CMV retinitis (CD4+ T cell count<100/uL) should undergo an ophthalmologic examination every 3 to 6 months. The majority of cases of CMV retinitis occur in patients with a CD4+ T cell count <50/uL. Prior to the availability ofHAART, this CMV reactivation syndrome was seen in 25 to 30% of patients with AIDS. CMV retinitis usualy presents as a painless, progressive loss of vision. Patients may also complain of blurred vision, "floaters," and scintillations. The disease is usually bilateral, affecting one eye more than the other. The diagnosis is made on clinical grounds by an experienced ophthalmologist. The characteristic retinal appearance is that of perivascular hemorrhage and exudate (seePlate III-1). In situations where the diagnosis is in doubt due to an atypical presentation or an unexpected lack of response to therapy, vitreous or aqueous humor sampling with molecular diagnostic techniques may be of value. CMV infection of the retina results in a necrotic inflammatory process, and the visual loss that develops is irreversible. As a consequence of retinal atrophy in areas or prior inflammation, CMV retinitis may be complicated by rhegmatogenous retinal detachment. Therapy for CMV retinitis consists of intravenous ganciclovir or foscarnet, with cidofovir as an alternative. Combination therapy with ganciclovir and foscarnet has been shown to be slightly more effective than either ganciclovir or foscarnet alone in the patient with relapsed CMV retinitis. A 3-week induction course is followed by maintenance therapy with one of these drugs systemically. While the majority of patients will require intravenous maintenance therapy, a ganciclovir prodrug with better oral bioavailability has shown promise in clinical trials. If CMV disease is limited to the eye, a ganciclovir-releasing intraocular implant, periodic injections of the antisense nucleic acid preparation formivirsen, or intravitreal injections of ganciclovir or foscarnet may be considered; some choose to combine intraocular implants with oral ganciclovir. Intravitreal injections of cidofovir are generally avoided due to the increased risk of uveitis and hypotony. Maintenance therapy is continued until the CD4+ T cell count remains >100 to 150/uL for>6 months. The majority of patients with HIV infection and CMV disease develop some degree of uveitis with the initiation of antiretroviral therapy. The etiology of this is unknown; however, it has been suggested that this may be due to the generation of an enhanced immune response to CMV. In some instances this has required the use of topical glucocorticoids.

BothHSV and varicella zoster virus can cause a rapidly progressing, bilateral necrotizing retinitis referred to as the *acute retinal necrosis syndrome*. This syndrome, in contrast toCMVretinitis, is associated with pain, keratitis, and iritis. It is often associated with orolabial HSV or trigeminal zoster. Ophthalmologic examination reveals widespread pale gray peripheral lesions. This condition is often complicated by retinal detachment. It

is important to recognize and treat this condition with intravenous acyclovir as quickly as possible to minimize the loss of vision.

Several other secondary infections may cause ocular problems in HIV-infected patients. *P. carinii* can cause a lesion of the choroid that may be detected as an incidental finding on ophthalmologic examination. These lesions are typically bilateral, are from half to twice the disc diameter in size, and appear as slightly elevated yellow-white plaques. They are usually asymptomatic and may be confused with cotton-wool spots. Chorioretinitis due to toxoplasmosis can be seen alone or, more commonly, in association withCNStoxoplasmosis.

Additional Disseminated Infections and Wasting Syndrome Infections with species of the small, gram-negative rickettsia-like organism *Bartonella* (Chap. 163) are seen with increased frequency in patients with HIV infection. While not considered an AIDS-defining illness by theCDC, many experts view infection with *Bartonella* as indicative of a severe defect in cell-mediated immunity. It is usually seen in patients with CD4+ T cell counts <100/uL. Among the clinical manifestations of *Bartonella* infection are bacillary angiomatosis, cat-scratch disease, and trench fever. *Bacillary angiomatosis* is usually due to infection with *B. henselae*. It is characterized by a vascular proliferation that leads to a variety of skin lesions that have been confused with the skin lesions ofKS. In contrast to the lesions of KS, the lesions of bacillary angiomatosis generally blanch, are painful, and typically occur in the setting of systemic symptoms. Infection can extend to the lymph nodes, liver (peliosis hepatis), spleen, bone, heart,CNS, respiratory tract, and gastrointestinal tract. *Cat-scratch disease* generally begins with a papule at the site of inoculation. This is followed several weeks later by the development of regional adenopathy and malaise. Infection with *B. quintana* is transmitted by lice and has been associated with case reports of trench fever, endocarditis, adenopathy, and bacillary angiomatosis. The organism is quite difficult to culture, and diagnosis often relies upon identifying the organism in biopsy specimens using the Warthin-Starry or similar stains. Treatment is with either erythromycin or doxycyline for at least 3 months.

Histoplasmosis is an opportunistic infection that is seen most frequently in patients in the Mississippi and Ohio River valleys, Puerto Rico, the Dominican Republic, and South America. These are all areas in which infection with *H. capsulatum* is endemic (Chap. 201). Because of this limited geographic distribution, the percentage of AIDS cases in the United States with histoplasmosis is only approximately 0.5. Histoplasmosis is generally a late manifestation of HIV infection; however, it may be the initial AIDS-defining condition. In one study, the median CD4+ T cell count for patients with histoplasmosis and AIDS was 33/uL. While disease due to *H. capsulatum* may present as a primary infection of the lung, disseminated disease, presumably due to reactivation, is the most common presentation in HIV-infected patients. Patients usually present with a 4- to 8-week history of fever and weight loss. Hepatosplenomegaly and lymphadenopathy are each seen in about 25% of patients.CNSdisease, either meningitis or a mass lesion, is seen in 15% of patients. Bone marrow involvement is common, with thrombocytopenia, neutropenia, and anemia occurring in 33% of patients. Approximately 7% of patients have mucocutaneous lesions consisting of a maculopapular rash and skin or oral ulcers. Respiratory symptoms are usually mild, with chest x-ray showing a diffuse infiltrate or diffuse small nodules in approximately half of

cases. Diagnosis is made by culturing the organisms from blood, bone marrow, or tissue. Treatment is typically with amphotericin B, 0.7 to 1.0 mg/kg daily to a total dose of 1 g followed by maintenance therapy with itraconazole. In the setting of mild infection, it may be appropriate to treat with itraconazole alone.

Following the spread of HIV infection to southeast Asia, disseminated infection with *Penicillium marneffei* was recognized as a complication of HIV infection and is considered an AIDS-defining condition in those parts of the world where it occurs. *P. marneffei* is the third most common AIDS-defining illness in Thailand, followingTB and cryptococcosis. It is more frequently diagnosed in the rainy than the dry season. Clinical features include fever, generalized lymphadenopathy, hepatosplenomegaly, anemia, thrombocytopenia, and papular skin lesions with central umbilication. Treatment is with amphotericin B followed by itraconazole.

Visceral leishmaniasis (Chap. 215) is recognized with increasing frequency in patients with HIV infection who live in or travel to areas endemic for this protozoal infection transmitted by sandflies. The clinical presentation is one of hepatosplenomegaly, fever, and hematologic abnormalities. Lymphadenopathy and other constitutional symptoms may be present. Organisms can be isolated from cultures of bone marrow aspirates. Histologic stains may be negative, and antibody titers are of little help. Patients with HIV infection usually respond well initially to standard therapy with pentavalent antimony compounds. Eradication of the organism is difficult, however, and relapses are common.

Generalized wasting is an AIDS-defining condition; it is defined as involuntary weight loss of>10% associated with intermittent or constant fever and chronic diarrhea or fatigue lasting >30 days in the absence of a defined cause other than HIV infection. It is the initial AIDS-defining condition in approximately 10% of patients with AIDS in the United States. A constant feature of this syndrome is severe muscle wasting with scattered myofiber degeneration and occasional evidence of myositis. Glucocorticoids may be of some benefit; however, this approach must be carefully weighed against the risk of compounding the immunodeficiency of HIV infection. Androgenic steroids, growth hormone, and total parenteral nutrition have been used as therapeutic interventions with variable success.

Neoplastic Diseases The neoplastic diseases clearly seen with an increased frequency in patients with HIV infection areKS and non-Hodgkin's lymphoma. In addition, there also appears to be an increased incidence of Hodgkin's disease; multiple myeloma; leukemia; melanoma; and cervical, brain, testicular, oral, and anal cancers. Recent years have witnessed a marked reduction in the incidence of KS (Fig. 309-28), felt to be primarily due to the use of potent antiretroviral therapy. Rates of non-Hodgkin's lymphoma have declined as well; however, this decline has not been as dramatic as the decline in rates of KS.

Kaposi's sarcoma is a multicentric neoplasm consisting of multiple vascular nodules appearing in the skin, mucous membranes, and viscera. The course ranges from indolent, with only minor skin or lymph node involvement, to fulminant, with extensive cutaneous and visceral involvement. In the initial period of the AIDS epidemic,KS was a prominent clinical feature of the first cases of AIDS, occurring in 79% of the patients diagnosed in 1981. By 1989 it was seen in only 25% of cases, by 1992 the number had

decreased to 9%, and by 1997 the number was<1%.HHV-8 orKSHV has been strongly implicated as a viral cofactor in the pathogenesis of KS (see above).

Clinically,KS has varied presentations and may be seen at any stage of HIV infection, even in the presence of a normal CD4+ T cell count. The initial lesion may be a small, raised reddish-purple nodule on the skin, a discoloration on the oral mucosa, or a swollen lymph node (see Plate IIB-20). Lesions often appear in sun-exposed areas, particularly the tip of the nose, and have a propensity to occur in areas of trauma (Koebner phenomenon). Because of the vascular nature of the tumors and the presence of extravasated red blood cells in the lesions, their color ranges from reddish to purple to brown and often take the appearance of a bruise, with yellowish discoloration and tattooing. Lesions range in size from a few millimeters to several centimeters in diameter and may be either discrete or confluent. KS lesions most commonly appear as raised macules; however, they also can be papular, particularly in patients with higher CD4+ T cell counts. Confluent lesions may give rise to surrounding lymphedema and may be disfiguring when they involve the face and disabling when they involve the lower extremities or the surfaces of joints. Apart from skin, lymph nodes, gastrointestinal tract, and lung are the organ systems most commonly affected by KS. Lesions have been reported in virtually every organ, including the heart and theCNS. In contrast to most malignancies, in which lymph node involvement implies metastatic spread and a poor prognosis, lymph node involvement may be seen very early in Kaposi's sarcoma and is of no special clinical significance. In fact, some patients may present with disease limited to the lymph nodes. These are generally patients with relatively intact immune function and thus the patients with the best prognosis. Pulmonary involvement with KS generally presents with shortness of breath. Some 80% of patients with pulmonary KS also have cutaneous lesions. The chest x-ray characteristically shows bilateral lower lobe infiltrates that obscure the margins of the mediastinum and diaphragm (Fig. 309-35). Pleural effusions are seen in 70% of cases of pulmonary KS, a fact that is often helpful in the differential diagnosis. Gastrointestinal involvement is seen in 50% of patients and usually takes one of two forms. The first is mucosal involvement, which may lead to bleeding that can be severe. These patients sometimes also develop symptoms of gastrointestinal obstruction if lesions become large. The second gastrointestinal manifestation is due to biliary tract involvement. KS lesions may infiltrate the gallbladder and biliary tree, leading to a clinical picture of obstructive jaundice similar to that seen with sclerosing cholangitis. Several staging systems have been proposed for KS. One in common use was developed by the National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group; it distinguishes patients on the basis of tumor extent, immunologic function, and presence or absence of systemic disease (Table 309-17).

A diagnosis ofKS is based upon biopsy of a suspicious lesion. Histologically one sees a proliferation of spindle cells and endothelial cells, extravasation of red blood cells, hemosiderin-laden macrophages, and, in early cases, an inflammatory cell infiltrate. Included in the differential diagnosis are lymphoma (particularly for oral lesions), bacillary angiomatosis, and cutaneous mycobacterial infections.

Management ofKS(Table 309-18) should be carried out in consultation with an expert since definitive treatment guidelines do not exist. In the majority of cases effective antiretroviral therapy will go a long way in achieving control. Indeed, spontaneous

regressions have been reported in the setting ofHAART. For patients in whom tumor persists or in whom control of HIV replication is not possible, a variety of options exist. In some cases, lesions remain quite indolent, and many of these patients can be managed with no specific treatment. Fewer than 10% of AIDS patients with KS die as a consequence of their malignancy, and death from secondary infections is considerably more common. Thus, whenever possible one should avoid treatment regimens that may further suppress the immune system and increase susceptibility to opportunistic infections. Treatment is indicated under two main circumstances. The first is when a single lesion or a limited number of lesions are causing significant discomfort or cosmetic problems, such as with prominent facial lesions, lesions overlying a joint, or lesions in the oropharynx that interfere with swallowing or breathing. Under these circumstances, treatment with localized radiation, intralesional vinblastine, or cryotherapy may be indicated. It should be noted that patients with HIV infection are particularly sensitive to the side effects of radiation therapy. This is especially true with respect to the development of radiation-induced mucositis; doses of radiation directed at mucosal surfaces, particularly in the head and neck region, should be adjusted accordingly. The use of systemic therapy, eitherIFN-aor chemotherapy, should be considered in patients with a large number of lesions or in patients with visceral involvement. The single most important determinant of response appears to be the CD4+ T cell count. This relationship between response rate and baseline CD4+ T cell count is particularly true for IFN-a. The response rate for patients with CD4+ T cell counts >600/uL is approximately 80%, while the response rate for patients with counts <150/uL is<10%. In contrast to the other systemic therapies, IFN-a provides an added advantage of having antiretroviral activity; thus, it may be the appropriate first choice for single-agent systemic therapy for early patients with disseminated disease. A variety of chemotherapeutic agents have also been shown to have activity against KS. Three of them, liposomal daunorubicin, liposomal doxorubicin, and paclitaxel have been approved by theFDA for this indication. Liposomal daunorubicin is approved as first-line therapy for patients with advanced KS. It has fewer side effects than conventional chemotherapy. In contrast, liposomal doxorubicin and paclitaxel are only approved for KS patients who have failed standard chemotherapy. Response rates vary from 23 to 88%, appear to be comparable to what had been achieved earlier with combination chemotherapy regimens, and are greatly influenced by CD4+ T cell count.

Lymphomas occur with an increased frequency in patients with congenital or acquired T cell immunodeficiencies (Chap. 308). AIDS is no exception; at least 6% of all patients with AIDS develop lymphoma at some time during the course of their illness. This is a 120-fold increase in incidence compared to the general population. In contrast to the situation withKS and most opportunistic infections, the incidence of AIDS-associated lymphomas has not experienced as dramatic a decrease as a consequence of the widespread use of effective antiretroviral therapy. Lymphoma occurs in all risk groups, with the highest incidence in patients with hemophilia and the lowest incidence in patients from the Caribbean or Africa with heterosexually acquired infection. Lymphoma is a late manifestation of HIV infection, generally occurring in patients with CD4+ T cell counts of <200/uL. As HIV disease progresses, the risk of lymphoma increases. In contrast to KS, which occurs at a relatively constant rate throughout the course of HIV disease, the attack rate for lymphoma increases exponentially with increasing duration of HIV infection and decreasing level of immunologic function. At 3 years following a diagnosis of HIV infection, the risk of lymphoma is 0.8% per year; by 8 years after

infection, it is 2.6% per year. As people with HIV infection live longer as a consequence of improved antiretroviral therapy and better treatment and prophylaxis of opportunistic infections, it is anticipated that the incidence of lymphomas will increase.

Three main categories of lymphoma are seen in patients with HIV infection: grade III or IV immunoblastic lymphoma, Burkitt's lymphoma, and primaryCNSlymphoma. Approximately 90% of these lymphomas are B cell in phenotype, and half containEBV DNA. These tumors may be either monoclonal or oligoclonal in nature and are probably in some way related to the pronounced polyclonal B cell activation seen in patients with AIDS.

Immunoblastic lymphomas account for ~60% of the cases of lymphoma in patients with AIDS. These are generally high grade and would have been classified as diffuse histiocytic lymphomas in earlier classification schemes. This tumor is more common in older patients, increasing in incidence from 0% in HIV-infected individuals <1 year old to>3% in those >50. One variant of immunoblastic lymphoma is body cavity lymphoma. This malignancy presents with lymphomatous pleural, pericardial, and/or peritoneal effusions in the absence of discrete nodal or extranodal masses. The tumor cells do not express surface markers for B cells or T cells.HHV-8 DNA sequences have been found in the genome of the malignant cells (see above).

Small non-cleaved cell lymphoma (*Burkitt's lymphoma*) accounts for ~20% of the cases of lymphoma in patients with AIDS. It is most frequent in patients 10 to 19 years old and usually demonstrates characteristic c-*myc* translocations from chromosome 8 to chromosomes 14 or 22. Burkitt's lymphoma is not commonly seen in the setting of immunodeficiency other than HIV-associated immunodeficiency, and the incidence of this particular tumor is over 1000-fold higher in the setting of HIV infection than in the general population. In contrast to African Burkitt's lymphoma, where 97% of the cases contain EBV genome, only 50% of HIV-associated Burkitt's lymphomas are EBV-positive.

Primary CNS lymphoma accounts for approximately 20% of the cases of lymphoma in patients with HIV infection. In contrast to HIV-associated Burkitt's lymphoma, primaryCNSlymphomas are usually positive forEBV. In one study, the incidence of Epstein-Barr positivity was 100%. This malignancy does not have a predilection for any particular age group. The median CD4+ T cell count at the time of diagnosis is approximately 50/uL. Thus, CNS lymphoma generally presents at a later stage of HIV infection than systemic lymphoma. This fact may at least in part explain the poorer prognosis for this subset of patients.

The clinical presentation of lymphoma in patients with HIV infection is quite varied, ranging from focal seizures to rapidly growing mass lesions in the oral mucosa (Fig. 309-36) to persistent unexplained fever. At least 80% of patients present with extranodal disease, and a similar percentage have B-type symptoms of fever, night sweats, or weight loss. Virtually any site in the body may be involved. The most common extranodal site is theCNS, which is involved in approximately one-third of all patients with lymphoma. Approximately 60% of these cases are primary CNS lymphoma. Primary CNS lymphoma generally presents with focal neurologic deficits, including cranial nerve findings, headaches, and/or seizures.MRI orCTgenerally reveals a limited

number (one to three) of 3- to 5-cm lesions (Fig. 309-37). The lesions often show ring enhancement on contrast administration and may occur in any location. Locations that are most commonly involved with CNS lymphoma are deep in the white matter. Contrast enhancement is usually less pronounced than that seen with toxoplasmosis. The main diseases in the differential diagnosis are cerebral toxoplasmosis and cerebral Chagas' disease. In addition to the 20% of lymphomas in HIV-infected individuals that are primary CNS lymphomas, CNS disease is also seen in HIV-infected patients with systemic lymphoma. Approximately 20% of patients with systemic lymphoma have CNS disease in the form of leptomeningeal involvement. This fact underscores the importance of lumbar puncture in the staging evaluation of patients with systemic lymphoma.

Systemic lymphoma is seen at earlier stages of HIV infection than primaryCNSlymphoma. In one series the mean CD4+ T cell count was 189/uL. In addition to lymph node involvement, systemic lymphoma may commonly involve the gastrointestinal tract, bone marrow, liver, and lung. Gastrointestinal tract involvement is seen in ~25% of patients. Any site in the gastrointestinal tract may be involved, and patients may complain of difficulty swallowing or abdominal pain. The diagnosis is usually suspected on the basis ofCT orMRI of the abdomen. Bone marrow involvement is seen in ~20% of patients and may lead to pancytopenia. Liver and lung involvement are each seen in ~10% of patients. Pulmonary disease may present as either a mass lesion, multiple nodules, or an interstitial infiltrate.

Both conventional and unconventional approaches have been employed in an attempt to treat HIV-related lymphomas. Systemic lymphoma is generally treated by the oncologist with combination chemotherapy. Earlier disappointing figures are being replaced with more optimistic results for the treatment of systemic lymphoma following the availability of more effective combination antiretroviral therapy. As in most situations in patients with HIV disease, those with the higher CD4+ T cell counts tend to do better. Response rates as high as 72% and disease-free intervals >15 months have been reported. Treatment of primaryCNSlymphoma remains a significant challenge. Treatment is complicated by the fact that this illness usually occurs in patients with advanced HIV disease. Palliative measures such as radiation therapy provide some relief. The prognosis remains poor in this group, with median survival <1 year.

Evidence of infection with *human papilloma virus*, associated with *intraepithelial dysplasia of the cervix or anus*, is approximately twice as common in HIV-infected individuals as in the general population and can lead to intraepithelial neoplasia and eventually invasive cancer. It is anticipated that both anal and cervical carcinomas will be seen with increased frequency in the HIV-infected population as survival is prolonged with combination antiretroviral therapy. In two separate studies, HIV-infected men without anorectal symptoms were studied for evidence of dysplasia, and Papanicolauo (Pap) smears were found to be abnormal in 40%. These changes were persistent at 1 year follow-up, raising the possibility of a subsequent transition to a more malignant condition. While the incidence of an abnormal Pap smear of the cervix is ~5% in otherwise healthy women, the incidence of abnormal cervical smears in women with HIV infection is 60%. Based on this finding, *invasive cervical cancer* was added to the list of AIDS-defining conditions. Thus far, however, only small increases in the incidence of cervical or anal cancer have been seen as a consequence of HIV infection. However,

given this high rate of dysplasia, a comprehensive gynecologic and rectal examination, including Pap smear, is indicated at the initial evaluation and 6 months later for all patients with HIV infection. If these examinations are negative at both time points, the patient should be followed with yearly evaluations. If an initial or repeat Pap smear shows evidence of severe inflammation with reactive squamous changes, the next Pap smear should be performed at 3 months. If, at any time, a Pap smear shows evidence of squamous intraepithelial lesions, colposcopic examination with biopsies as indicated should be performed.

IDIOPATHIC CD4+ T LYMPHOCYTOPENIA

A syndrome was recognized in 1992 that was characterized by an absolute CD4+ T cell count of<300/uL or <20% of total T cells on more than one occasion; no evidence of HIV-1, HIV-2,HTLV-I, or HTLV-II on testing; and the absence of any defined immunodeficiency or therapy associated with decreased levels of CD4+ T cells. By mid-1993, approximately 100 patients had been described. After extensive multicenter investigations, a series of reports were published in early 1993, which together allowed a number of conclusions. Idiopathic CD4+ lymphocytopenia (ICL) is a very rare syndrome, as determined by studies of blood donors and cohorts of HIV-seronegative homosexual men. Cases were clearly identified as early as 1983, and cases remarkably similar to ICL had been identified decades ago. The definition of ICL based on CD4+ T cell counts coincided with the ready availability of testing for CD4+ T cells in patients suspected of being immunosuppressed. Although, as a result of immune deficiency, certain patients with ICL develop some of the opportunistic diseases (particularly cryptococcosis) seen in HIV-infected patients, the syndrome is demographically, clinically, and immunologically unlike HIV infection and AIDS. Fewer than half of the reported ICL patients had risk factors for HIV infection, and there were wide geographic and age distributions. The fact that a significant proportion of patients did have risk factors probably reflects a selection bias, in that physicians who take care of HIV-infected patients are more likely to monitor CD4+ T cells. Approximately one-third of the patients are women, compared to 16% of women among HIV-infected individuals in the United States. Many patients with ICL remained clinically stable, and their condition did not deteriorate progressively as is common with seriously immunodeficient HIV-infected patients. Certain patients with ICL even experienced spontaneous reversal of the CD4+ T lymphocytopenia. Immunologic abnormalities in ICL are somewhat different from those of HIV infection. ICL patients often also have decreases in CD8+ T cells and in B cells. Furthermore, immunoglobulin levels were either normal or, more commonly, decreased in patients with ICL, compared to the usual hypergammaglobulinemia of HIV-infected individuals. Finally, virologic studies revealed no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II or of any other mononuclear cell-tropic virus. Furthermore, there was no epidemiologic evidence to suggest that a transmissible microbe was involved. The cases of ICL were widely dispersed, with no clustering. Close contacts and sexual partners who were studied were clinically well and were serologically, immunologically, and virologically negative for HIV. ICL is a heterogeneous syndrome, and it is highly likely that there is no common cause; however, there may be common causes among subgroups of patients that are currently unrecognized.

Patients who present with laboratory data consistent with ICL should be worked up for

underlying diseases that could be responsible for the immune deficiency. If no underlying cause is detected, no specific therapy should be initiated. However, if opportunistic diseases occur, they should be treated appropriately (see above). Depending on the level of the CD4+ T cell count, patients should receive prophylaxis for the commonly encountered opportunistic infections.

TREATMENT

General Principles of Patient Management The treatment of patients with HIV infection requires not only a comprehensive knowledge of the possible disease processes that may occur but also the ability to deal with the problems of a chronic, potentially life-threatening illness. Great advances have been made in the treatment of patients with HIV infection. The appropriate use of potent combination antiretroviral therapy and other treatment and prophylactic interventions is of critical importance in providing each patient with the best opportunity to live a long and healthy life despite the presence of HIV infection. In contrast to the earlier days of this epidemic, a diagnosis of HIV infection need no longer be equated with an inevitably fatal disease. In addition to medical interventions, the health care provider has a responsibility to provide each patient with appropriate counseling and education concerning their disease as part of a comprehensive care plan. Patients must be educated about the potential transmissibility of their infection and about the fact that while health care providers may refer to levels of the virus as "undetectable" this is more a reflection of the sensitivity of the assay being used to measure the virus than a comment on the presence or absence of the virus. It is important for patients to be aware and that the virus is still present and capable of being transmitted at all stages of HIV disease. Thus, there needs to be frank discussions concerning sexual practices and the sharing of needles. The treating physician must not only be aware of the latest medications available for patients with HIV infection but must also educate patients concerning the natural history of their illness and listen and be sensitive to their fears and concerns. As with other diseases, therapeutic decisions should be made in consultation with the patient, when possible, and with the patient's proxy if the patient is incapable of making decisions. In this regard, it is recommended that all patients with HIV infection, and in particular those with CD4+ T cell counts <200/uL, designate a trusted individual with durable power of attorney to make medical decisions on their behalf, if necessary.

No matter how well prepared a patient is for adversity, the discovery of a diagnosis of HIV infection is a devastating event. For this reason, it is recommended that anyone about to undergo testing have "pretest counseling" to prepare him or her at least partially should the results demonstrate the presence of HIV infection. Following a diagnosis of HIV infection, the health care provider should be prepared to activate support systems immediately for the newly diagnosed patient. These should include an experienced social worker or nurse who can spend time talking to the person and ensuring that he or she is emotionally stable. Most communities have HIV crisis centers that can be of great help in these difficult situations.

Following a diagnosis of HIV infection, there are several examinations and laboratory studies that should be performed to help determine the extent of disease and provide baseline standards for future reference (Table 309-19). In addition to routine chemistry and hematology screening panels and chest x-ray, one should also obtain a CD4+ T cell

count, two separate plasma HIV RNA levels, aVDRLtest, and an anti-*Toxoplasma* antibody titer. APPD test should be done, and aMMSEperformed and recorded. Patients should be immunized with pneumococcal polysaccharide and, if seronegative for these viruses, with hepatitis A and hepatitis B vaccines. In addition, patients should be counseled with regard to sexual practices and needle sharing, and counseling should be offered to those whom the patient knows or suspects may also be infected. Once these baseline activities are performed, short- and long-term medical management strategies should be developed based uoon the most recent information available and modified as new information becomes available. The field of HIV medicine is changing rapidly, and it is difficult to remain fully up to date. Fortunately there are a series of excellent sites on the World Wide Web that are frequently updated, and they provide the most recent information on a variety of topics, including consensus panel reports on treatment (Table 309-20).

Antiretroviral Therapy Combination antiretroviral therapy, orHAART, is the cornerstone of management of patients with HIV infection. Following the initiation of widespread use of HAART in the United States in 1995 to 1996, marked declines have been noted in the incidence of most AIDS-defining conditions (Fig. 309-28). Suppression of HIV replication is an important component in prolonging life as well as improving the quality of life in patients with HIV infection. Unfortunately, many of the most important questions related to the treatment of HIV disease currently lack definitive answers. Among them are the questions of when should therapy be started, what is the best initial regimen, when should a given regimen be changed, and what should it be changed to when a change is made. Notwithstanding these uncertainties, the physician and patient must come to a mutually agreeable plan based upon the best available data. In an effort to facilitate this process, the United States Department of Health and Human Services has published a series of frequently updated guidelines including the "*Principles of Therapy of HIV Infection*," "*Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents*," and "*Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus*." At present, an extensive clinical trials network, involving both clinical investigators and patient advocates, is in place attempting to develop improved approaches to therapy. Consortia comprising representatives of academia, industry, and the federal government are involved in the process of drug development, including clinical trials. As a result, new therapies and new therapeutic strategies are continually emerging. New drugs are often available through expanded access programs prior to official licensure. Given the complexity of this field, decisions regarding antiretroviral therapy are best made in consultation with experts. Currently licensed drugs for the treatment of HIV infection fall into two main categories: those that inhibit the viral reverse transcriptase enzyme (Table 309-21,Fig. 309-3*B*) and those that inhibit the viral protease enzyme. There are numerous drug-drug interactions that one must take into consideration when using these agents (Table 309-22).

TheFDA-approved reverse transcriptase inhibitors include the *nucleoside analogues* zidovudine, didanosine, zalcitabine, stavudine, lamivudine, and abacavir and the *nonnucleoside reverse transcriptase inhibitors* nevirapine, delavirdine, and efavirenz (Fig. 309-38;Table 309-21). These were the first class of drugs that were licensed for the treatment of HIV infection. They are indicated for this use as part of combination regimens. It should be stressed that none of these drugs should be used as

monotherapy for HIV infection. Thus, when lamivudine is used to treat hepatitis B infection in the setting of HIV infection, one should ensure that the patient is also on additional antiretroviral medication. The reverse transcriptase inhibitors block the HIV replication cycle at the point of RNA-dependent DNA synthesis, the reverse transcription step. While the nonnucleoside reverse transcriptase inhibitors are quite selective for the HIV-1 reverse transcriptase, the nucleoside analogues inhibit a variety of DNA polymerization reactions in addition to those of the HIV-1 reverse transcriptase. For this reason, serious side effects are more common with the nucleoside analogues and include mitochondrial damage that can lead to hepatic steatosis and lactic acidosis as well as peripheral neuropathy and pancreatitis.

Zidovudine (AZT; 3¢-azido-2¢,3¢-dideoxythymidine) was the first drug approved for the treatment of HIV infection and is the prototype nucleoside analogue. These compounds, in which the hydroxyl group in the 3¢ position of the ribose moiety is substituted with a hydrogen or other chemical group, act as DNA chain terminators owing to their inability to form a 3¢-5¢phosphodiester linkage with another nucleoside. They bind much more avidly to the active site of the RNA-dependent DNA polymerase of HIV (reverse transcriptase) than to the active site of mammalian cell DNA polymerases; this explains their selective effect on HIV replication. Zidovudine also has a relatively high avidity for the DNA polymerase-g of human mitochondria. This may contribute to the development of the fatty liver and the myopathy sometimes observed in patients taking zidovudine. As with all the nucleoside analogues, the active form of zidovudine is the triphosphate, and the rate of phosphorylation, a thymidine kinase-dependent pathway, may be different in different cells. This may explain why zidovudine is more effective at inhibiting HIV replication in some cells than others. The clinical efficacy of zidovudine was clearly established in 1986 in a phase II, randomized, placebo-controlled trial in patients with advanced HIV disease. However, while treatment of patients with early stages of HIV infection was associated with increases in CD4+ T cell count, it was not associated with a better overall outcome than later intervention. Subsequent trials established the ability of this drug to dramatically decrease the incidence of perinatal transmission of HIV from infected mother to infant. Eventually a series of studies demonstrated the superiority of combination antiretroviral regimens over zidovudine alone, and combination therapy (discussed below) remains the standard of treatment today. Among the side effects of zidovudine at the initiation of therapy are fatigue, malaise, nausea, and headache. These side effects often subside over time. Patients on zidovudine may develop a macrocytic anemia, myopathy, cardiomyopathy, and lactic acidosis associated with fatty infiltration of the liver. As with every antiretroviral drug, HIV has the ability to develop resistance to zidovudine. Zidovudine resistance has been reported to occur ~6 months following the initiation of zidovudine monotherapy. More recently, zidovudine-resistant viruses have been noted in patients with acute infection prior to the initiation of therapy, implying that zidovudine-resistant viruses can be transmitted from person to person. Resistance emerges more rapidly in late-stage patients, presumably as a consequence of a greater degree of viral replication and thus a greater opportunity for mutation. A variety of amino acid changes including substitutions, insertions, and deletions have been reported to confer zidovudine resistance (Fig. 309-39). A combination preparation, Combivir, consists of zidovudine and lamivudine.

Didanosine (ddI; 2¢,3¢-dideoxyinosine) was the second drug licensed for the treatment of HIV infection, followed shortly thereafter by zalcitabine. Didanosine is metabolized to

dideoxyadenosine in vivo. It is best absorbed on an empty stomach at a high pH. For this reason, the current formulations of didanosine contain a buffer, and each dose must be administered in no fewer than two tablets to ensure adequate buffering of stomach acid. The toxicity profile of didanosine is quite different from that of zidovudine. The most common toxicity is a painful sensory peripheral neuropathy that occurs in ~30% of patients receiving >400 mg/d. It generally resolves with discontinuation of the drug and may not recur if the drug is resumed at a reduced dose. At higher doses than are currently used one may see pancreatitis in ~10% of patients. Pancreatitis associated with didanosine therapy can be fatal. Didanosine should be discontinued if a patient experiences abdominal pain consistent with pancreatitis or if an elevated serum amylase or lipase is found in association with an edematous pancreas on ultrasound. Didanosine is contraindicated in patients with a prior history of pancreatitis, regardless of etiology.

Zalcitabine (ddC; 2¢,3¢-dideoxycytidine) is rarely used today in the management of patients with HIV infection. Among the nucleoside analogues licensed for the treatment of HIV infection, it is probably the weakest. The main toxicity of ddC is pancreatitis.

Stavudine (d4T; 2¢,3¢-didehydro-3¢-deoxythymidine) was the fourth drug licensed for the treatment of HIV infection. Like zidovudine, stavudine is a thymidine analogue. These two drugs are antagonistic in vitro and in vivo and should not be given together. Peripheral neuropathy and hepatic steatosis are the main toxicities of stavudine. It is commonly used with lamivudine as part of an initial treatment regimen.

Lamivudine (3TC; 2¢,3¢-dideoxy-3¢-thiacytidine) is the fifth of the nucleoside analogues to be licensed in the United States. It is licensed for use in combination with zidovudine in situations where zidovudine is indicated. In actual practice, lamivudine, is a frequent element of many different combination regimens currently in use. It is available either alone or in combination with zidovudine (Combivir). One reason behind the excellent synergy seen between lamivudine and the other nucleoside analogues may be that strains of HIV resistant to lamivudine (M184V substitution) appear to have enhanced sensitivity to other nucleosides, and thus development of dual resistance is quite difficult. In addition, there is a suggestion that 3TC-resistant strains of HIV may be less virulent and are less able to generate new mutants than are strains of HIV that are 3TC-sensitive. Lamivudine is among the best tolerated and least toxic nucleoside analogues.

Abacavir
lcub;(1S,cis)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclopentene-1-methanol sulfate (salt)(2:1)rcub; is a synthetic carbocyclic analogue of the nucleoside guanosine. It is licensed to be used in combination with other antiretroviral agents for the treatment of HIV-1 infection. Hypersensitivity reactions have been reported in ~5% of patients treated with this drug, and patients developing signs or symptoms of hypersensitivity such as fever, skin rash, fatigue, and gastrointestinal symptoms should discontinue the drug and not restart it. Fatal hypersensitivity reactions have been reported with rechallenge. Abacavir-resistant strains of HIV are typically also resistant to lamivudine, didanosine, and zalcitabine.

Nevirapine, *delavirdine*, and *efavirenz* are nonnucleoside inhibitors of the HIV-1 reverse

transcriptase. They are licensed for use in combination with nucleoside analogues for the treatment of HIV-infected adults. These agents inhibit reverse transcriptase by binding to regions of the enzyme outside the active site and causing conformational changes in the enzyme that render it inactive. Although these agents are active in the nanomolar range, they are also very selective for the reverse transcriptase of HIV-1, have no activity against HIV-2, and, when used as monotherapy, are associated with the rapid emergence of drug-resistant mutants (Table 309-21;Fig. 309-39). Efavirenz is administered once a day, nevirapine twice a day, and delavirdine three times a day. All three drugs are associated with the development of a maculopapular rash, generally seen within the first few weeks of therapy. While it is possible to treat through this rash, it is important to be sure that one is not dealing with a more severe eruption such as Stevens-Johnson syndrome by looking carefully for signs of mucosal involvement, significant fever, or painful lesions with desquamation. In addition to skin rash, many patients treated with efavirenz note a feeling of light-headedness, dizziness, or out of sorts following the initiation of therapy. Some complain of vivid dreams. These symptoms tend to disappear after several weeks of therapy. Aside from difficulties with dreams, taking efavirenz at bedtime may minimize the side effects. Nevirapine and efavirenz are both commonly used as part of initial treatment regimens in combination with two nucleoside analogues. Another common use of these drugs is as part of salvage regimens in patients whose current regimen is inadequate.

The introduction of the HIV-1 protease inhibitors (saquinavir, indinavir, ritonavir, nelfinavir, and amprenavir) to the therapeutic armamentarium of antiretrovirals has had a profound impact on the efficacy of antiretroviral therapy. When used as part of initial regimens in combination with reverse transcriptase inhibitors, these agents have been shown to be capable of suppressing levels of HIV replication to under 50 copies per milliliter in the majority of patients for a minimum of 3 years. As in the case of reverse transcriptase inhibitors, resistance to protease inhibitors can develop rapidly in the setting of monotherapy, and thus these agents should be used as part of combination therapeutic regimens. A summary of known resistance mutations for reverse transcriptase and protease inhibitors is shown in Fig. 309-39.

Saquinavir was the first of the HIV-1 protease inhibitors to be licensed. Initially provided as a hard gel (Invirase) with poor bioavailability, the current soft-get formulation (Fortavase) provides good plasma levels of drug, particularly when administered in conjunction with ritonavir. Saquinavir is metabolized by the cytochrome P450 system, and ritonavir therapy results in inhibition of cytochrome P450 action. Thus, when both drugs are administered together there is the potential for increases in saquinavir levels. The use of low doses of ritonavir to provide pharmacodynamic boosting of other agents has become a fairly common strategy in HIV therapy. Saquinavir is perhaps the best-tolerated protease inhibitor and the one with the fewest side effects.

Ritonavir was the first protease inhibitor for which clinical efficacy was demonstrated. In a study of 1090 patients with CD4+ T cell counts <100/uL who were randomized to receive either placebo or ritonavir in addition to any other licensed medications, patients receiving ritonavir had a reduction in the cumulative incidence of clinical progression or death from 34% to 17%. Mortality decreased from 10.1% to 5.8%. At full doses, ritonavir is poorly tolerated. Among the main side effects are nausea, diarrhea, abdominal pain, and circumoral paresthesia. Ritonavir has a high affinity for several isoforms of

cytochrome P450, and its use can result in large increases in the plasma concentrations of drugs metabolized by this pathway. Among the agents affected in this manner are saquinavir, indinavir, macrolide antibiotics, R-warfarin, ondansetron, rifampin, most calcium channel blockers, glucocorticoids, and some of the chemotherapeutic agents used to treatKS. In addition, ritonavir may increase the activity of glucuronyltransferases, thus decreasing the levels of drugs metabolized by this pathway. Overall, great care must be taken when prescribing additional drugs to patients taking ritonavir. As mentioned above, the pharmacodynamic boosting property of ritonavir, seen with doses as low as 100 to 200 mg twice a day, is often used in the setting of HIV infection to derive more convenient regimens. For example, when given with low-dose ritonavir, saquinavir and indinavir can both be given on twice-a-day schedules and taken with food.

Indinavir is among the best studied of the HIV-1 protease inhibitors. It was the first protease inhibitor used in combination with dual nucleoside therapy. The combination of zidovudine, lamivudine, and indinavir was the first "triple combination" shown to have a profound effect on HIV replication. The main side effects of indinavir are nephrolithiasis (seen in 4% of patients) and asymptomatic indirect hyperbilirubinemia (seen in 10%). Indinavir is predominantly metabolized by the liver. The dose should be lowered in patients with cirrhosis. Indinavir shares metabolic pathways with terfenadine, astemizole, cisapride, triazolam, and midazolam. To avoid the potential for cardiac arrhythmias or prolonged sedation, these drugs should not be administered to patients taking indinavir. Levels of indinavir are decreased during concurrent therapy with rifabutin or nevirapine and increased during concurrent therapy with ketoconazole, delavirdine, efavirenz, or ritonavir. Dosages should be modified appropriately in these circumstances (Table 309-22).

Nelfinavir was approved in 1997 and *amprenavir* was approved in 1999 for the treatment of adult or pediatric HIV infection when antiretroviral therapy is warranted. As with most of the newer antiretroviral agents, these approvals were based on randomized, controlled trials that demonstrated decreases in plasma HIV RNA levels and increases in CD4+ T cell counts. Both agents have unique resistance profiles. Nelfinavir resistance is associated with a D30N substitution in the protease gene. Viruses harboring this single mutation retain sensitivity to other protease inhibitors, and it has been suggested that for this reason nelfinavir is a good initial protease inhibitor. It is not clear, however, whether this theoretical consideration will be borne out in the results of clinical trials. Protease inhibitor resistance typically involves multiple amino acid substitutions and reduced susceptibility across the class. Amprenavir resistance is associated with a unique substitution at amino acid 50 (I50V), and it has been suggested that amprenavir may be of particular value in salvage regimens. This assumption also awaits verification in controlled clinical trials. Nelfinavir and amprenavir are both associated with gastrointestinal side effects. About 1% of patients receiving amprenavir have experienced severe and life-threatening skin reactions. An additional disadvantage of amprenavir is that the current formulation requires the patient to take 8 large capsules twice a day.

One of the main problems that has been encountered with the widespread use ofHAARTtherapy has been a syndrome of hyperlipidemia and fat distribution often referred to as *lipodystrophy syndrome* (discussed above under metabolic

abnormalities).

The principles of therapy for HIV infection have been articulated by a panel sponsored by the U.S. Department of Health and Human Services and the Henry J. Kaiser Family Foundation. These principles are summarized in Table 309-23. However, *one element of HIV disease not currently covered by these principles is that eradication of HIV infection has not yet been possible*. Treatment decisions must take into account the fact that one is dealing with a chronic infection. While early therapy is generally the rule in infectious diseases, immediate treatment of every HIV-infected individual upon diagnosis may not be prudent, and therapeutic decisions must take into account the balance between risks and benefits. At present, a reasonable course of action is to initiate antiretroviral therapy in anyone with the acute HIV syndrome; patients with symptomatic disease; patients with asymptomatic disease with CD4+ T cell counts<500/uL or with>20,000 copies of HIV RNA per milliliter (Table 309-24). In addition, one may wish to administer a 6-week course of therapy to uninfected individuals immediately following a high-risk exposure to HIV (see below).

Once the decision has been made to initiate therapy, the health care provider must decide which drugs to use as the first regimen. The decision regarding choice of drugs not only will affect the immediate response to therapy but also will have implications regarding options for future therapeutic regimens. The initial regimen is usually the most effective insofar as the virus has yet to develop significant resistance. The two options for initial therapy most commonly in use today are two different three-drug regimens. The first regimen utilizes two nucleoside analogues (one of which is usually lamivudine) and a protease inhibitor. The second regimen utilizes two nucleoside analogues and a nonnucleoside reverse transcriptase inhibitor. Unfortunately there are no clear data at present on which to base distinctions between these two approaches. Following the initiation of therapy one should expect a 1 log (tenfold) reduction in plasma HIV RNA levels within 1 to 2 months and eventually a decline in plasma HIV RNA levels to <50 copies per milliliter. During this same time there should be a rise in the CD4+ T cell count of 100 to 150/uL that is particularly brisk during the first month of therapy. Many clinicians feel that failure to achieve this endpoint is an indication for a change in therapy. Other reasons for a change in therapy include a persistently declining CD4+ T cell count, clinical deterioration, or drug toxicity (Table 309-25). As in the case of initiating therapy, changing therapy may have a lasting impact on future therapeutic options. When changing therapy because of treatment failure (clinical progression or worsening laboratory parameters), it is important to attempt to provide a regimen with at least two new drugs. In the patient in whom a change is made for reasons of drug toxicity, a simple replacement of one drug is reasonable. It should be stressed that in attempting to sort out a drug toxicity it may be advisable to hold all therapy for a period of time to distinguish between drug toxicity and disease progression. Drug toxicity will usually begin to show signs of reversal within 1 to 2 weeks. Prior to changing a treatment regimen because of drug failure, it is important to ensure that the patient has been adherent to the prescribed regimen. As in the case of initial therapy, the simpler the therapeutic regimen, the easier it is for the patient to be compliant. Plasma HIV RNA levels and CD4+ T lymphocyte counts should be monitored every 3 to 4 months during therapy and more frequently if one is contemplating a change in regimen or immediately following a change in regimen.

In an attempt to determine an optimal therapeutic regimen, one may attempt to measure antiretroviral drug susceptibility through genotyping or phenotyping of HIV quasispecies. Genotyping may be done through dideoxynucleotide sequencing, DNA chip hybridization, or line probe assays. Phenotypic assays measure the performance of reverse transcriptase or protease in the presence or absence of different concentrations of different drugs. These assays will generally detect quasispecies present at a frequency of at least 10%. The precise role of resistance testing in the management of patients with HIV infection is not yet clear. While randomized studies have suggested that information regarding HIV resistance profiles may improve therapeutic outcomes in patients failing their current antiretroviral regimen, the degree of improvement thus far has been small and the duration of the benefit limited. Resistance testing may be of particular value in distinguishing drug-resistant virus from poor patient compliance; it may also be of value to help guide initial therapy in a setting where transmission of a drug-resistant isolate is felt to be likely.

In addition to the licensed medications discussed above, a large number of experimental agents are being evaluated as possible therapies for HIV infection. Therapeutic strategies are being developed that interfere with virtually every step of the replication cycle of the virus (Fig. 309-3). In addition, as more is discovered about the role of the immune system in controlling viral replication, additional strategies, generically referred to as "immune-based therapies," are being developed as a complement to antiviral therapy. Among the antiviral agents in early clinical trials are additional nucleoside analogues, nucleotide analogues, additional protease inhibitors including nonpeptidomimetic compounds, integrase inhibitors, antisense nucleic acids, and fusion inhibitors. Among the immune-based therapies being evaluated areIFN-a, bone marrow transplantation, adoptive transfer of lymphocytes genetically modified to resist infection or enhance HIV-specific immunity, active immunotherapy with inactivated HIV, andIL-2.

HIV AND THE HEALTH CARE WORKER

Health care workers, especially those who deal with large numbers of HIV-infected patients, have a small but definite risk of becoming infected with HIV as a result of professional activities. As of January 1, 2000, 56 health care workers in the United States had been documented as having seroconverted to HIV following occupational exposure; 25 have developed AIDS. The individuals who seroconverted include 19 laboratory workers (16 of whom were clinical laboratory workers), 23 nurses, 6 physicians, 2 surgical technicians, 1 dialysis technician, 1 respiratory therapist, 1 health aide, 1 embalmer/morgue technician, and 2 housekeeper/maintenance workers. The exposures included 48 percutaneous (puncture/cut injury), 5 mucocutaneous (mucous membrane and/or skin), 2 both percutaneous and mucocutaneous, and 1 unknown route of exposure. Fifty exposures were to HIV-infected blood, three to concentrated virus in a laboratory, one to visibly bloody fluid, and one to unspecified fluid. As of January 1, 2000, there had been 136 other cases of HIV infection or AIDS among health care workers who have not reported other risk factors for HIV infection and who report a history of exposure to blood, body fluids, or HIV-infected laboratory material, but for whom seroconversion after exposure was not documented. The number of these workers who actually acquired their infection through occupational exposures is not known. Taken together, the data from several large studies suggest that the risk of HIV

infection following a percutaneous injury with an HIV-contaminated hollow-bore needle (in contrast to a solid-bore needle, i.e., a suture needle) is approximately 0.3%. A seroprevalence survey of 3420 orthopedic surgeons, 75% of whom practiced in an area with a relatively high prevalence of HIV infection and 39% of whom reported percutaneous exposure to patient blood, usually through an accident involving a suture needle, failed to reveal any cases of possible occupational infection, suggesting that the risk of infection with a suture needle may be considerably less than that with a blood-drawing needle.

Most cases of health care worker seroconversion occur as a result of needle-stick injuries. When one considers the circumstances that result in needle-stick injuries, it is immediately obvious that adhering to the standard guidelines for dealing with sharp objects would result in a significant decrease in this type of accident. In one study, 27% of needle-stick injuries resulted from improper disposal of the needle (over half of these were due to recapping the needle), 23% occurred during attempts to start an intravenous line, 22% occurred during blood drawing, 16% were associated with an intramuscular or subcutaneous injection, and 12% were associated with giving an intravenous infusion.

Recommendations regarding postexposure prophylaxis must take into account that several circumstances determine the risk of transmission of HIV following occupational exposure. In this regard, five factors have been associated with an increased risk for occupational transmission of HIV infection: deep injury, the presence of visible blood on the instrument causing the exposure, injury with a device that had been placed in the vein or artery of the source patient, terminal illness in the source patient, and lack of postexposure antiretroviral therapy in the exposed health care worker. Other important considerations include pregnancy in the health care worker and the possibility of exposure to drug-resistant virus. Regardless of the decision to use postexposure prophylaxis, the wound should be cleansed immediately and antiseptic applied. If a decision is made to offer postexposure prophylaxis, U.S. Public Health Service guidelines recommend (1) a combination of two nucleoside analogue reverse transcriptase inhibitors given for 4 weeks for routine exposures, or (2) a combination of two nucleoside analogue reverse transcriptase inhibitors plus a protease inhibitor given for 4 weeks for high-risk or otherwise complicated exposures, although most clinicians administer the latter regimen in all cases in which a decision is made to treat. Further details are available from the U.S. Public Health Service *Guidelines for the Management of Health-Care Worker Exposures to HIV and Recommendations for Postexposure Prophylaxis* (CDC, 1998).

Health care workers can minimize their risk of occupational HIV infection by following theCDCguidelines of July 1991, which include adherence to universal precautions, refraining from direct patient care if one has exudative lesions or weeping dermatitis, and disinfecting and sterilizing reusable devices employed in invasive procedures. The premise of universal precautions is that every specimen should be handled as if it came from someone infected with a bloodborne pathogen. All samples should be double-bagged, gloves should be worn when drawing blood, and spills should be immediately disinfected with bleach.

In attempting to put this small but definite risk to the health care worker in perspective, it

is important to point out that approximately 200 health care workers die each year as a result of occupationally acquired hepatitis B infection. The tragedy in this instance is that these infections and deaths due toHBVcould be greatly decreased by more extended use of the HBV vaccine. The risk of HBV infection following a needle-stick injury from a hepatitis antigen-positive patient is much higher than the risk of HIV infection (see "Transmission," above). There are multiple examples of needle-stick injuries where the patient was positive for both HBV and HIV and the health care worker became infected only with HBV. For these reasons, it is advisable, given the high prevalence of HBV infection in HIV-infected individuals, that all health care workers dealing with HIV-infected patients be immunized with the HBV vaccine.

TBis another infection common to HIV-infected patients that can be transmitted to the health care worker. For this reason, all health care workers should know theirPPDstatus, have it checked yearly, and receive one year of isoniazid treatment if their skin test converts to positive. In addition, all patients in whom a diagnosis of TB is being entertained should be placed immediately in respiratory isolation, pending results of the diagnostic evaluation. The emergence of drug-resistant organisms has made TB an increasing problem for health care workers. This is particularly true for the health care worker with preexisting HIV infection.

One of the most charged issues ever to come between health care workers and patients is that of transmission of infection from HIV-infected health care workers to their patients. This is discussed under "Occupational Transmission of HIV: Health Care Workers and Laboratory Workers," p. 1857. Theoretically, the same universal precautions that are used to protect the health care worker from the HIV-infected patient will also protect the patient from the HIV-infected health care worker.

VACCINES

Historically, vaccines have provided a safe, cost-effective, and efficient means of preventing illness, disability, and death from infectious diseases. Given the fact that human behavior, especially human sexual behavior, is extremely difficult to change, the best hope for preventing the spread of HIV infection rests with the development of a safe and effective vaccine. This task is problematic for a number of reasons, including the high mutability of the virus, the fact that the infection can be transmitted by cell-free or cell-associated virus, the likely need for the development of effective mucosal immunity, and the fact that it has been difficult to establish the precise correlates of protective immunity to HIV infection. Some HIV-infected individuals are long-term nonprogressors (see above), and a number of individuals have been exposed to HIV multiple times but remain uninfected; these facts suggest that there are protective elements of an HIV-specific immune response. In addition, studies using animal models, specificallySIV in the monkey and HIV-1 in the chimpanzee, have been encouraging and suggest that an HIV vaccine is possible. It should be pointed out that while the ideal goal of an HIV vaccine is to prevent infection, a vaccine given to an uninfected individual that significantly alters the course of disease or the infectivity of the individual, should that person become infected, could have an impact not only on the individual in question but also on the spread of infection in the community.

A number of clinical trials ranging from several small phase I trials to determine safety,

to fewer intermediate-sized phase II trials to determine safety and immunogenicity, to a single phase III trial to determine efficacy have been or are currently being conducted in humans. The single phase III trial is testing a bivalent gp 120 protein; this product has been shown to induce antibodies but not cytolytic T cells responses in phase I and II trials. The furthest advanced among phase II trials involves a combination approach using a live canarypox vector expressing one or multiple HIV epitopes given together with gp120 or using the gp120 as a boost. This approach has resulted in neutralizing antibodies in virtually all recipients and HIV-specific cytolytic T cells in approximately 30% of individuals at any given time during the course of the trial.

Other approaches currently being tested in phase I and/or phase II trials in humans include naked DNA; vaccines employing vectors such as modified vaccinia Ankara (MVA), salmonella, Venezuela equine encephalitis (VEE) virus, among others; peptide and subunit vaccines; and pseudovirions (Fig. 309-40). Live attenuated HIV vaccines have not proceeded into human trials at this time because of safety concerns. It is clear that it will take several years of clinical trials to establish the efficacy or lack thereof of a candidate vaccine for HIV.

PREVENTION

Education, counseling, and behavior modification are the cornerstones of an HIV prevention strategy. Widespread voluntary testing of individuals who have practiced or are practicing high-risk behavior, together with counseling of infected individuals, is recommended. Information gathered from such an approach should serve as the basis for behavior-modification programs, both for infected individuals who may be unaware of their HIV status and who could infect others and for uninfected individuals practicing high-risk behavior. The practice of "safer sex" is the most effective way for sexually active uninfected individuals to avoid contracting HIV infection and for infected individuals to avoid spreading infection. Abstinence from sexual relations is the only absolute way to prevent sexual transmission of HIV infection. However, this may not be feasible, and there are a number of relatively safe practices that can markedly decrease the chances of transmission of HIV infection. Partners engaged in monogamous sexual relationships who wish to be assured of safety should both be tested for HIV antibody. If both are negative, it must be understood that any divergence from monogamy puts both partners at risk; open discussion of the importance of honesty in such relationships should be encouraged. When the HIV status of either partner is not known, or when one partner is positive, there are a number of options. Use of condoms can markedly decrease the chance of HIV transmission. It should be remembered that condoms are not 100% effective in preventing transmission of HIV infection, and there is an ~10% failure rate of condoms used for contraceptive purposes. Most condom failures result from breakage or improper usage, such as not wearing the condom for the entire period of intercourse. Latex condoms are preferable, since virus has been shown to leak through natural skin condoms. Petroleum-based gels should never be used for lubrication of the condom, since they increase the likelihood of condom rupture. There has been a tendency among homosexual men to practice fellatio as a "minimal risk" activity compared to receptive anal intercourse. It should be emphasized that receptive oral fellatio is definitely not safe sex, and there has been clear-cut documentation of transmission of HIV where receptive fellatio was the only sexual act performed (see "Transmission," above). Topical microbicides for vaginal and anal use are being

pursued actively as a means by which individuals could avoid infection when the insertive partner cannot be relied on to use a condom. Kissing is considered safe, although there is a theoretical possibility of transmission via virus in saliva. The low concentration of virus in saliva of infected individuals, as well as the presence in saliva of HIV-inhibitory proteins (see above), lessens any risk of transmission by kissing.

The most effective way to prevent transmission of HIV infection amongIDUs is to stop the use of injectable drugs. Unfortunately, that is extremely difficult to accomplish unless the individual enters a treatment program. For those who will not or cannot participate in a drug treatment program and who will continue to inject drugs, the avoidance of sharing of needles and other paraphernalia ("works") is the next best way to avoid transmission of infection. The cultural and social factors that contribute to the sharing of paraphernalia are complex and difficult to overcome. In addition, needles and syringes may be in short supply. Under these circumstances, paraphernalia should be cleaned after each usage with a virucidal solution, such as undiluted sodium hypochlorite (household bleach). Data from a number of studies have indicated that programs that provide sterile needles to addicts in exchange for used needles have resulted in a decrease in HIV transmission without increasing the use of injection drugs. It is important for IDUs to be tested for HIV infection and counseled, to avoid transmission to their sexual partners. Secondary and tertiary spread of HIV infection by the heterosexual route within settings of a high level of injection drug use has increased greatly in the United States (see above).

Transmission of HIV via transfused blood or blood products has been decreased dramatically by a combination of screening of all blood donors for HIV infection by assays for both HIV antibody and p24 antigen and self-deferral of individuals at risk for HIV infection. In addition, clotting factor concentrates are heat-treated, essentially eliminating the risk to hemophiliacs who require these products. Autologous transfusions are preferable to transfusions from another individual. However, logistic constraints as well as the unpredictability of the need for most transfusions limit the feasibility of this approach. At present the risk of becoming HIV-infected from a contaminated blood transfusion is approximately 1 in 676,000 donations.

HIV can be transmitted via breast milk and colostrum. The avoidance of breast feeding may not be practical in developing countries, where nutritional concerns override the risk of HIV transmission. However, it is becoming appreciated that from 5 to 15% of infants who were born of HIV-infected mothers and who were fortunate enough not to have been infected intrapartum or peripartum become infected via breast feeding. Therefore, even in developing countries, breast feeding from an infected mother should be avoided if at all possible. Unfortunately, this is rarely the case, and given the disadvantages of withholding breast feeding in developing countries (see above), health authorities in most developing countries continue to recommend breast feeding despite the potential for HIV transmission. In developed countries such as the United States, where bottled formula and milk are readily accessible, breast feeding is absolutely contraindicated when a mother is HIV positive.

SECTION 2 -DISORDERS OF IMMUNE-MEDIATED INJURY

310. ALLERGIES, ANAPHYLAXIS, AND SYSTEMIC MASTOCYTOSIS - *K. Frank Austen*

The term *atopic allergy* implies a familial tendency to manifest such conditions as asthma, rhinitis, urticaria, and eczematous dermatitis (atopic dermatitis) alone or in combination. However, individuals without an atopic background may also develop hypersensitivity reactions, particularly urticaria and anaphylaxis, associated with the same class of antibody, IgE, found in atopic individuals. Inasmuch as the mast cell is the key effector cell of the biologic response in allergic rhinitis, urticaria, anaphylaxis, and systemic mastocytosis, the introduction to these clinical problems will consider the developmental biology, activation pathway, product profile, and target tissues for this cell type.

The fixation of IgE to human mast cells and basophils, a process termed *sensitization*, prepares these cells for subsequent antigen-specific activation. The interaction of the high-affinity Fc receptor for IgE, designated FceRI, upregulates the cellular expression of the receptor, possibly by ligand-mediated stabilization. FceRI is composed of onea, one b, and two disulfide-linked g chains, which together cross the plasma membrane seven times. The a chain is solely responsible for IgE binding, and the b andg chains are responsible for signal transduction that results from the aggregation of the tetrameric receptors by polymeric antigen.

The interaction of specific multivalent antigen with receptor-bound IgE results in clustering of the receptors to initiate signal transduction through the action of a *src* family-related tyrosine kinase, termed *Lyn*, that is constitutively associated with the b chain. Lyn transphosphorylates the canonical immunoreceptor tyrosine-based activation motifs (ITAMs) of theb and g chains of the receptor, resulting in recruitment of more active Lyn to theb chain and of the Syk/zap-70 family tyrosine kinases. The two phosphorylated tyrosines in the ITAMs function as binding sites for the tandem *src* homology two (SH2) domains within these kinases. It appears that Syk activates not only phospholipase Cg but also phosphatidylinositol-3-kinase to provide phosphatidyl-3,4,5-triphosphate, which allows membrane targeting of the Tec family kinases (Btk and Itk) and their activation by Lyn. The resulting Tec kinase-dependent phosphorylation of phospholipase Cg with cleavage of its phospholipid membrane substrate provides inositol-1,4,5-triphosphate (IP_3) and 1,2-diacylglycerols (1,2-DAGs) so as to mobilize intracellular calcium and activate protein kinase C. The subsequent opening of calcium-regulated activated channels provides the sustained elevations of intracellular calcium required to recruit the mitogen-activated protein kinases, JNK and p38 (serine/threonine kinases), which provide cascades to augment arachidonic acid release and to mediate nuclear translocation of transcription factors for various cytokines. The calcium ion-dependent activation of phospholipases cleaves membrane phospholipids to generate lysophospholipids, which, like 1,2-DAG, are fusogenic and may facilitate the fusion of the secretory granule perigranular membrane with the cell membrane, a step that releases the membrane-free granule containing the preformed or primary mediators of mast cell effects.

The secretory granule of the human mast cell has a crystalline structure, unlike mast

cells of lower species, and IgE-dependent cell activation can be characterized morphologically by solubilization and swelling of the granule contents within the first minute of receptor perturbation; this reaction is followed by the ordering of intermediate filaments about the swollen granule, movement toward the cell surface, and fusion of the perigranular membrane with that of other granules and with the plasmalemma to form extracellular channels for mediator release while maintaining cell viability.

In addition to exocytosis, aggregation of FceRI initiates two other pathways for generation of bioactive products, namely, lipid mediators and cytokines. The biochemical steps involved in expression of such cytokines as tumor necrosis factor a(TNF-a), interleukin (IL) 6, IL-4, IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF), and others have not been specifically defined for mast cells. Nonetheless, inhibition studies of cytokine production (IL-1b, TNF-a, and IL-6) in mouse mast cells with cyclosporine or FK506 reveal binding to the ligand-specific immunophilin and attenuation of the calcium ion- and calmodulin-dependent serine/threonine phosphatase, calcineurin.

Lipid mediator generation (Fig. 310-1) involves translocation of calcium ion-dependent cytosolic phospholipase A_2 to the perinuclear membrane, with subsequent release of arachidonic acid for metabolic processing by the distinct prostanoid and leukotriene pathways. The constitutive prostaglandin endoperoxide synthase (PGHS-1/cyclooxygenase-1) and the de novo inducible PGHS-2 (cyclooxygenase-2) convert released arachidonic acid to the sequential intermediates prostaglandin (PG) G_2 and PGH_2. The glutathione-dependent hematopoietic PGD_2synthase then converts PGH_2 to PGD_2, the predominant mast cell prostanoid.

For processing by the leukotriene pathway, the released arachidonic acid is translocated to an integral perinuclear membrane protein, the 5-lipoxygenase activating protein (FLAP). The calcium ion-dependent activation of 5-lipoxygenase involves translocation to the perinuclear membrane, which allows conversion of the arachidonic acid to the sequential intermediates, 5-hydroperoxyeicosatetraenoic acid and leukotriene (LT) A_4. LTA_4 is conjugated with reduced glutathione by LTC_4synthase, an integral membrane protein with significant homology to FLAP. Intracellular LTC_4 is released by a carrier-specific export step for extracellular conversion to the receptor-active cysteinyl leukotrienes LTD_4 and LTE_4 by sequential removal of glumatic acid and glycine. A cytosolic LTA_4hydrolase converts some LTA_4 to the dihydroxy leukotriene LTB_4, which then undergoes specific export for extracellular receptor-mediated actions. The lysophospholipid formed during release of arachidonic acid from 1-*O*-alkyl-2-acyl-*sn*-glyceryl-3-phosphorylcholine can be acetylated in the second position to form platelet-activating factor (PAF).

Unlike other cells of bone marrow origin, mast cells leave the marrow and circulate as committed progenitors lacking their definitive secretory granules. These committed progenitors express the receptor, c-*kit*, for stem cell factor (SCF) before the expression of FceRI. Whereas c-*kit* is lost or markedly diminished in expression by other cell types, it is retained by mature, differentiated mast cells and is an absolute requirement for the development of constitutive tissue mast cells residing in skin and connective tissue sites and for the T cell-dependent mast cells residing in mucosal surfaces or undergoing reactive hyperplasia. Indeed, in clinical T cell deficiencies, mast cells are absent from

the intestinal mucosa but are present in the submucosa. It is thus assumed that unrecognized mast cell progenitors enter the tissue and undergo regulated proliferation, differentiation, and maturation. Based on the immunodetection of secretory granule neutral proteases, mast cells in the lung parenchyma and intestinal mucosa selectively express tryptase; those in the intestinal and airway submucosa, skin, lymph nodes, and breast parenchyma express tryptase, chymase, and carboxypeptidase A (CPA); and occasional mast cells in intestinal submucosa express chymase and CPA but not tryptase. The secretory granules of mast cells selectively positive for tryptase in lung and intestinal mucosa exhibit closed scrolls with a periodicity suggestive of a crystalline structure by electron microscopy; whereas the secretory granules of mast cells with mutiple proteases residing in skin, lymph nodes, breast parenchyma, and submucosa of airways and intestine are scroll-poor, with an amorphous or latticelike appearance.

Mast cells are distributed at cutaneous and mucosal surfaces and in deeper tissues about venules and could regulate the entry of foreign substances by their rapid response capability (Fig. 310-2). Upon stimulus-specific activation in vitro, histamine and secretory granule-associated acid hydrolases are solubilized, whereas the neutral proteases, which are cationic, remain largely complexed to the anionic proteoglycans, heparin and chrondroitin sulfate E. The macromolecular complex serves to deliver the neutral proteases so that the endo- and exoproteases can function in concert at the substrate site to clear damaged tissue and facilitate repair. Histamine and the various lipid mediators (PGD_2,LTD_4/E_4,PAF) alter venular permeability, thereby allowing influx of plasma proteins such as complement and immunoglobulins, whereas LTB_4mediates leukocyte-endothelial cell adhesion with subsequent directed migration (chemotaxis). The accumulation of leukocytes and opsonins would facilitate defense of the microenvironment. The cysteinyl leukotrienes constrict both vascular and nonvascular smooth muscle and are much more potent than histamine in constricting human airway smooth muscle when administered by aerosol.

The cellular component of the inflammatory response elicited by preformed secretory granule-associated and membrane-derived lipid mediators would be augmented and sustained by the addition of cytokines of mast cell or T cell origin to the microenvironment. Activation of human skin mast cells in situ elicitsTNF-aproduction and release, which in turn induces endothelial cell responses favoring leukocyte adhesion. Activation of purified human lung mast cells in vitro results in substantial production ofIL-5 and lesser quantities of IL-4. Bronchial biopsies of patients with bronchial asthma reveal that mast cells are immunohistochemically positive for IL-4 and IL-5, but that the predominant localization of IL-4, IL-5, andGM-CSFis to T cells, defined as T_H2 by this profile. It is speculated that IL-4 modulates the T cell phenotype to the T_H2 subtype, and that IL-5 or GM-CSF converts infiltrating eosinophils to an activated, autoaggressive phenotype with augmented capacity for cytotoxicity and generation of O_2-and the cysteinyl leukotrienes.

The view of immediate and late cellular phase of allergic inflammation is supported by the response of the skin, nose, or lung of allergic humans to local allergen challenge; greater quantities of allergen are needed to elicit the cellular phase. In the immediate phase of a local challenge, there is pruritus and watery discharge from the nose, bronchospasm and mucous secretion in the lungs, and a wheal-and-flare response with pruritus in the skin. The reduced nasal patency, reduced pulmonary function, or evident

erythema with swelling at the skin site in a late-phase response at 6 to 8 h are associated with biopsy findings of infiltrating and activated T_H2 type T cells, eosinophils, basophils, and even some neutrophils. This allergic inflammation proceeding from early mast cell activation to late cellular infiltration is believed to promote end-organ hyperresponsivity, as would be characteristic of perennial rhinitis or bronchial asthma; for attenuation, it requires introduction of an anti-inflammatory agent such as a glucocorticoid. The particular chemokines responsible for directed migration of eosinophils and T cells after their integrin-dependent endothelial cell adhesion are not yet defined, although eotaxin is a likely contributor since both cell types, as well as basophils, express the selective receptor CCR-3.

Consideration of the mechanism of immediate type hypersensitivity diseases in the human has focused largely on the IgE-dependent recognition of otherwise nontoxic substances. A region of chromosome 5 (5q23-31) contains genes implicated in the control of IgE levels including IL-4 and IL-13, as well as IL-3 and IL-9 involved in reactive mast cell hyperplasia and IL-5 and GM-CSF central to eosinophil development and their enhanced tissue viability. Genes with linkage to the specific IgE response to particular allergens include those encoding the major histocompatibility complex (MHC) and certain chains of the T cell receptor (TCR-ad). The complexity of atopy and the associated diseases is such that susceptibility, severity, and therapeutic responses most likely relate not only to specific IgE but also to constitutive target tissue reactivity and the superimposed effects of the local inflammatory response mediated by T_H2 cells, mast cells, basophils, and eosinophils.

The induction of allergic disease requires sensitization of a predisposed individual to specific allergen. This sensitization can occur anytime in life, although the greatest propensity for the development of allergic disease appears to occur in childhood and early adolescence. Exposure of a susceptible individual to an allergen results in processing of the allergen by antigen-presenting cells, including macrophage-like cells located throughout the body at surfaces that contact the outside environment, such as the nose, lungs, eyes, skin, and intestine. These antigen-presenting cells process the allergen protein and present the epitope-bearing peptides via theirMHC to particular T cell subsets. The T cell response depends both on cognate recognition through various ligand/receptor interactions and on the cytokine microenvironment, withIL-4 directing a T_H2 response and interferon (IFN)g a T_H1 profile. T cells can potentially induce several responses to an allergen, including those typical of contact dermatitis, known as the T_H1 type response, and those mediated by IgE, known as the T_H2 allergic response. The T_H2 response is associated with activation of specific B cells that transform into plasma cells. Synthesis and release into the serum of allergen-specific IgE by plasma cells result in sensitization of IgE Fc receptor-bearing cells including mast cells and basophils, which subsequently are capable of becoming activated upon exposure to the specific allergen. In certain diseases, including those associated with atopy, the monocyte and eosinophil populations can express a trimeric high-affinity receptor, FceRI, which lacks the b chain, and yet respond to its aggregation.

ANAPHYLAXIS

DEFINITION

The life-threatening anaphylactic response of a sensitized human appears within minutes after administration of specific antigen and is manifested by respiratory distress often followed by vascular collapse or by shock without antecedent respiratory difficulty. Cutaneous manifestations exemplified by pruritus and urticaria with or without angioedema are characteristic of such systemic anaphylactic reactions. Gastrointestinal manifestations include nausea, vomiting, crampy abdominal pain, and diarrhea.

PREDISPOSING FACTORS AND ETIOLOGY

There is no convincing evidence that age, sex, race, occupation, or geographic location predisposes a human to anaphylaxis except through exposure to some immunogen. According to most studies, atopy does not predispose individuals to anaphylaxis from penicillin therapy or venom of a stinging insect but is a risk factor for allergens in food or latex.

The materials capable of eliciting the systemic anaphylactic reaction in humans include the following: heterologous proteins in the form of hormones (insulin, vasopressin, parathormone), enzymes (trypsin, chymotrypsin, penicillinase, streptokinase), pollen extracts (ragweed, grass, trees), nonpollen extracts (dust mites, dander of cats, dogs, horses, and laboratory animals), food (milk, eggs, seafood, nuts, grains, beans, gelatin in capsules), antiserum (antilymphocyte gamma globulin), occupation-related proteins (latex rubber products), and Hymenoptera venom (yellow jacket, yellow and baldfaced hornets, paper wasp, honey bee, imported fire ants); polysaccharides such as dextran and thiomerosal as a vaccine preservative; and most commonly drugs such as protamine and antibiotics (penicillins, cephalosporins, amphotericin B, nitrofurantoin, quinolones), local anesthetics (procaine, lidocaine), muscle relaxants (suxamethonium, gallamine, pancuronium), vitamins (thiamine, folic acid), diagnostic agents (sodium dehydrocholate, sulfobromophthalein), and occupation-related chemicals (ethylene oxide), which are considered to function as haptens that form immunogenic conjugates with host proteins. The conjugating hapten may be the parent compound, a nonenzymatically derived storage product, or a metabolite formed in the host.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Individuals differ in the time of appearance of symptoms and signs, but the hallmark of the anaphylactic reaction is the onset of some manifestation within seconds to minutes after introduction of the antigen, generally by injection or less commonly by ingestion. There may be upper or lower airway obstruction or both. Laryngeal edema may be experienced as a "lump" in the throat, hoarseness, or stridor, while bronchial obstruction is associated with a feeling of tightness in the chest and/or audible wheezing. Patients with bronchial asthma are predisposed to severe involvement of the lower airways. A characteristic feature is the eruption of well-circumscribed, discrete cutaneous wheals with erythematous, raised, serpiginous borders and blanched centers. These urticarial eruptions are intensely pruritic and may be localized or disseminated. They may coalesce to form giant hives, and they seldom persist beyond 48 h. A localized, nonpitting, deeper edematous cutaneous process, angioedema, may also be present. It may be asymptomatic or cause a burning or stinging sensation.

In fatal cases with clinical bronchial obstruction, the lungs show marked hyperinflation

on gross and microscopic examination. The microscopic findings in the bronchi, however, are limited to luminal secretions, peribronchial congestion, submucosal edema, and eosinophilic infiltration, and the acute emphysema is attributed to intractable bronchospasm that subsides with death. The angioedema resulting in death by mechanical obstruction occurs in the epiglottis and larynx, but the process is also evident in the hypopharynx and to some extent in the trachea; on microscopic examination there is wide separation of the collagen fibers and the glandular elements; vascular congestion and eosinophilic infiltration are also present. Patients dying of vascular collapse without antecedent hypoxia from respiratory insufficiency have visceral congestion with a presumptive loss of intravascular blood volume. The associated electrocardiographic abnormalities, with or without infarction, noted in some patients may reflect a primary cardiac event or be secondary to a critical reduction in blood volume.

The angioedematous and urticarial manifestations of the anaphylactic syndrome have been attributed to release of endogenous histamine. A role for the cysteinyl leukotrienes in altering pulmonary mechanics by causing marked bronchiolar constriction seems likely. Vascular collapse without respiratory distress in response to experimental challenge with the sting of a hymenopteran was associated not only with marked and prolonged elevations in blood histamine but also with evidence of intravascular coagulation and kinin generation. The findings that patients with systemic mastocytosis and episodic hypotension proceeding to vascular collapse excrete large amounts ofPGD_2 metabolites in addition to histamine and that these events are controlled by administration of a nonsteroidal agent but not by antihistamines alone suggest that PGD_2 is also of importance in the hypotensive anaphylactic reactions. The cysteinyl leukotrienes may be involved in the pathobiologic process in patients with myocardial ischemia without or with infarction.

DIAGNOSIS

The diagnosis of an anaphylactic reaction depends largely on an accurate history revealing the onset of the appropriate symptoms and signs within minutes after the responsible material is encountered. When only a portion of the full syndrome is present, such as isolated urticaria, sudden bronchospasm in a patient with asthma, or vascular collapse after intravenous administration of an agent, it may be appropriate to consider a complement-mediated immune complex reaction, an idiosyncratic response to any of the nonsteroidal anti-inflammatory agents, or the direct effect of certain drugs or diagnostic agents on mast cells. Intravenous administration of a chemical mast cell-degranulating agent, including opiate derivatives and radiographic contrast media, may elicit generalized urticaria, angioedema, and a sensation of retrosternal oppression with or without clinically detectable bronchoconstriction or hypotension. Aspirin and other nonsteroidal anti-inflammatory agents such as indomethacin, aminopyrine, and mefenamic acid may precipitate a life-threatening episode of obstruction of upper or lower airways, especially in patients with asthma, that is clinically reminiscent of anaphylaxis but is not associated with a detectable IgE response. This syndrome, which is commonly associated with nasal polyposis, is due to inhibition of PGHS-1 with corresponding unregulated, amplified generation of the cysteinyl leukotrienes via the 5-lipoxygenase/LTC_4 synthase pathway. In the transfusion anaphylactic reaction that occurs in patients with IgA deficiency, the responsible specificity resides in IgG or IgE

anti-IgA; the mechanism of the reaction mediated by IgG anti-IgA is presumed to be complement activation with secondary mast cell participation.

The presence of specific IgE in the heart blood of patients dying of systemic anaphylaxis has been demonstrated at postmortem by passive transfer of the serum intradermally into a normal recipient, followed in 24 h by antigen challenge into the same site, with subsequent development of a wheal and flare, the Prausnitz-Kustner reaction. To avoid the hazards of transferring hepatitis or other infections to a recipient, it is preferable to use the serum to seek passive sensitization of a human leukocyte suspension enriched with basophils for subsequent antigen-induced histamine release. Furthermore, radioimmunoassays have demonstrated specific IgE antibodies in patients with anaphylactic reactions, but such approaches require purified antigens. Elevations of b-tryptase levels in serum implicate mast cell activation in an adverse systemic reaction and are particularly informative with episodes of hypotension during general anesthesia or when there has been a fatal outcome.

TREATMENT

Early recognition of an anaphylactic reaction is mandatory, since death occurs within minutes to hours after the first symptoms. Mild symptoms such as pruritus and urticaria can be controlled by administration of 0.2 to 0.5 mL of 1:1000 epinephrine subcutaneously, with repeated doses as required at 20-min intervals for a severe reaction. If the antigenic material was injected into an extremity, the rate of absorption may be reduced by prompt application of a tourniquet proximal to the reaction site, administration of 0.2 mL of 1:1000 epinephrine into the site, and removal without compression of an insect stinger, if present. An intravenous infusion should be initiated to provide a route for administration of 2.5 mL epinephrine, diluted 1:10,000, at 5- to 10-min intervals, volume expanders such as normal saline, and vasopressor agents such as dopamine if intractable hypotension occurs. Replacement of intravascular volume due to postcapillary venular leakage may require several liters of saline. Epinephrine provides both a- andb-adrenergic effects, resulting in vasoconstriction, bronchial smooth-muscle relaxation, and attenuation of enhanced venular permeability. Beta blockers are relatively contraindicated in persons at risk for anaphylactic reactions, especially those sensitive to Hymenoptera venom or those undergoing immunotherapy for respiratory system allergy. When epinephrine fails to control the anaphylactic reaction, hypoxia due to airway obstruction or related to a cardiac arrhythmia, or both, must be considered. Oxygen via a nasal catheter or intermittent positive-pressure breathing of oxygen with 0.5 mL isoproterenol diluted 1:200 in saline may be helpful, but either endotracheal intubation or a tracheostomy is mandatory for oxygen delivery if progressive hypoxia develops. Ancillary agents such as the antihistamine diphenhydramine, 50 to 100 mg intramuscularly or intravenously, and aminophylline, 0.25 to 0.5 g intravenously, are appropriate for urticaria-angioedema and bronchospasm, respectively. Intravenous glucocorticoids are not effective for the acute event but may alleviate later recurrence of bronchospasm, hypotension, or urticaria. Furthermore, in a syndrome termed *idiopathic anaphylaxis* with recurrent angioedema of the upper airways, glucocorticoid administration may be beneficial by reducing the frequency of attacks and/or the severity of episodes.

PREVENTION

Prevention of anaphylaxis must take into account the sensitivity of the recipient, the dose and character of the diagnostic or therapeutic agent, and the effect of the route of administration on the rate of absorption. If there is a definite history of a past anaphylactic reaction, even though mild, it is advisable to select another agent or procedure. A knowledge of cross-reactivity among agents is critical since, for example, cephalosporins share a commonb-lactam ring with the penicillins. A skin test should be performed before the administration of certain materials that are likely to elicit anaphylactic reactions, such as allergenic extracts, or when the nature of the past adverse reaction is unknown. A scratch test should precede an intradermal test in very sensitive patients. With regard to penicillin, two-thirds of patients with a positive reaction history and positive skin tests to benzylpenicilloyl-polylysine (BPL) and/or the minor determinant mixture (MDM) of benzylpenicillin products experience allergic reactions with treatment, and these are almost uniformly of the anaphylactic type in those patients with minor determinant reactivity. Even patients without a history of previous clinical reactions have a 2 to 6 percent incidence of positive skin tests to the two test materials, and about 3 per 1000 with a negative history experience anaphylaxis with therapy, with a mortality of about 1 per 100,000. Skin testing for antibiotics should be performed only on patients with a positive clinical history consistent with an IgE-mediated reaction and in imminent need of the antibiotic in question; skin testing is of no value for non-IgE-mediated eruptions. Desensitization with most antibiotics can proceed by the intravenous, subcutaneous, or oral route. Typically, graded quantities of the antibiotic are given by the selected route using double doses until a therapeutic dosage is achieved. Due to the risk of systemic anaphylaxis during the course of desensitization, such a procedure should be performed only in a setting in which resuscitation equipment is at hand and an intravenous line is in place. It is critical to give the therapeutic agent at regular intervals to prevent the reestablishment of a sensitized cell pool of large size.

A different form of protection involves the development of blocking antibody of the IgG class, which is protective against Hymenoptera venom-induced anaphylaxis by interacting with antigen so that less reaches the sensitized tissue mast cells; to be effective, this immunotherapy requires the use of specific or cross-reacting Hymenoptera venom. Because sensitization can be transient, the maximal risk for systemic anaphylactic reactions in persons with Hymenoptera sensitivity occurs in association with a currently positive skin test. Although there is only low-grade cross-reactivity between honey bee and yellow jacket venoms, there is a high degree of cross-reactivity between yellow jacket venom and the rest of the vespid venoms (yellow or baldfaced hornets and wasps). Prevention involves modification of outdoor activities to exclude bare feet, wearing perfumed toiletries, eating in areas attractive to insects, clipping hedges or grass, and hauling away trash or fallen fruit. As with each anaphylactic sensitivity, the individual should wear an informational bracelet and have immediate access to an unexpired epinephrine kit. The limitations of lifestyle and the psychological duress can be addressed by venom immunotherapy to achieve a venom-specific IgG titer. Although it has been recommended that venom therapy be continued indefinitely or until the skin and specific serum IgE tests are unremarkable, there is evidence that 5 years of treatment induces a state of resistance to sting reactions that is independent of serum levels of specific IgG or IgE. This contrasts with the definite relation of sting immunity to specific IgG earlier in the treatment regime. For

children with a systemic reaction limited to skin, the likelihood of progression to more serious respiratory or vascular manifestations is low, and thus immunotherapy is not recommended.

URTICARIA AND ANGIOEDEMA

DEFINITION

Urticaria and angioedema may appear separately or together as cutaneous manifestations of localized nonpitting edema; a similar process may occur at mucosal surfaces of the upper respiratory or gastrointestinal tract. *Urticaria* involves only the superficial portion of the dermis, presenting as well-circumscribed wheals with erythematous raised serpiginous borders with blanched centers that may coalesce to become giant wheals. *Angioedema* is a well-demarcated localized edema involving the deeper layers of the skin, including the subcutaneous tissue. Recurrent episodes of urticaria and/or angioedema of less than 6 weeks' duration are considered acute, whereas attacks persisting beyond this period are designated chronic.

PREDISPOSING FACTORS AND ETIOLOGY

The occurrence of urticaria and angioedema is probably more frequent than usually described because of the evanescent, self-limited nature of such eruptions, which seldom require medical attention when limited to the skin. Although persons in any age group may experience acute or chronic urticaria and/or angioedema, these lesions increase in frequency after adolescence, with the highest incidence occurring in persons in the third decade of life; indeed, one survey of college students indicated that 15 to 20% had experienced a pruritic wheal reaction.

The classification of urticaria-angioedema presented in Table 310-1 focuses on the different mechanisms for eliciting clinical disease and can be useful for differential diagnosis; nonetheless, most cases of chronic urticaria are idiopathic. Urticaria and/or angioedema occurring during the appropriate season in patients with seasonal respiratory allergy or as a result of exposure to animals or molds is attributed to inhalation or physical contact with pollens, animal dander, and mold spores, respectively. However, urticaria and angioedema secondary to inhalation are relatively uncommon compared to urticaria and angioedema elicited by ingestion of fresh fruits, shellfish, fish, milk products, chocolate, legumes including peanuts, and various drugs that may elicit not only the anaphylactic syndrome with prominent gastrointestinal complaints but also chronic urticaria.

Additional etiologies include physical stimuli such as cold, heat, solar rays, exercise, and mechanical irritation. The physical urticarias can be distinguished by the precipitating event and other aspects of the clinical presentation. *Dermographism*, which occurs in 1 to 4% of the population, is defined by the appearance of a linear wheal at the site of a brisk stroke with a firm object or by any configuration appropriate to the eliciting event. Dermographism has a prevalence that peaks in the second to third decades. It is not influenced by an atopic diathesis and has a duration generally of less than 5 years. *Pressure urticaria*, which often accompanies dermographism or chronic idiopathic urticaria, presents in response to a sustained stimulus such as a shoulder

strap or belt, running (feet), or manual labor (hands). *Cholinergic urticaria* is distinctive in that the pruritic wheals are of small size (1 to 2 mm) and are surrounded by a large area of erythema; attacks are precipitated by fever, a hot bath or shower, or exercise and are presumptively attributed to a rise in core body temperature. *Exercise-related anaphylaxis* can be limited to erythema and pruritic urticaria but may progress to angioedema of the face, oropharynx, larynx, or intestine or to vascular collapse; it is distinguished from cholinergic urticaria by presenting with wheals of conventional size and by not occurring with fever or a hot bath. *Cold urticaria*, either acquired or hereditary, is local at body areas exposed to low ambient temperature or cold objects (ice cube) but can progress to vascular collapse with immersion in cold water (swimming). *Solar urticaria* is subdivided into three groups by the response to specific portions of the light spectrum. *Vibratory angioedema* may occur after years of occupational exposure or can be idiopathic; it may be accompanied by cholinergic urticaria. Other rare forms of physical allergy, always defined by stimulus-specific elicitation, include *local heat urticaria*, *aquagenic urticaria* from contact with water of any temperature (sometimes associated with polycythemia vera), and *contact urticaria* from direct interaction with some chemical substance.

Angioedema without urticaria occurs with C1 inhibitor (C1INH) deficiency that may be inborn as an autosomal dominant characteristic or may be acquired. The urticaria and angioedema associated with classic serum sickness or with hypocomplementemic cutaneous necrotizing angiitis are believed to be immune-complex diseases. The drug reactions to mast cell granule-releasing agents and to nonsteroidal anti-inflammatory drugs may be systemic, resembling anaphylaxis, or limited to cutaneous sites.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Urticarial eruptions are distinctly pruritic, involve any area of the body from the scalp to the soles of the feet, and appear in crops of 24- to 72-h duration, with old lesions fading as new ones appear. The most common sites for urticaria are the extremities and face, with angioedema often being periorbital and in the lips. Although self-limited in duration, angioedema of the upper respiratory tract may be life-threatening due to laryngeal obstruction, while gastrointestinal involvement may present with abdominal colic, with or without nausea and vomiting, and may precipitate unnecessary surgical intervention. No residual discoloration occurs with either urticaria or angioedema unless there is an underlying process leading to superimposed extravasation of erythrocytes.

The pathology of urticaria and angioedema is usually characterized by edema of the dermis in urticaria and of the subcutaneous tissue as well as the dermis in angioedema. Collagen bundles in affected areas are widely separated, and the venules are sometimes dilated. The perivenular infiltrate may consist of lymphocytes, eosinophils, and neutrophils that are present in varying combination and number throughout the dermis.

Perhaps the best-studied example of IgE- and mast cell-mediated urticaria and angioedema is *cold urticaria*. Cryoglobulins may be recognized, but not in the majority of patients. Immersion of an extremity in an ice bath precipitates angioedema of the distal portion with urticaria at the air interface within minutes of the challenge. Histologic studies reveal marked mast cell degranulation with associated edema of the dermis and

subcutaneous tissues. The venous effluent of the cold-challenged and angioedematous extremity reveals a marked rise in plasma content of histamine, whereas the venous effluent of the contralateral normal extremity contains none of this mediator. Elevated levels of histamine have been found in the plasma of venous effluent and in the fluid of suction blisters at experimentally induced lesional sites in patients with dermographism, pressure urticaria, vibratory angioedema, light urticaria, and heat urticaria. By ultrastructural analysis, the pattern of mast cell degranulation in cold urticaria resembles an IgE-mediated response with solubilization of granule contents, fusion of the perigranular and cell membranes, and discharge of granule contents, whereas in a dermographic lesion there is an additional superimposed zonal (piecemeal) degranulation. Elevations of plasma histamine levels with biopsy-proven mast cell degranulation have also been demonstrated with systemic attacks of *cholinergic urticaria* and *exercise-related anaphylaxis* precipitated experimentally in subjects exercising on a treadmill while wearing a wet suit; however, only in cholinergic urticaria is there a concomitant decrease in pulmonary function.

DIAGNOSIS

The rapid onset and self-limited nature of urticarial and angioedematous eruptions are distinguishing features. Additional characteristics are the occurrence of the urticarial crops in various stages of evolution and the asymmetric distribution of the angioedema. Urticaria and/or angioedema involving IgE-dependent mechanisms are often appreciated by historic considerations implicating specific allergens or physical stimuli, by seasonal incidence, and by exposure to certain environments. Direct reproduction of the lesion with physical stimuli is particularly valuable because it so often establishes the cause of the lesion. The diagnosis of an environmental allergen based on the clinical history can be confirmed by skin testing or assay for allergen-specific IgE in serum. IgE-mediated urticaria and/or angioedema may or may not be associated with an elevation of total IgE or with peripheral eosinophilia. Fever, leukocytosis, and an elevated sedimentation rate are absent.

The classification of urticarial and angioedematous states noted in Table 310-1 in terms of possible mechanisms necessarily includes some differential diagnostic points. Hypocomplementemia is not observed in IgE-mediated mast cell disease and may reflect either an acquired abnormality generally attributed to the formation of immune complexes or a genetic deficiency ofC1INH. Chronic recurrent urticaria, generally in females, associated with arthralgias, an elevated sedimentation rate, and normo- or hypocomplementemia suggests an underlying cutaneous necrotizing angiitis. Vasculitic urticaria typically persists longer than 72 h, whereas conventional urticaria often has a duration of less than 24 to 48 h. Confirmation depends on a biopsy that reveals cellular infiltration, nuclear debris, and fibrinoid necrosis of the venules. The same pathobiologic process accounts for the urticaria in association with such diseases as systemic lupus erythematosus or viral hepatitis with or without an associated arteritis. Serum sickness per se or a similar clinical entity due to drugs includes not only urticaria but also pyrexia, lymphadenopathy, myalgia, and arthralgia or arthritis. Urticarial reactions to blood products or intravenous administration of immunoglobulin are defined by the event and generally are not progressive unless the recipient is IgA-deficient in the former case or the reagent is aggregated in the latter.

Hereditary angioedema is an autosomal dominant disease due to a deficiency of antigenic and/or functionalC1INH. The diagnosis is suggested not only by family history but also by the lack of pruritus and of urticarial lesions, the prominence of recurrent gastrointestinal attacks of colic, and episodes of laryngeal edema. Laboratory diagnosis depends on demonstrating a deficiency of C1INH antigen (type 1) in most kindreds, but some kindreds have an antigenically intact nonfunctional protein (type 2) and require a functional assay to establish the diagnosis. The natural substrates of uninhibited C1 protease, C4 and C2, are chronically depleted but fall further during attacks due to the activation of additional C1. Because the C1INH protein also regulates the Hageman factor-initiated activation of kallikrein and of plasmin, the vasoactive peptides responsible for the angioedema are likely some combination of bradykinin and a plasmin-derived fragment of C1-cleaved C2. An acquired form of C1INH deficiency, associated with lymphoproliferative disorders, has the same clinical manifestations but differs in the lack of a familial element; in the reduction of C1 function and C1q protein as well as C1INH, C4, and C2; and in the presence of an anti-idiotypic antibody to the monoclonal immunoglobulin expressed on the B cells. A second acquired form of C1INH deficiency with angioedema due to the appearance of IgG anti-C1INH may be associated with systemic lupus erythematosus.

Urticaria and angioedema must be differentiated from contact sensitivity, a vesicular eruption that progresses to chronic thickening of the skin with continued allergenic exposure. They must also be differentiated from atopic dermatitis, a condition that may present as erythema, edema, papules, vesiculation, and oozing proceeding to a subacute and chronic stage in which vesiculation is less marked or absent and scaling, fissuring, and lichenification predominate in a distribution that characteristically involves the flexor surfaces. In cutaneous mastocytosis, the reddish brown macules and papules, characteristic of urticaria pigmentosa, urticate with pruritus upon trauma; and in systemic mastocytosis, without or with urticaria pigmentosa, there is an episodic systemic flushing with or without urticaria but no angioedema.

TREATMENT

Identification of the etiologic factor(s) and their elimination provide the most satisfactory therapeutic program; this approach is feasible to varying degrees with IgE-mediated reactions to allergens or physical stimuli. For most forms of urticaria, H_1antihistamines such as chlorpheniramine or diphenhydramine, and including the nonsedating class such as loratadine or cetirizine, are effective in attenuating both urtication and pruritus. Cyproheptadine and especially hydroxyzine have proven effective when H_1antihistamines have been inadequate. Doxepin, a dibenzoxepin tricyclic compound with both H_1 and H_2receptor antagonist activity, is yet another alternative. Topical glucocorticoids are of no value in the management of urticaria and/or angioedema. Systemic glucocorticoids are generally avoided in idiopathic, allergen-induced, or physical urticarias due to their long-term toxicity. However, systemic glucocorticoids are useful in the management of patients with pressure urticaria, with vasculitic urticaria (especially with eosinophil prominence), with idiopathic angioedema with or without urticaria, or with chronic urticaria that responds poorly to conventional treatment. With persistent vasculitic urticaria, hydroxychloroquine or colchicine may be added to the regimen after hydroxyzine and before or along with systemic glucocorticoids.

The therapy of inbornC1INHdeficiency has been simplified by the finding that attenuated androgens correct the biochemical defect and afford prophylactic protection. Since the affected individuals are heterozygous, with the depletion of C1INH being due to deficient synthesis and consequent excessive utilization of the limited amount available, the efficacy of the attenuated androgens is attributed to production by the normal gene of an amount of functional C1INH sufficient to control the spontaneous activation of C1 to C1 protease. Since the use of such agents for children and pregnant women is not yet accepted, the antifibrinolytic agente-aminocaproic acid may be used occasionally to control spontaneous attacks or for preoperative prophylaxis in some patients. This agent should not be used in patients with thrombotic tendencies or ischemia due to arterial athrosclerosis. Infusion of isolated C1INH protein appears useful in prophylaxis and to ameliorate an attack but is not yet widely available.

SYSTEMIC MASTOCYTOSIS

DEFINITION

Systemic mastocytosis is defined by mast cell hyperplasia that in most instances is indolent and nonneoplastic. Since human mast cells originate from pluripotent bone marrow cells (CD34+), circulate as nonmetachromatically staining, c-*kit*-positive mononuclear cells, and undergo tissue-specific proliferation and maturation, the hyperplasia is generally recognized only in bone marrow and in the normal peripheral distribution sites of the cells, such as skin (Fig. 310-CD1), gastrointestinal mucosa, liver, and spleen. Mastocytosis occurs at any age and has a slight preponderance in males. The prevalence of systemic mastocytosis is not known, a familial occurrence has not been established, and atopy is not increased.

CLASSIFICATION, PATHOPHYSIOLOGY, AND CLINICAL MANIFESTATIONS

A recent consensus classification for systemic mastocytosis recognizes four forms (Table 310-2). The form designated as *indolent* accounts for the majority of patients and is not known to alter life expectancy. When a patient is classified as having indolent systemic mastocytosis, the concomitant clinical findings must be carefully noted, since they define the complications and directions for management. In systemic mastocytosis *associated with hematologic disorders*, the prognosis is determined by the nature of that disorder, which can range from dysmyelopoiesis to leukemia. In *aggressive* systemic mastocytosis, mast cell proliferation in parenchymal organs such as liver, spleen, and lymph nodes is marked and in a subset of patients is associated with prominent eosinophilia in affected organs or peripheral blood; the prognosis is poor due to widespread tissue infiltration. *Mast cell leukemia* is the rarest form of the disease and is invariably fatal at present; in contrast to the other forms, the peripheral blood contains circulating, metachromatically staining, atypical mast cells. In types II and IV systemic mastocytosis there is a point mutation of the c-*kit* tyrosine kinase in the leukocytes and mast cells, respectively; this mutation can also be detected in lesional tissue such as the small, reddish brown macules or papules, termed *urticaria pigmentosa*, at skin sites of patients with type I. The most common mutation, a substitution of valine for aspartate in codon 816 (V816D), leads to constitutively activated c-*kit*, which then drives proliferation independently of SCF. More than half of the cases of type II systemic mastocytosis with a V816D mutation exhibit cytogenetic abnormalities on routine karyotyping. In types I

and III there is excessive production of the c-*kit* ligand (SCF) in the microenvironment of the mast cells, and this may be autocrine in type III. In infants and children (type I) with cutaneous manifestations, namely, urticaria pigmentosa or bullous lesions, visceral involvement is usually lacking, and resolution is common because there are no mutations to activate the tyrosine kinase. The clinical manifestations of systemic mastocytosis, particularly types I and II, distinct from a leukemic complication, are due to tissue occupancy by the mast cell mass, the tissue response to that mass, and the release of bioactive substances acting at both local and distal sites. The pharmacologically induced manifestations are pruritus, flushing, palpitations and vascular collapse, gastric distress, lower abdominal crampy pain, and recurrent headache. The increase in cell burden is evidenced by the lesions of urticaria pigmentosa at skin sites, but it also contributes to bone pain and malabsorption. The mast cell-mediated fibrotic changes are limited to liver, spleen, and bone marrow and presumably relate to the functional characteristics of mast cells developing at those sites, as opposed to those at sites without fibrosis, such as the gastrointestinal tissue or skin. Immunofluorescent analysis of bone marrow and skin lesions in indolent mastocytosis and of spleen, lymph node, and skin in aggressive systemic mastocytosis has revealed only one mast cell phenotype, namely, scroll-poor cells expressing tryptase, chymase, and CPA.

The cutaneous lesions of urticaria pigmentosa respond to trauma with urtication and erythema (Darier's sign). The apparent incidence of these lesions is 90 percent or greater in patients with indolent systemic mastocytosis. Approximately 1 percent of patients with indolent mastocytosis have skin lesions that appear as tan-brown macules with striking patchy erythema and associated telangiectasia (telangiectasia macularis eruptiva perstans). In the upper gastrointestinal tract, histamine-mediated hypersecretion is the most common problem, with resultant gastritis and peptic ulcer. In the lower intestinal tract, the occurrence of diarrhea and abdominal pain is attributed to increased motility due to mast cell mediators, and this can be aggravated by malabsorption with secondary nutritional insufficiency and osteomalacia. The periportal fibrosis associated with mast cell infiltration and a prominence of eosinophils may lead to portal hypertension and ascites. In some patients, flushing and recurrent vascular collapse are markedly aggravated by an idiosyncratic response to a minimal dosage of nonsteroidal anti-inflammatory agents. The neuropsychiatric disturbances are clinically most evident as impaired recent memory, decreased attention span, and "migraine-like" headaches. Patients in every category of systemic mastocytosis may experience exacerbation of a specific clinical sign or symptom with alcohol ingestion, use of mast cell-interactive narcotics, or ingestion of nonsteroidal anti-inflammatory agents.

DIAGNOSIS

Although the diagnosis is generally suspected on the basis of the clinical history and physical findings, the contention can be strengthened by certain laboratory procedures and established only by a tissue diagnosis. A 24-h urine collection for measurement of histamine, histamine metabolites, or metabolites of$PGD_2$is currently the most common noninvasive approach. A convenient alternative is to measure blood levels of the mast cell-derived neutral protease tryptase. Thea form of tryptase is elevated in more than one-half of patients with type I systemic mastocytosis and in virtually all those with types II and III, whereas the b form is increased in patients undergoing an anaphylactic

reaction. Additional studies directed by the presentation include a bone scan or skeletal survey; contrast studies of the upper gastrointestinal tract with small-bowel follow-through, computed tomography scan, or endoscopy; and a neuropsychiatric evaluation, including an electroencephalogram. The tissue diagnosis is straightforward if there are lesions of urticaria pigmentosa, but the diagnosis of systemic mastocytosis requires involvement of other organs and is most frequently established by bone marrow biopsy and aspiration. The bone marrow lesions consist of focal and paratrabecular aggregates of spindle-shaped mast cells, often mixed with eosinophils, lymphocytes, and, on occasion, plasma cells, histiocytes, and fibroblasts.

The differential diagnosis requires the exclusion of other flushing disorders. The 24-h urine assessment of 5-hydroxy-indoleacetic acid and metanephrines should exclude a carcinoid tumor or a pheochromocytoma. Most patients with recurrent anaphylaxis, including the idiopathic group, present with angioedema and/or wheezing, which are not manifestations of systemic mastocytosis.

TREATMENT

The management of systemic mastocytosis uses a stepwise and symptom/sign-directed approach that includes an H_1antihistamine for flushing and pruritus, an H_2antihistamine or proton pump inhibitor for gastric acid hypersecretion, oral cromolyn sodium for diarrhea and abdominal pain, and a nonsteroidal anti-inflammatory agent for severe flushing associated with vascular collapse despite use of H_1 and H_2antihistamines to block biosynthesis ofPGD_2. Systemic glucocorticoids appear to alleviate the malabsorption. Headaches are generally managed with tricyclic antidepressants and other neurotransmitter-modifying agents. Ketotifen has been used to alleviate flushing in patients with gastric intolerance to nonsteroidal anti-inflammatory agents and in patients with bone pain or intractable headaches. The efficacy ofIFN-ain aggressive systemic mastocytosis is controversial, and this may relate to the difficulty in achieving the necessary dosage in some patients due to the attendant side effects. Treatment with hydroxyurea to reduce the mast cell lineage progenitors may have merit in type III systemic mastocytosis. Chemotherapy is appropriate for the frank leukemias in types II and IV.

ALLERGIC RHINITIS

DEFINITION

Allergic rhinitis is characterized by sneezing; rhinorrhea; obstruction of the nasal passages; conjunctival, nasal, and pharyngeal itching; and lacrimation, all occurring in a temporal relationship to allergen exposure. Although commonly seasonal due to elicitation by airborne pollens, it can be perennial in an environment of chronic exposure. The incidence of allergic rhinitis in North America is about 7%, with the peak occurring in childhood and adolescence.

PREDISPOSING FACTORS AND ETIOLOGY

Allergic rhinitis generally presents in atopic individuals, i.e., in persons with a family history of a similar or related symptom complex and a personal history of collateral

allergy expressed as eczematous dermatitis, urticaria, and/or asthma (Chap. 252). Symptoms generally appear before the fourth decade of life and tend to diminish gradually with aging, although complete spontaneous remissions are uncommon. A relatively small number of weeds that depend on wind rather than insects for cross-pollination, as well as certain grasses and trees, produce sufficient quantities of pollen suitable for wide distribution by air currents to elicit seasonal allergic rhinitis. The dates of pollination of these species generally vary little from year to year in a particular locale but may be quite different in another climate. In the temperate areas of North America, trees typically pollinate from March through May, grasses in June and early July, and ragweed from mid-August to early October. Molds, which are widespread in nature because they occur in soil or decaying organic matter, may propagate spores in a pattern dependent on climatic conditions. Perennial allergic rhinitis occurs in response to allergens that are present throughout the year such as in desquamating epithelium in animal dander or cockroach-derived proteins, the processed materials or chemicals utilized in an industrial setting, or the dust accumulating at work or at home. Dust has a diverse allergen content including *Dermatophagoides farinae* and *D. pteronyssinus*, which may be present alone or together in house dust. Dust mites are scavengers of flecks of human skin and coat the digestate with mite-specific protein for subsequent excretion as part of a fecal ball. In up to two-thirds of patients with perennial rhinitis, no clear-cut allergen can be demonstrated. The ability of allergens to cause rhinitis rather than lower respiratory symptoms may be attributed to their size, 10 to 100 um, and retention within the nose.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Episodic rhinorrhea, sneezing, obstruction of the nasal passages with lacrimation, and pruritus of the conjunctiva, nasal mucosa, and oropharynx are the hallmarks of allergic rhinitis. The nasal mucosa is pale and boggy, the conjunctiva congested and edematous, and the pharynx is generally unremarkable. Swelling of the turbinates and mucous membranes with obstruction of the sinus ostia and eustachian tubes precipitates secondary infections of the sinuses and middle ear, respectively, commonly in perennial but rarely in seasonal disease. Nasal polyps, representing mucosal protrusions containing edema fluid with variable numbers of eosinophils, arise concurrently with edema and/or infection within the sinuses and increase obstructive symptoms.

The nose presents a large mucosal surface area through the folds of the turbinates and serves to adjust the temperature and moisture content of inhaled air and to filter out particulate materials above 10 um in size by impingement in a mucous blanket; ciliary action moves the entrapped particles toward the pharynx. Entrapment of pollen and digestion of the outer coat by mucosal enzymes such as lysozymes release protein allergens generally of 10,000 to 40,000 molecular weight. The initial interaction occurs between the allergen and intraepithelial mast cells and then proceeds to involve deeper perivenular mast cells, both of which are sensitized with specific IgE. During the symptomatic season when the mucosae are already swollen and hyperemic, there is enhanced adverse reactivity to the seasonal pollen as well as to antigenically unrelated pollens for which there is underlying hypersensitivity due to improved penetration of the allergens. Biopsy specimens of nasal mucosa during seasonal rhinitis show submucosal edema with infiltration by eosinophils, along with some basophils and neutrophils.

The mucosal surface fluid contains IgA that is present because of its secretory piece and also IgE, which apparently arrives by diffusion from plasma cells in proximity to mucosal surfaces. IgE fixes to mucosal and submucosal mast cells, and the intensity of the clinical response to inhaled allergens is quantitatively related to the naturally occurring pollen dose. Specific IgE is distributed also to circulating basophilic leukocytes; patients with more severe clinical disease have basophils that release histamine in response to lesser concentrations of allergen in vitro than do cells from patients with milder disease. In sensitive individuals, the introduction of allergen into the nose is associated with sneezing, "stuffiness," and discharge, and the fluid contains histamine,PGD_2, and leukotrienes. Thus the mast cells of the nasal mucosa and submucosa generate and release mediators through IgE-dependent reactions that are capable of producing tissue edema and eosinophilic infiltration.

DIAGNOSIS

The diagnosis of seasonal allergic rhinitis depends largely on an accurate history of occurrence coincident with the pollination of the offending weeds, grasses, or trees. The continuous character of perennial allergic rhinitis due to contamination of the home or place of work makes historic analysis difficult, but there may be a variability in symptoms that can be related to exposure to animal dander, dust mite and/or cockroach allergens, or work-related allergens such as latex. Patients with perennial rhinitis commonly develop the problem in adult life, are more often women than men, and manifest nasal polyps and thickening of the sinus membranes demonstrated by radiography. The term *vasomotor rhinitis* designates a condition of enhanced reactivity of the nasopharynx in which a symptom complex resembling perennial allergic rhinitis occurs with nonspecific stimuli. Other entities to be excluded are structural abnormalities of the nasopharynx; exposure to irritants; upper respiratory infection; pregnancy with prominent nasal mucosal edema; prolonged topical use of a-adrenergic agents in the form of nose drops (rhinitis medicamentosa); and the use of certain therapeutic agents such as rauwolfia, b-adrenergic antagonists, or estrogens.

The nasal secretions of allergic patients are rich in eosinophils, and peripheral eosinophilia is a common feature. Local or systemic neutrophilia implies infection. Total serum IgE is frequently elevated, but the demonstration of immunologic specificity for IgE is critical to an etiologic diagnosis. A skin test by the epicutaneous route (scratch or prick) with the allergens of interest provides a rapid and reliable approach to identifying allergen-specific IgE that has sensitized cutaneous mast cells. An intradermal test may follow if indicated by history when the epicutaneous test is negative, but it is less reliable due to the reactivity of some asymptomatic individuals at the test dose. Skin testing by scratch or prick for food allergens is controversial but does seem to have predictive value for the absence of specific IgE sensitivity. A double-blind, placebo-controlled challenge may document a food allergy, but such a procedure does bear the risk of an anaphylactic reaction. An elimination diet is safer but is tedious and less definitive. Food allergy is uncommon as a cause of allergic rhinitis.

Newer methodology for detecting total IgE, including the development of enzyme-linked immunosorbent assays (ELISA) employing anti-IgE bound to either a solid-phase or a liquid-phase paramagnetic particle, provides rapid and cost effective determinations.

Measurements of specific anti-IgE in serum are obtained by its binding to a solid-phase allergen and quantitation by subsequent uptake of radiolabeled anti-IgE. This radioallergosorbent technique correlates with the bioassay of specific IgE by skin test, which is mast cell-dependent, and by histamine release from peripheral blood leukocytes, which is basophil-dependent. As compared to the skin test, the assay of specific IgE in serum is less sensitive but has high specificity. Furthermore, ELISA utilizing reactions that generate visible light or fluorescence have replaced the radioimmunoassays, and newer chemiluminescent tracers provide additional sensitivity for detection of minute quantities of allergen-specific IgE.

PREVENTION

Avoidance of exposure to the offending allergen is the most effective means of controlling allergic diseases; removal of pets from the home to avoid animal danders, utilization of air filtration devices to minimize the concentrations of airborne pollens, elimination of cockroach-derived proteins by chemical destruction of the pest and careful food storage, travel to nonpollinating areas during the critical periods, and even a change of domicile to eliminate a mold spore problem may be necessary. Control of dust mites by allergen avoidance includes use of plastic-lined covers for mattresses, pillows, and comforters, and elimination of carpets and drapes.

TREATMENT

Management with pharmacologic agents represents the standard approach to seasonal or perennial allergic rhinitis. Antihistamines of the H_1 class are effective for nasopharyngeal itching, sneezing, and watery rhinorrhea and for such ocular manifestations as itching, tearing, and erythema, but they are not efficacious for the nasal congestion. The older antihistamines are sedating, and their anticholinergic (muscarinic) effects include visual disturbance, urinary retention, and even arrhythmias. Because the newer H_1antihistaminics such as loratadine and cetirizine are less lipophilic, their ability to cross the blood-brain barrier is reduced, and thus their sedating and anticholinergic side effects are minimized. Because life-threatening ventricular arrhythmias with some fatalities have been caused by prolongation of the QT interval resulting from inhibition of the metabolism of terfenadine and astemizole by their interactions with macrolide antibiotics, these agents have been subtantially replaced by loratadine, fexofenadine, and cetirizine.a-Adrenergic agents such as phenylephrine or oximetazoline are generally used topically to alleviate nasal congestion and obstruction, but the duration of efficacy is limited because of rebound rhinitis and such systemic responses as insomnia, irritability, and hypertension. The latter are more frequent with use of oral a-adrenergic agonists, which nonetheless are useful in relieving nasal congestion and diminishing the sedating effects of conventional antihistamines. Cromolyn sodium, a nasal spray, is essentially without side effects and is used prophylactically on a continuous basis during the season to attenuate allergen activation of nasal mast cells. The clinical efficacy of cromolyn sodium and that of nonsedating antihistamines are roughly equivalent. Intranasal high-potency glucocorticoids are the most potent drugs available for the relief of established rhinitis, seasonal or perennial, and even vasomotor rhinitis; they provide efficacy with substantially reduced side effects as compared with this same class of agent administered orally. Their most frequent side effect is local irritation, with *Candida* overgrowth being a rare occurrence. The

topical-to-systemic activity of flunisolide or budesonide is significantly greater than for beclomethasone or triamcinolone with much less systemic absorption. For patients who do not benefit adequately from a full dosage of a nonsedating H_1antihistamine and a maintenance dosage of cromolyn sodium, ana-adrenergic agent for short-term relief should be replaced by high-potency topical glucocorticoids. For systemic symptoms not related to the nasopharynx, such as allergic conjunctivitis, treatment may be local.

Immunotherapy, often termed *hyposensitization*, consists of repeated subcutaneous injections of gradually increasing concentrations of the allergen(s) considered to be specifically responsible for the symptom complex. Controlled studies of ragweed, grass, dust mite, and cat dander allergens administered for treatment of allergic rhinitis have demonstrated at least partial relief of symptoms and signs. The duration of such immunotherapy is 3 to 5 years, with discontinuation being based on minimal symptoms over two consecutive seasons of exposure. Clinical benefit appears related to the administration of a high dose of allergen at weekly or biweekly intervals. Patients should remain at the treatment site for at least 20 min after allergen administration so that any anaphylactic consequence can be managed. Local reactions with erythema and induration are not uncommon and may persist for 1 to 3 days. Immunotherapy is contraindicated in patients with significant cardiovascular disease or unstable asthma and should be conducted with particular caution in any patient requiringb-adrenergic blocking therapy because of the difficulty in managing an anaphylactic complication. The immunologic characteristics of a response include a rise in antibodies of the IgG class, a small increase in specific IgE early in the treatment course followed by a plateau or decline, and a decline in the percentage of histamine released from peripheral blood basophilic leukocytes challenged with a fixed concentration of the allergen. The antibodies of the IgG class might well reduce or neutralize the quantity of allergen available for interaction with the tissue mast cells but, more important, could modify the seasonal booster response in specific IgE synthesis. None of the individual parameters of the response to immunotherapy correlates well with the assessments of clinical efficacy, suggesting that benefit is derived from a complex of effects that likely includes a reduction in T cell cytokine production. Immunotherapy should be reserved for clearly documented seasonal or perennial rhinitis, clinically related to defined allergen exposure with confirmation by the presence of allergen-specific IgE, which has failed management by allergen avoidance and pharmacotherapy due to lack of efficacy or side effects. A sequence for the management of allergic or perennial rhinitis based on an allergen-specific diagnosis and stepwise management as required for symptom control would include the following: (1) identification of the offending allergen(s) by history with confirmation of the presence of allergen-specific IgE by skin test (epicutaneous) and/or serum assay; (2) avoidance of the offending allergen; (3) for mild symptoms, prophylactic management with topical cromolyn sodium or treatment with a single bedtime dose of chlorpheniramine (if the latter is associated with undue side effects, substitute a second-generation nonsedating antihistimine); combination with an oral decongestant such as pseudoephedrine can be beneficial; (4) for prominent symptoms, utilization of topical beclomethasone, budesonide, fluticasone, momestasone, or triamcinalone may be needed for a satisfactory clinical outcome; and (5) for management failures despite avoidance and pharmacotherapy, progression to immunotherapy.

311. SYSTEMIC LUPUS ERYTHEMATOSUS - *Bevra Hannahs Hahn*

DEFINITION AND PREVALENCE

Systemic lupus erythematosus (SLE) is a disease of unknown etiology in which tissues and cells are damaged by pathogenic autoantibodies and immune complexes. Ninety percent of cases are in women, usually of child-bearing age, but children, men, and the elderly can be affected. In the United States, the prevalence of SLE in urban areas varies from 15 to 50 per 100,000 population; it is more common in blacks than in whites. Hispanic and Asian populations are also susceptible.

PATHOGENESIS AND ETIOLOGY

SLEresults from tissue damage caused by pathogenic subsets of autoantibodies and immune complexes. The abnormal immune responses include (1) polyclonal and antigen-specific T and B lymphocyte hyperactivity, and (2) inadequate regulation of that hyperactivity. These abnormal immune responses probably depend upon interactions between susceptibility genes and environment. Evidence for genetic predisposition includes increased concordance for disease in monozygotic (24 to 58%) compared with dizygotic (0 to 6%) twins, al_s> 10, and a 10 to 15% frequency of patients with more than one affected family member. Studies of association, linkage, and genome scanning show complex genetic susceptibility. Most people with homozygous deficiencies of early components of complement (C1q, C2, C4) have SLE or similar disease (accounting for <5% of SLE patients), suggesting that these genes are major predisposing factors. Most patients must inherit multiple susceptibility genes, and probably experience environmental stimuli as well, to develop clinical disease. A defective or deleted class III allele, C4AQO, is the most common genetic marker associated with SLE in many ethnic groups (40 to 50% of patients compared with 15% of healthy controls). One extended haplotype, B8.DR3.DQw2.C4AQO, predisposes to SLE in populations with Northern European heritage. SLE is associated with HLA-DR2 or -DR3 in many groups, and single-gene associations occur between HLA class II (especially DQ_b) and autoantibodies that associate with clinical subsets of lupus. For example, antibodies to Ro/La (SS-A/SS-B) are associated with subacute cutaneous lupus and certain DQA and DQB genes that are usually inherited with DR3. Normal alleles of FcgRIIA or of FcgRIIIA that bind IgG2 or IgG1 and IgG3, respectively, less efficiently than other alleles are associated with SLE, particularly with nephritis. FcgRIIA predisposes to SLE in African Americans and South Koreans; FcgRIIIA predisposes across different ethnic groups. Such alleles might account for impaired clearing of autoantibodies and immune complexes, thus predisposing to their deposition in tissues. Genome scanning from several laboratories has shown two regions of chromosome 1 that link to disease in sibpairs or multiplex families. One region, 1q23, contains the FcgRIIA gene; the other, 1q41-42, contains poly (ADP-ribosyl) polymerase (PARP), which may be another predisposing gene that plays a role in DNA repair and apoptosis. Other results of genome scanning suggest that at least 10 other regions on various chromosomes, in addition to HLA and the two regions on chromosome 1 discussed above, participate in susceptibility. Some genes may be "autoimmunity" genes common to different autoimmune diseases across different ethnic groups; others are likely to be restricted to a single disease and/or a single ethnic group. Family studies suggest that females are more likely than males to express the autoimmune manifestations of their genotypes.

Environmental factors that cause flares ofSLE are largely unknown, with the exception of ultraviolet (UV)-B (and sometimes UV-A) light. As many as 70% of patients are photosensitive. Other factors, such as ingested alfalfa sprouts, and chemicals, such as hydrazines, have been implicated. Searches for viral/retroviral disease inducers have been inconclusive. Although some drugs can induce lupus-like disease, there are notable clinical and autoantibody differences between drug-induced and spontaneous lupus. Femaleness is clearly a susceptibility factor, since the prevalence in women of child-bearing years is seven to nine times higher than in men, whereas the female:male ratio is 3:1 in pre- and postmenopausal years. Metabolism of estrogenic and androgenic hormones may be abnormal in lupus patients. Sex hormones also influence immune tolerance.

Abnormal immune responses permit sustained production of pathogenic subsets of autoantibodies and immune complexes. Some autoantibodies, such as anti-DNA, can bind to tissue via charge or cross-reactivity, or in immune complexes, and cause complement-mediated damage. Some subsets of anti-DNA and anti-RNP can bind and enter living cells, altering their function. Other autoantibodies cause damage by direct binding to cell membranes (erythrocytes, platelets) that cause those cells to be phagocytized and destroyed. T cell help is critical to development of full-blown disease; cells of CD4+CD8-, CD4-CD8+, and CD4-CD8- phenotypes all help autoantibody production inSLE. The abnormalities that permit hyperactivated self-reactive B and T cells to dominate immune repertoires in murine and human SLE are multiple and include defects in cell activation, tolerance, apoptosis, idiotypic networks, immune complex clearance, and generation of regulatory cells. The structure of antigens that stimulate autoantibodies is under investigation. Some are clearly derived from self (nucleosomes, ribonucleoprotein, erythrocyte and lymphocyte surface antigens); others may be from the external environment and mimic self (e.g., components of vesicular stomatitis virus mimic peptides in Sm antigen). Many DNA/protein and RNA/protein antigens may be presented to the immune system in surface blebs of apoptotic cells. SinceUV light induces apoptosis in skin cells, this might be a mechanism for flaring disease. Autoantibodies characteristic of SLE are listed inTable 311-1.

In summary, some individuals are genetically predisposed toSLE. Under the influence of multiple genes, possibly triggered by environmental challenges and highly influenced by sex, they may develop a number of different clinical syndromes that fulfill diagnostic criteria for SLE. The etiology of these syndromes is complex and probably differs between patients.

CLINICAL MANIFESTATIONS

At onset,SLE may involve only one organ system (additional manifestations occur later) or may be multisystemic. Clinical manifestations are listed inTable 311-2; those that fulfill American Rheumatism Association (currently the American College of Rheumatology) updated criteria for a diagnosis of SLE are listed inTable 311-3. Autoantibodies are detectable at disease onset. Severity varies from mild and intermittent to persistent and fulminant. Most patients experience exacerbations interspersed with periods of relative quiescence. True remissions with no symptoms and requiring no therapy occur in up to 20% but are usually not permanent. Systemic

symptoms are usually prominent and include fatigue, malaise, fever, anorexia, and weight loss.

Musculoskeletal Manifestations Almost all patients experience arthralgias and myalgias; most develop intermittent arthritis. Pain is often out of proportion to physical findings. Symmetric fusiform swelling in joints [most frequently proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of the hands, wrists, and knees], diffuse puffiness of hands and feet, and tenosynovitis can be seen. Joint deformities are unusual, with 10% of patients developing swan-neck deformities of fingers and ulnar drift at MCP joints. Erosions are rare; subcutaneous nodules occur. Myopathy can be inflammatory (during periods of active disease), or secondary to treatment (hypokalemia, glucocorticoid myopathy, hydroxychloroquine myopathy). Ischemic necrosis of bone is a common cause of hip, knee, or shoulder pain in patients receiving glucocorticoids.

Cutaneous Manifestations The malar ("butterfly") rash is a photosensitive, fixed erythematous rash, flat or raised, over the cheeks and bridge of the nose, often involving the chin and ears. Scarring is absent; telangiectases may develop. A more diffuse maculopapular rash, predominant in sun-exposed areas, is also common and usually indicates disease flare. Loss of scalp hair is usually patchy but can be extensive; hair often regrows inSLElesions but not in lesions of discoid lupus erythematosus (DLE). DLE occurs in about 20% of patients with SLE and can be disfiguring, since the lesions have central atrophy and scarring, with permanent loss of appendages. DLE lesions are circular with an erythematous raised rim, scaliness, follicular plugging, and telangiectasia. They occur over the scalp, ears, face, and sun-exposed areas of the arms, back, and chest. Only 5% of patients with DLE subsequently develop SLE. Less frequent SLE skin lesions include urticaria, bullae, erythema multiforme, lichen planus-like lesions, and panniculitis ("lupus profundus").

Patients with subacute cutaneous lupus erythematosus (SCLE) are a distinct subset with recurring extensive dermatitis. Arthritis and fatigue are frequent; central nervous system and renal involvement are not. Some patients are antinuclear antibody (ANA)-negative. Most have antibodies to Ro (SS-A) or to single-stranded (ss) DNA. Skin lesions are photosensitive and either annular or papulosquamous psoriasiform; they occur over the arms, trunk, and face but do not scar.

Patients withSLE,DLE, orSCLE can develop vasculitic skin lesions. These include purpura, subcutaneous nodules, nail fold infarcts, ulcers, vasculitic urticaria, panniculitis, and gangrene of digits. Shallow, slightly painful ulcers in the mouth and nose are frequent in patients with SLE.

Renal Manifestations Most patients withSLE have immunoglobulins deposited in glomeruli, but only one-half have clinical nephritis, defined by proteinuria. Early in the disease most are asymptomatic, although some develop the edema of nephrotic syndrome. Urinalysis shows hematuria, cylindruria, and proteinuria. Most patients with mesangial or mild focal proliferative nephritis (see discussion under "Pathology," below) maintain good renal function. Patients with diffuse proliferative nephritis develop renal failure if untreated. Because severe nephritis requires aggressive immunosuppression with high-dose glucocorticoids and cytotoxic drugs and mild lesions do not, renal biopsy

may provide information that affects therapy. Patients with rapidly deteriorating renal function and active urine sediment require prompt, aggressive therapy; biopsy is not necessary unless they fail to respond. However, patients with a slow rise in serum creatinine to levels>265 umol/L (>3 mg/dL) should be biopsied; a high proportion of sclerotic glomeruli on biopsy suggests that these patients are unlikely to respond to immunosuppressive therapies and are candidates for dialysis or transplantation. Patients with persistently abnormal urinalyses, high titers of anti-dsDNA, and/or hypocomplementemia are at risk for severe nephritis; kidney biopsy may guide therapy.

Nervous System Any region of the brain can be involved inSLE, as can the meninges, spinal cord, and cranial and peripheral nerves. Central nervous system (CNS) events may be single or multiple and often occur when SLE is active in other organ systems. Mild cognitive dysfunction is the most frequent manifestation. Headaches are common and may be migraine-like or nonspecific. Seizures of any type may occur. Less frequent manifestations include psychosis, acute confusional states, demyelinating disorders, cerebrovascular disease, movement disorders, aseptic meningitis, myelopathy, mononeuropathy or polyneuropathy of cranial or peripheral nerves, autonomic dysfunction, acute demyelinating polyneuropathy (Guillain-Barre), mood disorders, optic neuritis, subarachnoid hemorrhage, pseudotumor cerebri, and hypothalamic dysfunction with inappropriate secretion of vasopressin. Depression and anxiety are frequent.

Laboratory diagnosis of CNSlupus can be difficult. Abnormal electroencephalograms occur in about 70% of patients with neurologic complaints and usually show diffuse slowing or focal abnormalities. Cerebrospinal fluid (CSF) shows elevated protein levels in 50% and increased mononuclear cells in 30% of patients; oligoclonal bands and increased Ig synthesis may be found. Lumbar puncture is recommended when the diagnosis of CNS lupus is in doubt or when infection is a possible cause of symptoms. Magnetic resonance imaging (MRI) with contrast is the most sensitive radiographic technique to detect acute and chronic lesions ofSLE; changes are often nonspecific. Patients with focal neurologic lesions are more likely to have positive MRI scans than those with diffuse manifestations. Computed tomography (CT) scans are useful to rule out bleeding or mass lesions, if indicated. Angiograms can detect vasculitis and vascular occlusions or emboli; they cannot visualize vessels smaller than 50 um; lupus vasculitis usually involves smaller vessels. Laboratory measures of disease activity often do not correlate with neurologic manifestations. Neurologic problems (with the exception of deficits resulting from large infarcts) usually improve with immunosuppressive therapy and/or time; recurrences are seen in approximately one-third of patients.

Vascular System Thrombosis in vessels of any size can be a major problem. Although vasculitis may underly thrombosis, there is increasing evidence that antibodies against phospholipids [lupus anticoagulant (LA), anticardiolipin (aCL)] are associated with clotting without inflammation. The source of cerebral emboli may be the lesions of Libman-Sacks endocarditis. In addition, degenerative vascular changes after years of exposure of blood vessels to circulating immune complexes and hyperlipidemia from glucocorticoid therapy predispose to degenerative cerebral and coronary artery disease in lupus patients. Therefore, anticoagulation is more appropriate than immunosuppression in some patients.

Hematologic Manifestation Anemia of chronic disease occurs in most patients when lupus is active. Hemolysis occurs in a small proportion of those with positive Coombs' tests; it is usually responsive to high-dose glucocorticoids; resistant cases may respond to splenectomy. Leukopenia (usually lymphopenia) is common but is rarely associated with recurrent infections and does not require treatment. Mild thrombocytopenia is common; severe thrombocytopenia with bleeding and purpura occurs in 5% of patients and should be treated with high-dose glucocorticoids. Short-term improvement can be achieved by administration of intravenous gamma globulin. If the platelet count fails to reach acceptable levels in 2 weeks, addition of cytotoxic drugs, cyclosporine, danazole, and/or splenectomy should be considered.

TheLAbelongs to a family of antiphospholipid antibodies. It is recognized by prolongation of the partial thromboplastin time and failure of added normal plasma to correct the prolongation. More sensitive tests include the Russell viper venom time.aCL are detected in enzyme-linked immunosorbent assays. Clinical manifestations of LA and aCL include thrombocytopenia, recurrent venous or arterial clotting, recurrent fetal loss, and valvular heart disease. If the LA is associated with hypoprothrombinemia or thrombocytopenia, bleeding may occur. Less commonly, antibodies to clotting factors (VIII, IX) arise; they cause bleeding. Bleeding syndromes usually respond to glucocorticoids; clotting syndromes do not.

Cardiopulmonary System Pericarditis is the most frequent manifestation of cardiac lupus; effusions can occur and occasionally lead to tamponade; constrictive pericarditis is rare. Myocarditis can cause arrhythmias, sudden death, and/or heart failure. Valvular insufficiency (usually aortic or mitral) can occur, with or without Libman-Sacks endocarditis. Lesions on valves are best detected by transesophageal echocardiography. Myocardial infarcts usually result from degenerative disease, although they can result from vasculitis.

Pleurisy and pleural effusions are common manifestations ofSLE. Lupus pneumonitis causes fever, dyspnea, and cough; x-rays show fleeting infiltrates and/or areas of platelike atelectasis; this syndrome responds to glucocorticoids. However, *the most common cause of pulmonary infiltrates in patients with SLE is infection*. Interstitial pneumonitis leading to fibrosis occurs occasionally; the inflammatory phase may respond to treatment; the fibrosis does not. Pulmonary hypertension is an uncommon, grave manifestation of SLE. Infrequent pulmonary manifestations with high mortality rates include adult respiratory distress syndrome and massive intraalveolar hemorrhage.

Gastrointestinal System Common gastrointestinal (GI) symptoms include nausea, diarrhea, and vague discomfort. Symptoms may result from lupus peritonitis and may herald a flare ofSLE. Vasculitis of the intestine is the most dangerous manifestation, presenting with acute crampy abdominal pain, vomiting, and diarrhea. Intestinal perforation can occur and usually requires immediate surgery. Patients with pseudoobstruction have abdominal pain; x-rays show dilated loops of small bowel which may be edematous; surgery should be avoided unless frank obstruction is present. Glucocorticoid therapy is useful for all these GI syndromes. Some patients have GI motility disorders similar to those in scleroderma; they are not benefited by steroids. Acute pancreatitis occurs and can be severe, resulting from active SLE or from therapy

with glucocorticoids or azathioprine. Elevated amylase levels may reflect pancreatitis, salivary gland inflammation, or macroamylasemia. Elevated serum transaminase levels are common in patients with active SLE but are not associated with significant hepatic damage; they return to normal as the disease is treated.

Ocular Manifestation Retinal vasculitis is a serious manifestation; blindness can develop over a few days, and aggressive immunosuppression should be instituted. Examination shows areas of sheathed, narrow retinal arterioles and cytoid bodies (white exudates) adjacent to vessels. Other ocular abnormalities include conjunctivitis, episcleritis, optic neuritis, and the sicca syndrome.

PATHOLOGY

Cutaneous Lesions Lesions of acuteSLE,DLE, andSCLEshow similar histopathology, with degeneration of the basal layer of the epidermis, disruption of the dermal-epidermal junction (DEJ), and mononuclear infiltrates around vessels and appendages in the upper dermis. In DLE, follicular plugging and hyperkeratosis are prominent. Deposits of Ig and C¢ are seen in the DEJ in 80 to 100% of lesional and 50% of nonlesional skin in active SLE; the proportions are lower during remissions. Only 50% of SCLE lesions are positive for Ig and C¢ deposits. Ig deposition in the DEJ is not specific for SLE. Vasculitic skin lesions usually show leukocytoclastic angiitis.

Renal Lesions Glomerulonephritis (GN) is caused by deposition of circulating immune complexes or in situ complex formation in mesangium and glomerular basement membrane. Renal biopsy should be considered when results would affect therapy. Information regarding location of immune deposits, histologic pattern of renal damage, and activity and chronicity of lesions are all useful in predicting prognosis and selecting appropriate treatment. In mild GN unlikely to lead to renal failure, Ig deposits are confined to the mesangium, and histology shows no changes or mesangial proliferation. If Ig and C¢ are deposited outside the mesangium in capillary glomerular basement membrane, prognosis worsens. Histologic changes that should be treated with aggressive immunosuppression include focal proliferative, membranoproliferative, and diffuse proliferative GN (Chap. 275). Progression from focal to diffuse lesions can occur. Membranous changes without proliferation are uncommon but have a better prognosis than proliferative GN. Activity and chronicity scores indicate severity and reversibility of lesions. *Reversible "active" lesions* associated with high risk of progression to renal failure are glomerular necrosis, cellular epithelial crescents, hyaline thrombi, interstitial inflammatory infiltrates, and necrotizing vasculitis. *Irreversible changes unlikely to respond to immunosuppression* and highly associated with renal failure include glomerular sclerosis, fibrous crescents, interstitial fibrosis, and tubular atrophy. In patients with high chronicity scores, treatment of lupus should be determined by extrarenal disease.

LABORATORY MANIFESTATIONS

The presence of characteristic antibodies (Table 311-1) confirms the diagnosis ofSLE.ANAs are the best screening test. If the test substrate contains human nuclei (WIL-2 or HEP-2 cells), more than 95% of lupus patients will be positive. A positive ANA test is not specific for SLE; ANAs occur in some normal individuals (usually in low titer);

the frequency increases with aging. Other autoimmune diseases, viral infections, chronic inflammatory processes, and several drugs induce ANAs. Therefore, a positive ANA test supports the diagnosis of SLE but is not specific; a negative ANA test makes the diagnosis unlikely but not impossible. Antibodies to double-stranded DNA (dsDNA) and to Sm are relatively specific for SLE; other autoantibodies listed in Table 311-1 are not. However, determining the complete autoantibody profile of each patient helps predict clinical subsets. High serum levels of ANAs and anti-dsDNA and low levels of complement usually reflect disease activity, especially in patients with nephritis. Total functional hemolytic complement (CH_{50}) levels are the most sensitive measure of complement activation but are also most subject to laboratory error. Quantitative levels of C3 and C4 are widely available. Very low levels of CH_{50} with normal levels of C3 suggest inherited deficiency of a complement component, which is highly associated with SLE and with ANA negativity.

Hematologic abnormalities include anemia (usually normochromic normocytic but occasionally hemolytic), leukopenia, lymphopenia, and thrombocytopenia. The Westergren erythrocyte sedimentation rate correlates with disease activity in some patients.

Urinalysis should be performed and serum creatinine levels should be measured periodically in patients with SLE. With active nephritis, the urinalysis usually shows proteinuria, hematuria, and cellular or granular casts. Urinary protein excretion measured over 24 h increases during periods of activity. (See the discussion under "Pathology" for a description of renal biopsy.)

PREGNANCY

Fertility rates are normal in patients with SLE, but spontaneous abortion and stillbirths are frequent (10 to 30%), especially in women with LA and/or aCL. The treatment of choice for pregnant women with prior fetal loss and antiphospholipid antibodies is low-dose heparin, e.g., 5000 units subcutaneously twice a day. This may be associated with maternal bone loss. If there are contraindications to heparin therapy, low-dose aspirin or low- to moderate-dose glucocorticoids may be used.

Pregnancy has varied effects on SLE activity. Disease flares in a small proportion, especially during the 6 weeks postpartum. If severe renal or cardiac disease is absent and SLE activity is controlled, most patients complete pregnancy safely and deliver normal infants. Glucocorticoids (except dexamethasone and betamethasone) are inactivated by placental enzymes and do not cause fetal abnormalities in humans; they should be used to suppress disease activity. Neonatal lupus, caused by transmission of maternal anti-Ro across the placenta, consists of transient skin rash and (rarely) permanent heart block. Transient thrombocytopenia from maternal antiplatelet antibodies also occurs.

DIFFERENTIAL DIAGNOSIS

The American Rheumatism Association published diagnostic criteria for SLE (Table 311-3) which were updated in 1997. Any four of the manifestations listed establish a diagnosis of SLE. Early disease confined to a few systems is more difficult to classify; it

may take several years for a patient to fulfill criteria. Disorders with which SLE can be confused include rheumatoid arthritis; various forms of dermatitis; neurologic disorders such as epilepsy, multiple sclerosis, and psychiatric disorders; and hematologic diseases such as idiopathic thrombocytopenic purpura. Many autoimmune disorders have overlapping features so that exact classification may be difficult. Mixed connective tissue disease has features of SLE, rheumatoid arthritis, polymyositis, and scleroderma, accompanied by high titers of anti-ribonucleoprotein antibodies (Chap. 313); patients have a low incidence of nephritis and CNSdisease and a high incidence of pulmonary manifestations and evolution into scleroderma. The possibility of drug-induced lupus should always be considered.Figure 311-1 presents an algorithm for diagnosis of SLE.

DRUG-INDUCED LUPUS

Several drugs can cause a syndrome resemblingSLE, including procainamide, hydralazine, isoniazid, chlorpromazine, D-penicillamine, practolol, methyldopa, quinidine, interferon a, and possibly hydantoin, ethosuximide, and oral contraceptives. The syndrome is rare with all but procainamide, the most frequent offender, and hydralazine. There is genetic predisposition to drug-induced lupus, partly determined by drug acetylation rates. Procainamide inducesANA in 50 to 75% of individuals within a few months; hydralazine induces ANA in 25 to 30%. Between 10 and 20% of ANA-positive individuals develop lupus-like symptoms. Most common are systemic complaints and arthralgias; polyarthritis and pleuropericarditis occur in 25 to 50%. Renal andCNSinvolvement are rare. All patients have ANA and most have antibodies to histones. Antibodies to dsDNA and hypocomplementemia are rare -- a helpful point in distinguishing drug-induced from idiopathic lupus. Anemia, leukopenia,LA,aCL, thrombocytopenia, cryoglobulins, rheumatoid factors, false-positive VDRL, and positive direct Coombs' tests can occur. The initial therapeutic approach is withdrawal of the offending drug; most patients improve in a few weeks. If symptoms are severe, a short course (2 to 10 weeks) of glucocorticoids is indicated. Symptoms rarely persist more than 6 months; ANA may persist for years. Most lupus-inducing drugs can be used safely in patients with idiopathic SLE.

PROGNOSIS

Survival in patients withSLE is 90 to 95% at 2 years, 82 to 90% at 5 years, 71 to 80% at 10 years, and 63 to 75% at 20 years. The following factors have been associated with poor prognosis (approximately 50% mortality in 10 years): high serum creatinine levels [>124 umol/L(>1.4 mg/dL)], hypertension, nephrotic syndrome (24-h urine protein excretion>2.6 g), anemia [hemoglobin< 124 g/L(<12.4g/dL)], hypoalbuminemia and hypocomplementemia at the time of diagnosis, and low socioeconomic status. Other factors associated with a poor prognosis in most studies include thrombocytopenia, seriousCNSinvolvement, antibodies to phospholipids, and African American race. Disability in SLE patients is common. However, approximately 20% of patients experience disease remissions (usually transient), and the likelihood of remission increases with each decade after diagnosis. Infections and active SLE, especially renal failure, are the leading causes of death in the first decade of disease. Thromboembolic events are frequent causes of death in the second decade.

TREATMENT

There is no cure forSLE. Complete sustained remissions are rare. Therefore, patient and physician should plan to control acute, severe flares and to develop maintenance strategies in which symptoms are suppressed to an acceptable level, usually at the cost of some drug side effects. Approximately 25% of SLE patients have mild disease with no life-threatening manifestations, although pain and fatigue may be disabling. These patients should be managed without glucocorticoids. Arthralgias, arthritis, myalgias, fever, and mild serositis may improve on nonsteroidal anti-inflammatory drugs (NSAIDs) including salicylates. However, NSAID toxicities such as elevated serum transaminases, aseptic meningitis, and renal impairment are especially frequent in SLE. The role of NSAIDs, which are primarily COX-2 inhibitors, in treatment of SLE has not been studied; they are likely to be useful. The dermatitides of SLE, fatigue, and lupus arthritis may respond to antimalarials. Doses of 400 mg hydroxychloroquine daily may improve skin lesions in a few weeks. Side effects are uncommon and include retinal toxicity, rash, myopathy, and neuropathy. Regular ophthalmologic examinations should be performed at least annually, since retinal toxicity is related to cumulative dose. Other therapies include sunscreens (an SPF rating³ 15 is recommended), topical or intralesional glucocorticoids, quinacrine, retinoids, and dapsone. Recent studies suggest that daily oral doses of dihydroepiandrosterone may lower disease activity in patients with mild SLE. Systemic glucocorticoids should be reserved for patients with disabling disease unresponsive to these conservative measures.

Life-threatening, severely disabling manifestations ofSLE that are responsive to immunosuppression should be treated with high doses of *glucocorticoids* (1 to 2 mg/kg per day). When disease is active, glucocorticoids should be given in divided doses every 8 to 12 h. After the disease is controlled, therapy should be consolidated to one morning dose; thereafter the daily dose should be tapered as rapidly as clinical disease permits. Ideally, patients should be slowly converted to alternate-day therapy with a single morning dose of short-acting glucocorticoid (prednisone, prednisolone, methylprednisolone) to minimize side effects. However, the disease may flare on the day off steroids, in which case the lowest single daily dose that suppresses disease should be used. Acutely ill lupus patients, including those with proliferativeGN, can be treated with 3 to 5 days of 1000 mg intravenous "pulses" of methylprednisolone, followed by maintenance daily or alternate-day glucocorticoids. Disease flares are probably controlled more rapidly by this approach, but it is unclear whether long-term outcome is changed.

Undesirable effects of chronic glucocorticoid therapy include cushingoid habitus, weight gain, hypertension, infection, capillary fragility, acne, hirsutism, accelerated osteoporosis, ischemic necrosis of bone, cataracts, glaucoma, diabetes mellitus, myopathy, hypokalemia, irregular menses, irritability, insomnia, and psychosis. Prednisone doses of 15 mg daily (or less) given before noon usually do not suppress the hypothalamic-pituitary axis. Some side effects can be minimized; sustained hyperglycemia, hypertension, edema, and hypokalemia should be treated; infections should be identified and treated early; immunizations with influenza and pneumococcal vaccines are safe if disease is stable. To minimize osteoporosis, supplemental calcium (1000 mg daily) should be added in most patients; in those with 24-h urinary calcium excretion<120 mg, vitamin D, 50,000 units one to three times weekly, can be added (monitor for hypercalcemia). Estrogen replacement therapy (ERT) should be considered

at menopause. There is debate regarding the ability of oral contraceptives or ERT to cause flares ofSLE in some patients; these therapies should be withheld from patients with a history of thrombosis. Calcitonin and bisphosphonates (alendronate, didronel, or acetonel) are also useful in preventing and treating osteoporosis.

The use of *cytotoxic agents* (azathioprine, chlorambucil, cyclophosphamide, methotrexate, mycophenolate mofetil) inSLE is probably beneficial in controlling active disease, reducing the rate of disease flares, and reducing steroid requirements. Patients with lupus nephritis have significantly less renal failure and better survival if treated with combinations of glucocorticoids plus intravenous cyclophosphamide; azathioprine as the second drug is less beneficial but is also effective in preventing renal failure. Open trials suggest that mycophenolate, and possibly methotrexate, are also effective second drugs and sometimes benefit patients who fail to respond to cyclophosphamide plus glucocorticoids. Undesirable side effects of cytotoxic drugs include bone marrow suppression, increased infection with opportunistic organisms such as herpes zoster, irreversible ovarian failure, hepatotoxicity (azathioprine, methotrexate, and mycophenolate), bladder toxicity (cyclophosphamide), alopecia, and increased risk for malignancy. Azathioprine is the least toxic; recommended doses are 2 to 3 mg/kg per day orally. Cyclophosphamide is the most effective and the most toxic. Intravenous pulse doses (10 to 15 mg/kg) once every 4 weeks have less urinary bladder toxicity than daily oral doses. Cyclophosphamide can also be used in daily oral doses (1.5 to 2.5 mg/kg per day of each). Mycophenolate can be given orally (1 to 2.5 g a day in divided doses) or methotrexate (5 to 20 mg once a week, orally or subcutaneously). After disease activity has been controlled for a few months, tapering of cytotoxic agents and attempts to discontinue them are appropriate.Figure 311-2 presents an algorithm for treatment of SLE.

Some manifestations ofSLE do not respond to immunosuppression, including clotting disorders, some behavioral abnormalities, and end-stageGN. Anticoagulation is the therapy of choice for prevention of clotting; chronic warfarin therapy in relatively high doses (maintaining INR at 2.5 to 3.0) is effective in preventing venous and arterial clotting in patients with antiphospholipid syndromes; the effects of aspirin, ticlopidine, and heparin on arterial thrombosis are unclear. Psychoactive drugs should be used when appropriate. "Pure" membranous GN may not respond to immunosuppression; several weeks of therapy can be tried but should be abandoned if improvement is not obvious. With regard to renal transplantation, patients with SLE have about twice the rate of allograft failure as do patients with renal failure due to other diseases; the 5-year rate of allograft loss is about 50%. However, overall patient survival is good, >90% at 5 years.

Alternatives to therapy with glucocorticoids plus cytotoxic agents for patients who do not respond to or cannot tolerate these regimens include addition of high-dose intravenous pulse therapy with methylprednisolone, which is ultimately converted to daily prednisone, plus cyclophosphamide, and combinations of cytotoxic drugs; there is some evidence for efficacy of high-dose intravenous glucocorticoids plus intravenous cyclophosphamide and of azathioprine plus cyclophosphamide. All of these regimens increase infection rates. Less well studied, but effective in some patients, are plasmapheresis (which must be accompanied by cytotoxic treatment to prevent rebound of undesirable autoantibodies), cyclosporine, and intravenous immunoglobulin.

Experimental therapies in progress include studies of efficacy of inducing tolerance to DNA, interruption of T and B cell second signals with antibodies to CD40L, and immunoablation with high-dose cyclophosphamide with or without autologous stem cell transplantation.

312. RHEUMATOID ARTHRITIS - *Peter E. Lipsky*

Rheumatoid arthritis (RA) is a chronic multisystem disease of unknown cause. Although there are a variety of systemic manifestations, the characteristic feature of RA is persistent inflammatory synovitis, usually involving peripheral joints in a symmetric distribution. The potential of the synovial inflammation to cause cartilage destruction and bone erosions and subsequent changes in joint integrity is the hallmark of the disease. Despite its destructive potential, the course of RA can be quite variable. Some patients may experience only a mild oligoarticular illness of brief duration with minimal joint damage, whereas others will have a relentless progressive polyarthritis with marked functional impairment.

EPIDEMIOLOGY AND GENETICS

The prevalence ofRA is approximately 0.8% of the population (range 0.3 to 2.1%); women are affected approximately three times more often than men. The prevalence increases with age, and sex differences diminish in the older age group. RA is seen throughout the world and affects all races. However, the incidence and severity seem to be less in rural sub-Saharan Africa and in Caribbean blacks. The onset is most frequent during the fourth and fifth decades of life, with 80% of all patients developing the disease between the ages of 35 and 50. The incidence of RA is more than six times as great in 60- to 64-year-old women compared to 18- to 29-year-old women.

Family studies indicate a genetic predisposition. For example, severeRA is found at approximately four times the expected rate in first-degree relatives of individuals with disease associated with the presence of the autoantibody, rheumatoid factor; approximately 10% of patients with RA will have an affected first-degree relative. Moreover, monozygotic twins are at least four times more likely to be concordant for RA than dizygotic twins, who have a similar risk of developing RA as nontwin siblings. Only 15 to 20% of monozygotic twins are concordant for RA, however, implying that factors other than genetics play an important etiopathogenic role. Of note, the highest risk for concordance of RA is noted in twins who have two HLA-DRB1 alleles known to be associated with RA. The class II major histocompatibility complex allele HLA-DR4. (DRB1*0401) and related alleles are known to be major genetic risk factors for RA. Early studies showed that as many as 70% of patients with classic or definite RA express HLA-DR4 compared with 28% of control individuals. An association with HLA-DR4 has been noted in many populations, including North American and European whites, Chippewa Indians, Japanese, and native populations in India, Mexico, South America, and southern China. In a number of groups, including Israeli Jews, Asian Indians, and Yakima Indians of North America, however, there is no association between the development of RA and HLA-DR4. In these individuals, there is an association between RA and HLA-DR1 in the former two groups and HLA-Dw16 in the latter. Molecular analysis of HLA-DR antigens has provided insight into these apparently disparate findings. The HLA-DR molecule is composed of two chains, a nonpolymorphic a chain and a highly polymorphic b chain. Allelic variations in the HLA-DR molecule reflect differences in the amino acids of theb chain, with the major amino acid changes occurring in the three hypervariable regions of the molecule. Each of the HLA-DR molecules that is associated with RA has the same or a very similar sequence of amino acids in the third hypervariable region of the b chain of the molecule. Thus the b chains

of the HLA-DR molecules associated with RA, including HLA-Dw4 (DRb1*0401), HLA-Dw14 (DRb1*0404), HLA-Dw15 (DRb1*0405), HLA-DR1 (DRb1*0101), and HLA-Dw16 (DRb1*1402), contain the same amino acids at positions 67 through 74, with the exception of a single change of one basic amino acid for another (arginine ® lysine) in position 71 of HLA-Dw4. All other HLA-DR b chains have amino acid changes in this region that alter either their charge or hydrophobicity. These results indicate that a particular amino acid sequence in the third hypervariable region of the HLA-DR molecule is a major genetic element conveying susceptibility to RA, regardless of whether it occurs in HLA-DR4, HLA-Dw16, or HLA-DR1. It has been estimated that the risk of developing RA in a person with HLA-Dw4 (DRb1*0401) or HLA-Dw14 (DRb1*0404) is 1 in 35 and 1 in 20, respectively, whereas the presence of both alleles puts persons at an even greater risk. The lack of association of HLA-DR4 and RA in certain populations is explained by the major member of the DR4 family found in that population. HLA-DR4 is a family of closely related, serologically defined molecules, including HLA-Dw4, -Dw10, -Dw13, and -Dw15. Different members of the HLA-DR family of molecules are found to predominate in different ethnic groups. Thus, in HLA-DR4-positive North American whites, HLA-Dw4 and -Dw14 are the most frequent, whereas HLA-Dw15 is most frequent in Japanese and southern Chinese. Each of these is associated with RA. By contrast, HLA-Dw10, which is not associated with RA and contains nonconservative amino acid changes in positions 70 and 71 of theb chain, is most common in Israeli Jews. Therefore, HLA-DR4 is not associated with RA in this population. In certain groups of patients, there does not appear to be a clear association between HLA-DR4-related epitopes and RA. Thus, nearly 75% of African American RA patients do not have this genetic element. Moreover, there is an association with HLA-DR10 (DRB1*1001) in Spanish and Italian patients, with HLA-DR9 (DRB1*0901) in Chileans, and with HLA-DR3 (DRB1*0301) in Arab populations.

Additional genes in the HLA-D complex may also convey altered susceptibility toRA. Certain HLA-DR alleles, including HLA-DR5 (DRB1*1101), HLA-DR2 (DRB1*1501), HLA-DR3 (DRB1*0301), and HLA-DR7 (DRB1*0701), may protect against the development of RA in that they tend to be found at lower frequency in RA patients than in controls. Moreover, the HLA-DQ alleles, DQB1*0301 and DQB1*0302, that are in linkage disequilibrium with HLA-DR4 and DQB1*0501, have also been associated with RA. This has raised the possibility that HLA-DQ alleles may represent the actual RA susceptibility genes, whereas specific HLA-DR alleles may convey protection. In this model, the complement of HLA-DR and DQ alleles determines RA susceptibility. Disease manifestations have also been associated with HLA phenotype. Thus, early aggressive disease and extraarticular manifestations are more frequent in patients with DRB1*0401 or DRB1*0404, and more slowly progressive disease in those with DRB1*0101. The presence of both DRB1*0401 and DRB1*0404 appears to increase the risk for both aggressive articular and extraarticular disease. It has been estimated that HLA genes contribute only a portion of the genetic susceptibility to RA. Thus genes outside the HLA complex also contribute. These include genes controlling the expression of the antigen receptor on T cells and both immunoglobulin heavy and light chains. Moreover, polymorphisms in the tumor necrosis factor (TNF)a and the interleukin (IL) 10 genes are also associated with RA, as is a region on chromosome 3 (3q13).

Genetic risk factors do not fully account for the incidence ofRA, suggesting that

environmental factors also play a role in the etiology of the disease. This is emphasized by epidemiologic studies in Africa that have indicated that climate and urbanization have a major impact on the incidence and severity of RA in groups of similar genetic background.

ETIOLOGY

The cause ofRAremains unknown. It has been suggested that RA might be a manifestation of the response to an infectious agent in a genetically susceptible host. Because of the worldwide distribution of RA, it has been hypothesized that if an infectious agent is involved, the organism must be ubiquitous. A number of possible causative agents have been suggested, including *Mycoplasma*, Epstein-Barr virus (EBV), cytomegalovirus, parvovirus, and rubella virus, but convincing evidence that these or other infectious agents cause RA has not emerged. The process by which an infectious agent might cause chronic inflammatory arthritis with a characteristic distribution also remains a matter of controversy. One possibility is that there is persistent infection of articular structures or retention of microbial products in the synovial tissues which generates a chronic inflammatory response. Alternatively, the microorganism or response to the microorganism might induce an immune response to components of the joint by altering its integrity and revealing antigenic peptides. In this regard, reactivity to type II collagen and heat shock proteins has been demonstrated. Another possibility is that the infecting microorganism might prime the host to cross-reactive determinants expressed within the joint as a result of "molecular mimicry." Recent evidence of similarity between products of certain gram-negative bacteria and EBV and the HLA-DR4 molecule itself has supported this possibility. Finally, products of infecting microorganisms might induce the disease. Recent work has focused on the possible role of "superantigens" produced by a number of microorganisms, including staphylococci, streptococci and *M. arthritidis*. Superantigens are proteins with the capacity to bind to HLA-DR molecules and particular V_b segments of the heterodimeric T cell receptor and stimulate specific T cells expressing the V_b gene products (Chap. 305). The role of superantigens in the etiology of RA remains speculative. Of all the potential environmental triggers, the only one clearly associated with the development of RA is cigarette smoking.

PATHOLOGY AND PATHOGENESIS

Microvascular injury and an increase in the number of synovial lining cells appear to be the earliest lesions in rheumatoid synovitis. The nature of the insult causing this response is not known. Subsequently, an increased number of synovial lining cells is seen along with perivascular infiltration with mononuclear cells. Before the onset of clinical symptoms, the perivascular infiltrate is predominantly composed of myeloid cells, whereas in symptomatic arthritis, T cells can also be found, although their number does not appear to correlate with symptoms. As the process continues, the synovium becomes edematous and protrudes into the joint cavity as villous projections.

Light-microscopic examination discloses a characteristic constellation of features, which include hyperplasia and hypertrophy of the synovial lining cells; focal or segmental vascular changes, including microvascular injury, thrombosis, and neovascularization; edema; and infiltration with mononuclear cells, often collected into aggregates around

small blood vessels (Fig. 312-1). The endothelial cells of the rheumatoid synovium have the appearance of high endothelial venules of lymphoid organs and have been altered by cytokine exposure to facilitate entry of cells into tissue. Rheumatoid synovial endothelial cells express increased amounts of various adhesion molecules involved in this process. Although this pathologic picture is typical ofRA, it can also be seen in a variety of other chronic inflammatory arthritides. The mononuclear cell collections are variable in composition and size. The predominant infiltrating cell is the T lymphocyte. CD4+ T cells predominate over CD8+ T cells and are frequently found in close proximity to HLA-DR+ macrophages and dendritic cells. Increased numbers of a separate population of T cells expressing the gd form of the T cell receptor have also been found in the synovium, although they remain a minor population there and their role in RA has not been delineated. The major population of T cells in the rheumatoid synovium is composed of CD4+ memory T cells that form the majority of cells aggregated around postcapillary venules. Scattered throughout the tissue are CD8+ T cells. Both populations express the early activation antigen, CD69. Besides the accumulation of T cells, rheumatoid synovitis is also characterized by the infiltration of variable numbers of B cells and antibody-producing plasma cells. In advanced disease, structures similar to germinal centers of secondary lymphoid organs may be observed in the synovium. Both polyclonal immunoglobulin and the autoantibody rheumatoid factor are produced within the synovial tissue, which leads to the local formation of immune complexes. Finally, the synovial fibroblasts in RA manifest evidence of activation in that they produce a number of enzymes such as collagenase and cathepsins that can degrade components of the articular matrix. These activated fibroblasts are particularly prominent in the lining layer and at the interface with bone and cartilage. Osteoclasts are also prominent at sites of bone erosion.

The rheumatoid synovium is characterized by the presence of a number of secreted products of activated lymphocytes, macrophages, and fibroblasts. The local production of these cytokines and chemokines appears to account for many of the pathologic and clinical manifestations ofRA. These effector molecules include those that are derived from T lymphocytes such as interleukinIL-2, interferon (IFN) g, IL-6, IL-10, granulocyte-macrophage colony stimulating factor (GM-CSF),TNF-a, transforming growth factor b(TGF-b); IL-13, IL-16, and IL-17; those originating from activated myeloid cells, including IL-1, TNF-a, IL-6, IL-8, IL-10, IL-12, GM-CSF, macrophage CSF, platelet-derived growth factor, insulin-like growth factor, and TGF-b; as well as those secreted by other cell types in the synovium, such as fibroblasts and endothelial cells, including IL-1, IL-6, IL-8, GM-CSF, IL-15, IL-16, IL-18, and macrophage CSF. The activity of these chemokines and cytokines appears to account for many of the features of rheumatoid synovitis, including the synovial tissue inflammation, synovial fluid inflammation, synovial proliferation, and cartilage and bone damage, as well as the systemic manifestations of RA. In addition to the production of effector molecules that propagate the inflammatory process, local factors are produced that tend to slow the inflammation, including specific inhibitors of cytokine action and additional cytokines, such as TGF-b, which inhibits many of the features of rheumatoid synovitis including T cell activation and proliferation, B cell differentiation, and migration of cells into the inflammatory site.

These findings have suggested that the propagation ofRA is an immunologically mediated event, although the original initiating stimulus has not been characterized.

One view is that the inflammatory process in the tissue is driven by the CD4+ T cells infiltrating the synovium. Evidence for this includes (1) the predominance of CD4+ T cells in the synovium; (2) the increase in solubleIL-2 receptors, a product of activated T cells, in blood and synovial fluid of patients with active RA; and (3) amelioration of the disease by removal of T cells by thoracic duct drainage or peripheral lymphapheresis or suppression of their function by drugs, such as cyclosporine or nondepleting monoclonal antibodies to CD4. In addition, the association of RA with certain HLA-DR or -DQ alleles, whose only known functions are to shape the repertoire of CD4+ T cells during ontogeny in the thymus and bind and present antigenic peptides to CD4+ T cells in the periphery, strongly implies a role for CD4+ T cells in the pathogenesis of the disease. Finally, patients with established RA who become infected with HIV also have been noted to improve, although this has not been a uniform finding. Within the rheumatoid synovium, the CD4+ T cells differentiate predominantly into Th1-like effector cells producing the proinflammatory cytokineIFN-gand appear to be deficient in differentiation into Th2-like effector cells capable of producing the anti-inflammatory cytokine IL-4. As a result of the ongoing secretion of IFN-g without the regulatory influences of IL-4, macrophages are activated to produce the proinflammatory cytokines IL-1 andTNF-aand also increase expression of HLA molecules. Moreover, T lymphocytes express surface molecules such as CD154 (CD40 ligand) and also produce a variety of cytokines that promote B cell proliferation and differentiation into antibody-forming cells and therefore also may promote local B cell stimulation. The resultant production of immunoglobulin and rheumatoid factor can lead to immune-complex formation with consequent complement activation and exacerbation of the inflammatory process by the production of the anaphylatoxins, C3a and C5a, and the chemotactic factor C5a. The tissue inflammation is reminiscent of delayed type hypersensitivity reactions occurring in response to soluble antigens or microorganisms, although it has become clear that the number of T cells producing cytokines such as IFN-g is less than is found in typical delayed type hypersensitivity reactions, perhaps owing to the large amount of reactive oxygen species produced locally in the synovium that can dampen T cell function. It remains unclear whether the persistent T cell activity represents a response to a persistent exogenous antigen or to altered autoantigens such as collagen, immunoglobulin, or one of the heat shock proteins, or perhaps both. Alternatively, it could represent persistent responsiveness to activated autologous cells such as might occur as a result ofEBVinfection or persistent response to a foreign antigen or superantigen in the synovial tissue. Finally, rheumatoid inflammation could reflect persistent stimulation of T cells by synovial-derived antigens that cross-react with determinants introduced during antecedent exposure to foreign antigens or infectious microorganisms.

Overriding the chronic inflammation in the synovial tissue is an acute inflammatory process in the synovial fluid. The exudative synovial fluid contains more polymorphonuclear leukocytes than mononuclear cells. A number of mechanisms play a role in stimulating the exudation of synovial fluid. Locally produced immune complexes can activate complement and generate anaphylatoxins and chemotactic factors. Local production, by a variety of cells, of chemokines and cytokines with chemotactic activity as well as inflammatory mediators such as leukotriene B_4 and products of complement activation can attract neutrophils. Moreover, many of these same agents can also stimulate the endothelial cells of postcapillary venules to become more efficient at binding circulating cells. The net result is the enhanced migration of polymorphonuclear

leukocytes into the synovial site. In addition, vasoactive mediators such as histamine produced by the mast cells that infiltrate the rheumatoid synovium may also facilitate the exudation of inflammatory cells into the synovial fluid. Finally, the vasodilatory effects of locally produced prostaglandin E_2 may also facilitate entry of inflammatory cells into the inflammatory site. Once in the synovial fluid, the polymorphonuclear leukocytes can ingest immune complexes, with the resultant production of reactive oxygen metabolites and other inflammatory mediators, further adding to the inflammatory milieu. Locally produced cytokines and chemokines can additionally stimulate polymorphonuclear leukocytes. The production of large amounts of cyclooxygenase and lipoxygenase pathway products of arachidonic acid metabolism by cells in the synovial fluid and tissue further accentuates the signs and symptoms of inflammation.

The precise mechanism by which bone and cartilage destruction occurs has not been completely resolved. Although the synovial fluid contains a number of enzymes potentially able to degrade cartilage, the majority of destruction occurs in juxtaposition to the inflamed synovium, or pannus, that spreads to cover the articular cartilage. This vascular granulation tissue is composed of proliferating fibroblasts, small blood vessels, and a variable number of mononuclear cells and produces a large amount of degradative enzymes, including collagenase and stromelysin, that may facilitate tissue damage. The cytokinesIL-1 andTNF-aplay an important role by stimulating the cells of the pannus to produce collagenase and other neutral proteases. These same two cytokines also activate chondrocytes in situ, stimulating them to produce proteolytic enzymes that can degrade cartilage locally and also inhibiting synthesis of new matrix molecules. Finally, these two cytokines may contribute to the local demineralization of bone by activating osteoclasts that accumulate at the site of local bone resorption. Prostaglandin E_2produced by fibroblasts and macrophages may also contribute to bone demineralization. The common final pathway of bone erosion is likely to involve the activation of osteoclasts that are present in large numbers at these sites. Systemic manifestations ofRA can be accounted for by release of inflammatory effector molecules from the synovium. These include IL-1, TNF-a, and IL-6, which account for many of the manifestations of active RA, including malaise, fatigue, and elevated levels of serum acute-phase reactants. The importance of TNF-a in producing these manifestations is emphasized by the prompt amelioration of symptoms following administration of a monoclonal antibody to TNF-a or a soluble TNF-a receptor Ig construct to patients with RA. In addition, immune complexes produced within the synovium and entering the circulation may account for other features of the disease, such as systemic vasculitis.

As shown inFig. 312-2, the pathology ofRAevolves over the duration of this chronic disease. The earliest event appears to be a nonspecific inflammatory response initiated by an unknown stimulus and characterized by accumulation of macrophages and other mononuclear cells within the sublining layer of the synovium. The activity of these cells is demonstrated by the increased appearance of macrophage-derived cytokines, includingTNF-a,IL-1b, and IL-6. Subsequently, activation of CD4+ T cells is induced, presumably in response to antigenic peptides displayed by a variety of antigen-presenting cells in the synovial tissue. The activated T cells are capable of producing cytokines, especiallyIFN-g, which amplify and perpetuate the inflammation. The presence of activated T cells expressing CD154 (CD40 ligand) can induce polyclonal B cell stimulation and the local production of rheumatoid factor. The cascade of cytokines produced in the synovium activates a variety of cells in the synovium, bone,

and cartilage to produce effector molecules that can cause tissue damage characteristic of chronic inflammation. It is important to emphasize that there is no current way to predict the progress from one stage of inflammation to the next, and once established, each can influence the other. Important features of this model include the following: (1) the major pathologic events vary with time in this chronic disease; (2) the time required to progress from one step to the next may vary in different patients and the events, once established, may persist simultaneously; (3) once established, the major pathogenic events operative in an individual patient may vary at different times; and (4) the process is chronic and reiterative, with successive events stimulating progressive amplification of inflammation. These considerations have important implications with regard to appropriate treatment.

CLINICAL MANIFESTATIONS

Onset Characteristically,RA is a chronic polyarthritis. In approximately two-thirds of patients, it begins insidiously with fatigue, anorexia, generalized weakness, and vague musculoskeletal symptoms until the appearance of synovitis becomes apparent. This prodrome may persist for weeks or months and defy diagnosis. Specific symptoms usually appear gradually as several joints, especially those of the hands, wrists, knees, and feet, become affected in a symmetric fashion. In approximately 10% of individuals, the onset is more acute, with a rapid development of polyarthritis, often accompanied by constitutional symptoms, including fever, lymphadenopathy, and splenomegaly. In approximately one-third of patients, symptoms may initially be confined to one or a few joints. Although the pattern of joint involvement may remain asymmetric in a few patients, a symmetric pattern is more typical.

Signs and Symptoms of Articular Disease Pain, swelling, and tenderness may initially be poorly localized to the joints. Pain in affected joints, aggravated by movement, is the most common manifestation of establishedRA. It corresponds in pattern to the joint involvement but does not always correlate with the degree of apparent inflammation. Generalized stiffness is frequent and is usually greatest after periods of inactivity. Morning stiffness of greater than 1-h duration is an almost invariable feature of inflammatory arthritis and may serve to distinguish it from various noninflammatory joint disorders. Notably, however, the presence of morning stiffness may not reliably distinguish between chronic inflammatory and noninflammatory arthritides, as it is also found frequently in the latter. The majority of patients will experience constitutional symptoms such as weakness, easy fatigability, anorexia, and weight loss. Although fever to 40°C occurs on occasion, temperature elevation in excess of 38°C is unusual and suggests the presence of an intercurrent problem such as infection.

Clinically, synovial inflammation causes swelling, tenderness, and limitation of motion. Warmth is usually evident on examination, especially of large joints such as the knee, but erythema is infrequent. Pain originates predominantly from the joint capsule, which is abundantly supplied with pain fibers and is markedly sensitive to stretching or distention. Joint swelling results from accumulation of synovial fluid, hypertrophy of the synovium, and thickening of the joint capsule. Initially, motion is limited by pain. The inflamed joint is usually held in flexion to maximize joint volume and minimize distention of the capsule. Later, fibrous or bony ankylosis or soft tissue contractures lead to fixed

deformities.

Although inflammation can affect any diarthrodial joint,RA most often causes symmetric arthritis with characteristic involvement of certain specific joints such as the proximal interphalangeal and metacarpophalangeal joints. The distal interphalangeal joints are rarely involved. Synovitis of the wrist joints is a nearly uniform feature of RA and may lead to limitation of motion, deformity, and median nerve entrapment (carpal tunnel syndrome). Synovitis of the elbow joint often leads to flexion contractures that may develop early in the disease. The knee joint is commonly involved with synovial hypertrophy, chronic effusion, and frequently ligamentous laxity. Pain and swelling behind the knee may be caused by extension of inflamed synovium into the popliteal space (Baker's cyst). Arthritis in the forefoot, ankles, and subtalar joints can produce severe pain with ambulation as well as a number of deformities. Axial involvement is usually limited to the upper cervical spine. Involvement of the lumbar spine is not seen, and lower back pain cannot be ascribed to rheumatoid inflammation. On occasion, inflammation from the synovial joints and bursae of the upper cervical spine leads to atlantoaxial subluxation. This usually presents as pain in the occiput but on rare occasions may lead to compression of the spinal cord.

With persistent inflammation, a variety of characteristic joint changes develop. These can be attributed to a number of pathologic events, including laxity of supporting soft tissue structures; damage or weakening of ligaments, tendons, and the joint capsule; cartilage degradation; muscle imbalance; and unopposed physical forces associated with the use of affected joints. Characteristic changes of the hand include (1) radial deviation at the wrist with ulnar deviation of the digits, often with palmar subluxation of the proximal phalanges ("Z" deformity); (2) hyperextension of the proximal interphalangeal joints, with compensatory flexion of the distal interphalangeal joints (swan-neck deformity); (3) flexion contracture of the proximal interphalangeal joints and extension of the distal interphalangeal joints (boutonniere deformity); and (4) hyperextension of the first interphalangeal joint and flexion of the first metacarpophalangeal joint with a consequent loss of thumb mobility and pinch. Typical joint changes may also develop in the feet, including eversion at the hindfoot (subtalar joint), plantar subluxation of the metatarsal heads, widening of the forefoot, hallux valgus, and lateral deviation and dorsal subluxation of the toes.

Extraarticular Manifestations RA is a systemic disease with a variety of extraarticular manifestations. Although these occur frequently, not all of them have clinical significance. However, on occasion, they may be the major evidence of disease activity and source of morbidity and require management per se. As a rule, these manifestations occur in individuals with high titers of autoantibodies to the Fc component of immunoglobulin G (rheumatoid factors).

Rheumatoid nodules develop in 20 to 30% of persons withRA. They are usually found on periarticular structures, extensor surfaces, or other areas subjected to mechanical pressure, but they can develop elsewhere, including the pleura and meninges. Common locations include the olecranon bursa, the proximal ulna, the Achilles tendon, and the occiput. Nodules vary in size and consistency and are rarely symptomatic, but on occasion they break down as a result of trauma or become infected. They are found almost invariably in individuals with circulating rheumatoid factor. Histologically,

rheumatoid nodules consist of a central zone of necrotic material including collagen fibrils, noncollagenous filaments, and cellular debris; a midzone of palisading macrophages that express HLA-DR antigens; and an outer zone of granulation tissue. Examination of early nodules has suggested that the initial event may be a focal vasculitis. In some patients, treatment with methotrexate can increase the number of nodules dramatically.

Clinical weakness and atrophy of skeletal muscle are common. Muscle atrophy may be evident within weeks of the onset ofRA and is usually most apparent in musculature approximating affected joints. Muscle biopsy may show type II fiber atrophy and muscle fiber necrosis with or without a mononuclear cell infiltrate.

Rheumatoid vasculitis (Chap. 317), which can affect nearly any organ system, is seen in patients with severeRA and high titers of circulating rheumatoid factor. Rheumatoid vasculitis is very uncommon in African Americans. In its most aggressive form, rheumatoid vasculitis can cause polyneuropathy and mononeuritis multiplex, cutaneous ulceration and dermal necrosis, digital gangrene, and visceral infarction. While such widespread vasculitis is very rare, more limited forms are not uncommon, especially in white patients with high titers of rheumatoid factor. Neurovascular disease presenting either as a mild distal sensory neuropathy or as mononeuritis multiplex may be the only sign of vasculitis. Cutaneous vasculitis usually presents as crops of small brown spots in the nail beds, nail folds, and digital pulp. Larger ischemic ulcers, especially in the lower extremity, may also develop. Myocardial infarction secondary to rheumatoid vasculitis has been reported, as has vasculitic involvement of lungs, bowel, liver, spleen, pancreas, lymph nodes, and testes. Renal vasculitis is rare.

Pleuropulmonary manifestations, which are more commonly observed in men, include pleural disease, interstitial fibrosis, pleuropulmonary nodules, pneumonitis, and arteritis. Evidence of pleuritis is found commonly at autopsy, but symptomatic disease during life is infrequent. Typically, the pleural fluid contains very low levels of glucose in the absence of infection. Pleural fluid complement is also low compared with the serum level when these are related to the total protein concentration. Pulmonary fibrosis can produce impairment of the diffusing capacity of the lung. Pulmonary nodules may appear singly or in clusters. When they appear in individuals with pneumoconiosis, a diffuse nodular fibrotic process (Caplan's syndrome) may develop. On occasion, pulmonary nodules may cavitate and produce a pneumothorax or bronchopleural fistula. Rarely, pulmonary hypertension secondary to obliteration of the pulmonary vasculature occurs. In addition to pleuropulmonary disease, upper airway obstruction from cricoarytenoid arthritis or laryngeal nodules may develop.

Clinically apparent heart disease attributed to the rheumatoid process is rare, but evidence of asymptomatic pericarditis is found at autopsy in 50% of cases. Pericardial fluid has a low glucose level and is frequently associated with the occurrence of pleural effusion. Although pericarditis is usually asymptomatic, on rare occasions death has occurred from tamponade. Chronic constrictive pericarditis may also occur.

RAtends to spare the central nervous system directly, although vasculitis can cause peripheral neuropathy. *Neurologic manifestations* may also result from atlantoaxial or midcervical spine subluxations. Nerve entrapment secondary to proliferative synovitis or

joint deformities may produce neuropathies of median, ulnar, radial (interosseous branch), or anterior tibial nerves.

The rheumatoid process involves the *eye* in fewer than 1% of patients. Affected individuals usually have long-standing disease and nodules. The two principal manifestations are episcleritis, which is usually mild and transient, and scleritis, which involves the deeper layers of the eye and is a more serious inflammatory condition. Histologically, the lesion is similar to a rheumatoid nodule and may result in thinning and perforation of the globe (scleromalacia perforans). From 15 to 20% of persons withRA may develop Sjogren's syndrome with attendant keratoconjunctivitis sicca.

Felty's syndrome consists of chronicRA, splenomegaly, neutropenia, and, on occasion, anemia and thrombocytopenia. It is most common in individuals with long-standing disease. These patients frequently have high titers of rheumatoid factor, subcutaneous nodules, and other manifestations of systemic rheumatoid disease. Felty's syndrome is very uncommon in African Americans. It may develop after joint inflammation has regressed. Circulating immune complexes are often present, and evidence of complement consumption may be seen. The leukopenia is a selective neutropenia with polymorphonuclear leukocyte counts of <1500 cells per microliter and sometimes <1000 cells per microliter. Bone marrow examination usually reveals moderate hypercellularity with a paucity of mature neutrophils. However, the bone marrow may be normal, hyperactive, or hypoactive; maturation arrest may be seen. Hypersplenism has been proposed as one of the causes of leukopenia, but splenomegaly is not invariably found and splenectomy does not always correct the abnormality. Excessive margination of granulocytes caused by antibodies to these cells, complement activation, or binding of immune complexes may contribute to granulocytopenia. Patients with Felty's syndrome have increased frequency of infections usually associated with neutropenia. The cause of the increased susceptibility to infection is related to the defective function of polymorphonuclear leukocytes as well as the decreased number of cells.

Osteoporosis secondary to rheumatoid involvement is common and may be aggravated by glucocorticoid therapy. Glucocorticoid treatment may cause significant loss of bone mass, especially early in the course of therapy, even when low doses are employed. Osteopenia inRAinvolves both juxtaarticular bone and long bones distant from involved joints. RA is associated with a modest decrease in mean bone mass and a moderate increase in the risk of fracture. Bone mass appears to be adversely affected by functional impairment and active inflammation, especially early in the course of the disease.

RA in the Elderly The incidence ofRAcontinues to increase past age 60. It has been suggested that elderly-onset RA might have a poorer prognosis, as manifested by more persistent disease activity, more frequent radiographically evident deterioration, more frequent systemic involvement, and more rapid functional decline. Aggressive disease is largely restricted to those patients with high titers of rheumatoid factor. By contrast, elderly patients who develop RA without elevated titers of rheumatoid factor (seronegative disease) generally have less severe, often self-limited disease.

LABORATORY FINDINGS

No tests are specific for diagnosingRA. However, rheumatoid factors, which are autoantibodies reactive with the Fc portion of IgG, are found in more than two-thirds of adults with the disease. Widely utilized tests largely detect IgM rheumatoid factors. The presence of rheumatoid factor is not specific for RA. Rheumatoid factor is found in 5% of healthy persons. The frequency of rheumatoid factor in the general population increases with age, and 10 to 20% of individuals over 65 years old have a positive test. In addition, a number of conditions besides RA are associated with the presence of rheumatoid factor. These include systemic lupus erythematosus, Sjogren's syndrome, chronic liver disease, sarcoidosis, interstitial pulmonary fibrosis, infectious mononucleosis, hepatitis B, tuberculosis, leprosy, syphilis, subacute bacterial endocarditis, visceral leishmaniasis, schistosomiasis, and malaria. In addition, rheumatoid factor may appear transiently in normal individuals after vaccination or transfusion and may also be found in relatives of individuals with RA.

The presence of rheumatoid factor does not establish the diagnosis ofRA as the predictive value of the presence of rheumatoid factor in determining a diagnosis of RA is poor. Thus fewer than one-third of unselected patients with a positive test for rheumatoid factor will be found to have RA. Therefore, the rheumatoid factor test is not useful as a screening procedure. However, the presence of rheumatoid factor can be of prognostic significance because patients with high titers tend to have more severe and progressive disease with extraarticular manifestations. Rheumatoid factor is uniformly found in patients with nodules or vasculitis. In summary, a test for the presence of rheumatoid factor can be employed to confirm a diagnosis in individuals with a suggestive clinical presentation and, if present in high titer, to designate patients at risk for severe systemic disease. A number of additional autoantibodies may be found in patients with RA, including antibodies to filaggrin, citrulline, calpastatin, components of the spliceosome (RA-33), and an unknown antigen, Sa. Some of these may be useful in diagnosis in that they may occur early in the disease before rheumatoid factor is present or may be associated with aggressive disease.

Normochromic, normocytic anemia is frequently present in activeRA. It is thought to reflect ineffective erythropoiesis; large stores of iron are found in the bone marrow. In general, anemia and thrombocytosis correlate with disease activity. The white blood cell count is usually normal, but a mild leukocytosis may be present. Leukopenia may also exist without the full-blown picture of Felty's syndrome. Eosinophilia, when present, usually reflects severe systemic disease.

The erythrocyte sedimentation rate is increased in nearly all patients with activeRA. The levels of a variety of other acute-phase reactants including ceruloplasmin and C-reactive protein are also elevated, and generally such elevations correlate with disease activity and the likelihood of progressive joint damage.

Synovial fluid analysis confirms the presence of inflammatory arthritis, although none of the findings is specific. The fluid is usually turbid, with reduced viscosity, increased protein content, and a slightly decreased or normal glucose concentration. The white cell count varies between 5 and 50,000/uL; polymorphonuclear leukocytes predominate. A synovial fluid white blood cell count >2000/uL with more than 75% polymorphonuclear leukocytes is highly characteristic of inflammatory arthritis, although not diagnostic ofRA. Total hemolytic complement, C3, and C4 are markedly diminished in synovial fluid

relative to total protein concentration as a result of activation of the classic complement pathway by locally produced immune complexes.

RADIOGRAPHIC EVALUATION

Early in the disease, roentgenograms of the affected joints are usually not helpful in establishing a diagnosis. They reveal only that which is apparent from physical examination, namely, evidence of soft tissue swelling and joint effusion. As the disease progresses, abnormalities become more pronounced, but none of the radiographic findings is diagnostic ofRA. The diagnosis, however, is supported by a characteristic pattern of abnormalities, including the tendency toward symmetric involvement. Juxtaarticular osteopenia may become apparent within weeks of onset. Loss of articular cartilage and bone erosions develop after months of sustained activity. The primary value of radiography is to determine the extent of cartilage destruction and bone erosion produced by the disease, particularly when one is monitoring the impact of therapy with disease-modifying drugs or surgical intervention. Other means of imaging bones and joints, including^{99m}Tc bisphosphonate bone scanning and magnetic resonance imaging, may be capable of detecting early inflammatory changes that are not apparent from standard radiography but are rarely necessary in the routine evaluation of patients with RA.

CLINICAL COURSE AND PROGNOSIS

The course ofRA is quite variable and difficult to predict in an individual patient. Most patients experience persistent but fluctuating disease activity, accompanied by a variable degree of joint abnormalities and functional impairment. After 10 to 12 years, fewer than 20% of patients will have no evidence of disability or joint abnormalities. Within 10 years, approximately 50% of patients will have work disability. A number of features are correlated with a greater likelihood of developing joint abnormalities or disabilities. These include the presence of more than 20 inflamed joints, a markedly elevated erythrocyte sedimentation rate, radiographic evidence of bone erosions, the presence of rheumatoid nodules, high titers of serum rheumatoid factor, the presence of functional disability, persistent inflammation, advanced age at onset, the presence of comorbid conditions, low socioeconomic status or educational level, or the presence of HLA-DRB1*0401 or -DRB*0404. The presence of one or more of these implies the presence of more aggressive disease with a greater likelihood of developing progressive joint abnormalities and disability. Persistent elevation of the erythrocyte sedimentation rate, disability, and pain on longitudinal follow-up are good predictors of work disability. Patients who lack these features have more indolent disease with a slower progression to joint abnormalities and disability. The pattern of disease onset does not appear to predict the development of disabilities. Approximately 15% of patients with RA will have a short-lived inflammatory process that remits without major disability. These individuals tend to lack the aforementioned features associated with more aggressive disease.

Several features of patients withRAappear to have prognostic significance. Remissions of disease activity are most likely to occur during the first year. White females tend to have more persistent synovitis and more progressively erosive disease than males. Persons who present with high titers of rheumatoid factor, C-reactive protein, and

haptoglobin also have a worse prognosis, as do individuals with subcutaneous nodules or radiographic evidence of erosions at the time of initial evaluation. Sustained disease activity of more than 1 year's duration portends a poor outcome, and persistent elevation of acute-phase reactants appears to correlate strongly with radiographic progression. A large proportion of inflamed joints manifest erosions within 2 years, whereas the subsequent course of erosions is highly variable; however, in general, radiographic damage appears to progress at a constant rate in patients with RA. Foot joints are affected more frequently than hand joints. Despite the decrease in the rate of progressive joint damage with time, functional disability, which develops early in the course of the disease, continues to worsen at the same rate, although the most rapid rate of functional loss occurs within the first 2 years of disease.

The median life expectancy of persons with RAis shortened by 3 to 7 years. Of the 2.5-fold increase in mortality rate, RA itself is a contributing feature in 15 to 30%. The increased mortality rate seems to be limited to patients with more severe articular disease and can be attributed largely to infection and gastrointestinal bleeding. Drug therapy may also play a role in the increased mortality rate seen in these individuals. Factors correlated with early death include disability, disease duration or severity, glucocorticoid use, age at onset, and low socioeconomic or educational status.

DIAGNOSIS

The mean delay from disease onset to diagnosis is 9 months. This is often related to the nonspecific nature of initial symptoms. The diagnosis ofRA is easily made in persons with typical established disease. In a majority of patients, the disease assumes its characteristic clinical features within 1 to 2 years of onset. The typical picture of bilateral symmetric inflammatory polyarthritis involving small and large joints in both the upper and lower extremities with sparing of the axial skeleton except the cervical spine suggests the diagnosis. Constitutional features indicative of the inflammatory nature of the disease, such as morning stiffness, support the diagnosis. Demonstration of subcutaneous nodules is a helpful diagnostic feature. Additionally, the presence of rheumatoid factor, inflammatory synovial fluid with increased numbers of polymorphonuclear leukocytes, and radiographic findings of juxtaarticular bone demineralization and erosions of the affected joints substantiate the diagnosis.

The diagnosis is somewhat more difficult early in the course when only constitutional symptoms or intermittent arthralgias or arthritis in an asymmetric distribution may be present. A period of observation may be necessary before the diagnosis can be established. A definitive diagnosis ofRAdepends predominantly on characteristic clinical features and the exclusion of other inflammatory processes. The isolated finding of a positive test for rheumatoid factor or an elevated erythrocyte sedimentation rate, especially in an older person with joint pains, should not itself be used as evidence of RA.

In 1987, the American College of Rheumatology developed revised criteria for the classification ofRA(Table 312-1). These criteria demonstrate a sensitivity of 91 to 94% and a specificity of 89% when used to classify patients with RA compared with control subjects with rheumatic diseases other than RA. Although these criteria were developed as a means of disease classification for epidemiologic purposes, they can be useful as

guidelines for establishing the diagnosis. Failure to meet these criteria, however, especially during the early stages of the disease, does not exclude the diagnosis. Moreover, in patients with early arthritis, the criteria do not discriminate effectively between patients who subsequently develop persistent, disabling, or erosive disease and those who do not.

TREATMENT

General Principles The goals of therapy ofRA are (1) relief of pain, (2) reduction of inflammation, (3) protection of articular structures, (4) maintenance of function, and (5) control of systemic involvement. Since the etiology of RA is unknown, the pathogenesis is not completely delineated, and the mechanisms of action of many of the therapeutic agents employed are uncertain, therapy remains largely empirical. None of the therapeutic interventions is curative, and therefore all must be viewed as palliative, aimed at relieving the signs and symptoms of the disease. The various therapies employed are directed at nonspecific suppression of the inflammatory or immunologic process in the hope of ameliorating symptoms and preventing progressive damage to articular structures.

Management of patients withRAinvolves an interdisciplinary approach, which attempts to deal with the various problems that these individuals encounter with functional as well as psychosocial interactions. A variety of physical therapy modalities may be useful in decreasing the symptoms of RA. Rest ameliorates symptoms and can be an important component of the total therapeutic program. In addition, splinting to reduce unwanted motion of inflamed joints may be useful. Exercise directed at maintaining muscle strength and joint mobility without exacerbating joint inflammation is also an important aspect of the therapeutic regimen. A variety of orthotic and assistive devices can be helpful in supporting and aligning deformed joints to reduce pain and improve function. Education of the patient and family is an important component of the therapeutic plan to help those involved become aware of the potential impact of the disease and make appropriate accommodations in life-style to maximize satisfaction and minimize stress on joints.

Medical management ofRAinvolves five general approaches. The first is the use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) and simple analgesics to control the symptoms and signs of the local inflammatory process. These agents are rapidly effective at mitigating signs and symptoms, but they appear to exert minimal effect on the progression of the disease. Recently, specific inhibitors of the isoform of cyclooxygenase (Cox) that is upregulated at inflammatory sites (Cox-2) have been developed. Cox-2-specific inhibitors (CSIs) have been shown to be as effective as classic NSAIDs, which inhibit both isoforms of Cox, but to cause significantly less gastroduodenal ulceration. The second line of therapy involves use of low-dose oral glucocorticoids. Although low-dose glucocorticoids have been widely used to suppress signs and symptoms of inflammation, recent evidence suggests that they may also retard the development and progression of bone erosions. Intraarticular glucocorticoids can often provide transient symptomatic relief when systemic medical therapy has failed to resolve inflammation. The third line of agents includes a variety of agents that have been classified as the disease-modifying or slow-acting antirheumatic drugs. These agents appear to have the capacity to decrease elevated levels of acute-phase

reactants in treated patients and, therefore, are thought to modify the inflammatory component of RA and thus its destructive capacity. Recently, combinations of disease-modifying antirheumatic drugs (DMARDs) have shown promise in controlling the signs and symptoms of RA. A fourth group of agents are theTNF-aneutralizing agents, which have been shown to have a major impact on the signs and symptoms of RA. A fifth group of agents are the immunosuppressive and cytotoxic drugs that have been shown to ameliorate the disease process in some patients. Additional approaches have been employed in an attempt to control the signs and symptoms of RA. Substituting omega-3 fatty acids such as eicosapentaenoic acid found in certain fish oils for dietary omega-6 essential fatty acids found in meat has also been shown to provide symptomatic improvement in patients with RA. A variety of nontraditional approaches have also been claimed to be effective in treating RA, including diets, plant and animal extracts, vaccines, hormones, and topical preparations of various sorts. Many of these are costly, and none has been shown to be effective. However, belief in their efficacy ensures their continued use by some patients.

Drugs

Nonsteroidal Anti-Inflammatory Drugs Besides aspirin, manyNSAIDsare available to treatRA. As a result of the capacity of these agents to block the activity of theCoxenzymes and therefore the production of prostaglandins, prostacyclin, and thromboxanes, they have analgesic, anti-inflammatory, and antipyretic properties. In addition, the agents may exert other anti-inflammatory effects. These agents are all associated with a wide spectrum of toxic side effects. Some, such as gastric irritation, azotemia, platelet dysfunction, and exacerbation of allergic rhinitis and asthma, are related to the inhibition of cyclooxygenase activity, whereas a variety of others, such as rash, liver function abnormalities, and bone marrow depression, may not be. None of the NSAIDs has been shown to be more effective than aspirin in the treatment of RA. However, these nonaspirin drugs are associated with a lower incidence of gastrointestinal intolerance. None of the newer NSAIDs appears to show significant therapeutic advantages over the other available agents. In addition, there is no consistent advantage of any of these newer agents over the others with respect to the incidence or severity of toxic manifestations. Recent evidence indicates that two separate enzymes, Cox-1 and -2, are responsible for the initial metabolism of arachidonic acid into various inflammatory mediators. The former is constitutively present in many cells and tissues, including the stomach and the platelet, whereas the latter is specifically induced in response to inflammatory stimuli. Inhibition of Cox-2 accounts for the anti-inflammatory effects of NSAIDs, whereas inhibition of Cox-1 induces much of the mechanism-based toxicity. As the currently available NSAIDs inhibit both enzymes, therapeutic benefit and toxicity are intertwined.CSIshave now been approved for the treatment of RA. Clinical trials have shown that CSIs suppress the signs and symptoms of RA as effectively as classic Cox-nonspecific NSAIDs but are associated with a significantly reduced incidence of gastroduodenal ulceration. This suggests that CSIs might be considered instead of classic Cox-nonspecific NSAIDs, especially in persons with increased risk of NSAID-induced major upper gastrointestinal side effects, including persons over 65, those with a history of peptic ulcer disease, persons receiving glucocorticoids or anticoagulants, or those requiring high doses of NSAIDs.

Disease-Modifying Antirheumatic Drugs Clinical experience has delineated a number of agents that appear to have the capacity to alter the course ofRA. This group of agents includes methotrexate, gold compounds, D-penicillamine, the antimalarials, and sulfasalazine. Despite having no chemical or pharmacologic similarities, in practice these agents share a number of characteristics. They exert minimal direct nonspecific anti-inflammatory or analgesic effects, and thereforeNSAIDsmust be continued during their administration, except in a few cases when true remissions are induced with them. The appearance of benefit fromDMARDtherapy is usually delayed for weeks or months. As many as two-thirds of patients develop some clinical improvement as a result of therapy with any of these agents, although the induction of true remissions is unusual. In addition to clinical improvement, there is frequently an improvement in serologic evidence of disease activity, and titers of rheumatoid factor and C-reactive protein and the erythrocyte sedimentation rate frequently decline. Moreover, emerging evidence suggests that DMARDs actually retard the development of bone erosions or facilitate their healing. Furthermore, developing evidence suggests that early aggressive treatment with DMARDs may be effective at slowing the appearance of bone erosions.

WhichDMARDshould be the drug of first choice remains controversial, and trials have failed to demonstrate a consistent advantage of one over the other. Despite this, methotrexate has emerged as the DMARD of choice because of its relatively rapid onset of action, its capacity to effect sustained improvement with ongoing therapy, and the high level of patient retention on therapy. Each of the DMARDs is associated with considerable toxicity, and therefore careful patient monitoring is necessary. Toxicity of the various agents also becomes important in determining the drug of first choice. Of note, failure to respond or development of toxicity to one DMARD does not preclude responsiveness to another. Thus, a similar percentage ofRApatients who have failed to respond to one DMARD will respond to another when it is given as the second disease-modifying drug.

No characteristic features of patients have emerged that predict responsiveness to aDMARD. Moreover, the indications for the initiation of therapy with one of these agents are not well defined, although recently the trend has been to begin DMARD therapy early in the course of the disease, and data have begun to emerge to support the conclusion that this approach may slow the development of bone erosions, although this remains controversial.

The folic acid antagonist methotrexate, given in an intermittent low dose (7.5 to 30 mg once weekly), is currently a frequently utilizedDMARD. Most rheumatologists recommend use of methotrexate as the initial DMARD, especially in individuals with evidence of aggressiveRA. Recent trials have documented the efficacy of methotrexate and have indicated that its onset of action is more rapid than other DMARDs, and patients tend to remain on therapy with methotrexate longer than they remain on other DMARDs because of better clinical responses and less toxicity. Long-term trials have indicated that methotrexate does not induce remission but rather suppresses symptoms while it is being administered. Maximal improvement is observed after 6 months of therapy, with little additional improvement thereafter. Major toxicity includes gastrointestinal upset, oral ulceration, and liver function abnormalities that appear to be dose-related and reversible and hepatic fibrosis that can be quite insidious, requiring liver biopsy for detection in its early stages. Drug-induced pneumonitis has also been

reported. Liver biopsy is recommended for individuals with persistent or repetitive liver function abnormalities. Concurrent administration of folic acid or folinic acid may diminish the frequency of some side effects without diminishing effectiveness.

Glucocorticoid Therapy Systemic glucocorticoid therapy can provide effective symptomatic therapy in patients withRA. Low-dose (<7.5 mg/d) prednisone has been advocated as useful additive therapy to control symptoms. Moreover, recent evidence suggests that low-dose glucocorticoid therapy may retard the progression of bone erosions. Monthly pulses with high-dose glucocorticoids may be useful in some patients and may hasten the response when therapy with aDMARD is initiated.

TNF-aneutralizing agents Recently, biologic agents that bind and neutralizeTNF-ahave become available. One of these is a TNF-a type II receptor fused to IgG1 (etanercept), and the second is a chimeric mouse/human monoclonal antibody to TNF-a (infliximab). Clinical trials have shown that parenteral administration of either TNF-a neutralizing agent is remarkably effective at controlling signs and symptoms ofRA in patients who have failedDMARDtherapy. Repetitive therapy with these agents is effective with or without concomitant methotrexate. Although these agents are notably effective in persistently controlling signs and symptoms of RA in a majority of patients, their impact on the progression of bone erosions has not been proven. Side effects include the potential for an increased risk of serious infections and the development of anti-DNA antibodies, but with no associated evidence of signs and symptoms of systemic lupus erythematosus. Although these side effects are uncommon, their occurrence mandates that TNF-aneutralizing therapy be supervised by physicians with experience in their use.

Immunosuppressive Therapy The immunosuppressive drugs azathioprine, leflunomide, cyclosporine, and cyclophosphamide have been shown to be effective in the treatment ofRA and to exert therapeutic effects similar to those of theDMARDs. However, these agents appear to be no more effective than the DMARDs. Moreover, they cause a variety of toxic side effects, and cyclophosphamide appears to predispose the patient to the development of malignant neoplasms. Therefore, these drugs have been reserved for patients who have clearly failed therapy with DMARDs. On occasion, extraarticular disease such as rheumatoid vasculitis may require cytotoxic immunosuppressive therapy.

Surgery Surgery plays a role in the management of patients with severely damaged joints. Although arthroplasties and total joint replacements can be done on a number of joints, the most successful procedures are carried out on hips, knees, and shoulders. Realistic goals of these procedures are relief of pain and reduction of disability. Reconstructive hand surgery may lead to cosmetic improvement and some functional benefit. Open or arthroscopic synovectomy may be useful in some patients with persistent monarthritis, especially of the knee. Although synovectomy may offer short-term relief of symptoms, it does not appear to retard bone destruction or alter the natural history of the disease. In addition, early tenosynovectomy of the wrist may prevent tendon rupture.

Approach to the Patient

An approach to the medical management of patients withRA is depicted in Fig. 312-3.

The principles underlying care of these patients reflect the variability of the disease, the frequent persistent nature of the inflammation and its potential to cause disability, the relationship between sustained inflammation and bone erosions, and the need to reevaluate the patient frequently for symptomatic response to therapy, progression of disability and joint damage, and side effects of treatment. At the onset of disease it is difficult to predict the natural history of an individual patient's illness. Therefore, the usual approach is to attempt to alleviate the patient's symptoms withNSAIDsor CSIs. Some patients may have mild disease that requires no additional therapy.

At some time during most patients' course, the possibility of initiatingDMARDtherapy and/or low-dose oral glucocorticoids is entertained. With aggressive disease this might occur sooner, often within 1 to 3 months of diagnosis, whereas in patients with more indolent disease, smoldering activity may not require such therapy for many years. The development of bone erosions or radiographic evidence of cartilage loss is clear-cut evidence of the destructive potential of the inflammatory process and indicates the need for DMARD therapy. The other indications as outlined above, including persistent pain, joint swelling, or functional impairment, are much more subjective, however. As persistent inflammation, involvement of multiple joints, elevated levels of acute-phase reactants, and rheumatoid factor titers correlate with the development of disability and/or bony erosions, some have advocated the use of these prognostic indicators of aggressive disease in the decision to employ DMARDs early in the course ofRA. The decision to begin use of a DMARD and/or low-dose oral glucocorticoids requires experience and clinical judgment as well as the ability to assess joint swelling and functional activity and the patient's pain tolerance and expectation of therapy accurately. In this setting, the fully informed patient must play an active role in the decision to begin DMARD and/or low-dose oral glucocorticoid therapy, after careful review of the therapeutic and toxic potential of the various drugs.

If a patient responds to aDMARD, therapy is continued with careful monitoring to avoid toxicity. All DMARDs provide a suppressive effect and therefore require prolonged administration. Even with successful therapy, local injection of glucocorticoids may be necessary to diminish inflammation that may persist in a limited number of joints. In addition,NSAIDsor CSIsmay be necessary to mitigate symptoms. Even after inflammation has totally resolved, symptoms from loss of cartilage and supervening degenerative joint disease or altered joint function may require additional treatment. Surgery may also be necessary to relieve pain or diminish the functional impairment secondary to alterations in joint function. Recently an alternative approach to treat patients withRA has been suggested. This involves the initiation of therapy with multiple agents early in the course of disease in an attempt to control inflammation, followed by maintenance on one or more agents as necessary to control disease activity. The effectiveness of this therapeutic alternative has not been proved.

313. SYSTEMIC SCLEROSIS (SCLERODERMA) - *Bruce C. Gilliland*

DEFINITION

Systemic sclerosis (SSc) is a chronic multisystem disorder of unknown etiology characterized clinically by thickening of the skin caused by accumulation of connective tissue and by involvement of visceral organs, including the gastrointestinal tract, lungs, heart, and kidneys. Classification of SSc and sclerodermal-like disorders is shown in (Table 313-1). Vascular abnormalities, especially of the microvasculature are a prominent feature of SSc. The degree and rate of skin and internal organ involvement vary among patients. Two subsets, however, can be identified, even though there is some overlap (Table 313-2). One subset is referred to as *diffuse cutaneous scleroderma* and is characterized by the rapid development of symmetric skin thickening of proximal and distal extremities, face, and trunk. These patients are at greater risk for developing kidney and other visceral disease early in their course. The other subset is *limited cutaneous scleroderma*, which is defined by symmetric skin thickening limited to distal extremities and face. This subset frequently has features of the *CREST syndrome*, standing for *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia. The prognosis in limited cutaneous scleroderma is better except for those patients who, after many years, develop pulmonary arterial hypertension or biliary cirrhosis. Involvement of visceral organs may also occur in the absence of any skin involvement, which is referred to as *systemic sclerosis sine scleroderma*. Survival is determined by the severity of visceral disease, especially involving the lungs, heart, and/or kidneys.

Preliminary criteria for the classification of systemic sclerosis were developed by the American Rheumatism Association (now called the American College of Rheumatology) for the purpose of uniformity in clinical studies. A major criterion was the presence of sclerodermatous skin changes of the fingers of both hands plus involvement at any location proximal to the metacarpal phalangeal joints, entire extremity, face, neck, chest, and abdomen. Minor criteria were sclerodactyly, digital pitting scars or tissue loss of the volar pads of the fingertips, and bibasilar pulmonary fibrosis. The diagnosis ofSSc was based on the presence of the major criterion or two or more minor criteria. The sensitivity of these criteria was 97%, and the specificity 98%. These criteria are not, however, applicable to clinical practice as many patients have SSc who do not meet these criteria. Scleroderma can also occur in a localized form limited to the skin, subcutaneous tissue, and muscle and without systemic involvement. Localized scleroderma occurs most often in children and young women but can affect any age group. The two localized forms are *morphea*, which occurs as single or multiple plaques of skin induration, and *linear scleroderma*, which involves an extremity or face. Linear scleroderma of one side of the forehead and scalp produces a disfiguration referred to as *en coup de sabre* because it resembles a wound from a sword. It may be associated with hemiatrophy of the same side of the face.

SScalso occurs in association with features of other connective tissue diseases. The term *overlap syndrome* has been used to describe such patients. Undifferentiated connective tissue disease has been suggested as a designation for patients who do not have diagnostic criteria for any one connective tissue disease. *Mixed connective tissue disease* (MCTD), a syndrome involving features of systemic lupus erythematosus (SLE),

SSc, polymyositis, and rheumatoid arthritis and very high titers of circulating antibody to nuclear ribonucleoprotein (RNP) antigen, will be discussed later in the chapter. *Eosinophilic fasciitis* and the *eosinophilia-myalgia syndrome* (EMS) associated with contaminated L-tryptophan ingestion (Chap. 382) are scleroderma-like illnesses and will also be discussed in this chapter.

EPIDEMIOLOGY

SScha has a worldwide distribution and affects all races. The onset of disease is unusual in childhood and young men. The incidence increases with age, peaking in the third to fifth decade. Women overall are affected approximately three times as often as men and even more often during the late childbearing years (³8:1). SSc is more frequent and severe in young black women. The annual incidence has been estimated to be 19 cases per million population. The reported prevalence of SSc is between 19 and 75 per 100,000 persons. An exceptionally high prevalence of SSc (472 per 100,000 persons) has been noted in the Choctaw Native Americans in Oklahoma -- the highest found to date in any ethnic group. Both incidence and prevalence may be underestimated because patients with early and atypical disease may be overlooked in surveys. The role of heredity has not been clarified. Several examples of familial SSc have been reported, and the finding of other connective tissue diseases and antinuclear antibodies in relatives of involved patients suggests a hereditary predisposition. However, spouses of SSc patients also have an increased incidence of antinuclear antibodies, suggesting environmental factors. Discordance of SSc in identical twins speaks against a significant genetic predisposition to disease. Immunogenetic studies have not shown strong associations between the major histocompatibility complex and susceptibility to SSc. Some studies have shown an association of SSc with HLA-A1, -B8, -DR3, or with DR3/DR52. C4A null alleles (C4AQ0) and HLA-DQA2 have been reported by some investigators to be markers for disease susceptibility. A more consistent relationship has been found between certain HLA types and the occurrence of specific autoantibodies in SSc patients. Anticentromere antibodies have been shown to be associated with HLA-DQB1*05 allele and, less often, with -DQB1*0301, -*0401, or -*0402. Antitopoisomerase 1 antibodies, on the other hand, are associated most frequently with HLA-DQB1*0301 in several populations, including Caucasians and African Americans.

Several environmental factors have been associated with the development ofSSc and scleroderma-like illnesses. SSc appears to be more common in coal and gold miners, especially in those with more extensive exposure, suggesting that silica dust may be a predisposing factor. Workers exposed to polyvinyl chloride may develop Raynaud's phenomenon, acroosteolysis, scleroderma-like skin lesions, pulmonary fibrosis, and nail fold capillary abnormalities similar to those observed in SSc. These workers may also develop hepatic fibrosis and angiosarcoma. The observation that individuals exposed to similar amounts of vinyl chloride do not develop the same degree of disease suggests that a genetic factor may determine susceptibility and disease severity. The development of scleroderma has also been associated with exposure to epoxy resins and aromatic hydrocarbons such as benzine, toluene, and trichloroethylene. In 1981, in Spain, a multisystem disease resembling scleroderma occurred following the ingestion of aniline-adulterated cooking oil (rapeseed oil). Approximately 20,000 people were affected. The patients initially developed interstitial pneumonitis, eosinophilia, arthralgias, arthritis, and myositis, followed subsequently by joint contractures, skin

thickening, Raynaud's phenomenon, pulmonary hypertension, sicca syndrome, and resorption of the distal fingertips. Extensive sclerosis of the dermis and subcutaneous tissue has been noted in patients receiving pentazocine, a nonnarcotic analgesic agent. Bleomycin, an anticancer agent, produces fibrotic skin nodules, linear hyperpigmentation, alopecia, Raynaud's phenomenon, gangrene of fingers, and pulmonary fibrosis affecting mainly the lower lobes. Scleroderma and other connective tissue diseases have been reported in women who have had silicone breast implants. Recent studies have not shown that women with these implants carry an increased risk for developing scleroderma or other connective tissue diseases. Localized fibrosis, however, can occur around the implant. While environmental factors or undefined infectious agents may be of etiologic significance, the cause of SSc remains unknown.

PATHOGENESIS

The outstanding feature ofSSc is overproduction and accumulation of collagen and other extracellular matrix proteins, including fibronectin, tenascin, and glycosaminoglycans, in skin and other organs. The disease process involves immunologic mechanisms, vascular endothelial cell activation and/or injury, and activation of fibroblasts resulting in production of excessive collagen.

An early event inSSc that precedes fibrosis is vascular injury involving small arteries, arterioles, and capillaries in the skin, gastrointestinal tract, kidneys, heart, and lungs. Raynaud's phenomenon, the initial symptom of SSc in the majority of patients, is a clinical expression of the abnormal regulation of blood flow resulting from vascular injury. Injury to endothelial cells and basal lamina occurs early and is followed by thickening of the intima, narrowing of the lumen, and eventual obliteration of the vessel. As vascular damage progresses, the microvascular bed in the skin and other sites is diminished, producing a state of chronic ischemia. Vascular abnormalities can be observed in the nail folds by wide-field microscopy, which shows drop-out of capillaries with dilatation and tortuosity of remaining ones. In the skin, remaining capillaries may proliferate and dilate to become visible telangiectasia. Endothelial cell damage is reflected in elevated levels of factor VIII/von Willebrand factor in the sera of some patients with SSc.

Several mechanisms for endothelial injury or activation have been proposed inSSc. Any or all of these mechanisms may be involved in a given patient; some evidence for each exists. A cytotoxic factor for endothelium has been identified in some patients that degrades the basal lamina, releasing fragments of type IV collagen and laminin. This factor, a type IV collagenase, is secreted by activated T cells and is referred to as *granzyme 1* because of its location in cytolytic T cells. Type IV collagen and laminin fragments may stimulate an immune response to the basal lamina. Both antibodies and cell-mediated immunity to type IV collagen and laminin have been observed in some SSc patients and may be involved in endothelial injury or may be an epiphenomenon. Anti-endothelial cell antibodies (AECA) may be another mechanism for microvascular damage. In 25% of SSc patients, AECA have been shown to mediate antibody-dependent cell cytotoxicity against human endothelial cells. Circulating AECA in general have been reported in the sera of SSc patients in amounts ranging from 21 to 85%. This wide variation reflects patient selection, type of assay, and the source of endothelium. These antibodies are not specific for SSc and are found in other

connective tissue diseases. The frequency of AECA is higher in patients with diffuse cutaneous SSc. They have also been shown to be associated with digital infarcts, pulmonary hypertension, and impaired alveolocapillary diffusion. Studies have show that AECA initiate programmed cell death (apoptosis), which may be an important event in the pathogenesis of SSc. These antibodies also induce expression of vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1), E-selectin, and P-selectin on endothelial cells in SSc and stimulate the production of chemoattractants [interleukin (IL) 1, IL-8, monocyte chemotactic protein], leading to the binding of lymphocytes to the endothelium and their migration into the perivascular tissue. Elevated serum levels of VCAM-1, ICAM-1, and P-selectin are observed in early stages of SSc.

The injury to the endothelium leads to a state favoring vasoconstriction and ischemia. The damaged endothelium produces decreased amounts of prostacylin, which is an important vasodilator and inhibitor of platelet aggregation. Platelets are activated on binding to the damaged endothelium and release thromboxane, a potent vasoconstrictor. Activated platelets also release platelet-derived growth factor (PDGF), which is chemotactic and mitogenic for both smooth-muscle cells and fibroblasts, and transforming growth factor (TGF)b, which stimulates fibroblast collagen synthesis. These and other cytokines stimulate intimal fibrosis and, with their passage through the injured endothelium, may produce adventitial and perivascular fibrosis. Endothelin-1, a vasoconstricting factor released from endothelial cells on cold exposure, is also increased in SSc patients. In addition, it stimulates fibroblasts and smooth-muscle cells. The vasoconstriction action of endothelin-1 is normally opposed by endothelium-derived relaxation factor (EDRF, nitric oxide), also secreted by endothelial cells. The normal compensatory increase in EDRF is not seen in some patients withSSc, suggesting impairment of its synthesis. A deficiency of vasodilatory neuropeptides resulting from sensory system nerve damage may also produce a condition favoring vasoconstriction. Vasoconstriction itself also contributes to endothelial damage through a mechanism of reperfusion injury, resulting in vascular occlusion and fibrosis.

Existing evidence indicates that cell-mediated immunity plays a central role in the development of fibrosis inSSc. T cells, macrophages, endothelial cells, and other cells along with cytokines and growth factors interact in a complex manner to stimulate fibrosis. The vascular endothelium has been proposed as a target for cell-mediated immunity. Laminin and type IV collagen, components of the subendothelial basement membrane, induce in vitro transformation of lymphocytes from SSc patients. In the early stages of SSc, a mononuclear cell infiltrate consisting predominantly of activated helper-inducer T cells surrounds small blood vessels in the dermis. Subsequently, mononuclear cell infiltrates are found in macroscopically normal-appearing skin adjacent to areas of fibrosis. T cell hyperactivity is reflected by increased serum levels of CD4+ T cells. The ratio of CD4+ to CD8+ T cells is also increased. Elevated circulating levels ofIL-2, a product of activated T cells, and IL-2 receptors have been shown to be associated with active fibrosis. In addition, serum levels of IL-4 are increased in SSc patients. IL-4, a product of activated T cells, stimulates fibroblast chemotaxis and proliferation and collagen production. In a recent study, CD8+ T cells isolated from bronchoalveolar lavage fluid from SSc patients made IL-4 and/or IL-5 mRNA. SSc patients with these type 2 cytokines were more likely to have alveolitis and a lower forced vital capacity. Although larger studies are needed, the findings suggest that these

cytokines are involved in the pathogenesis of interstitial pulmonary fibrosis. Another cytokine, interferong, is produced by activated T cells and stimulates macrophages but inhibits collagen synthesis by fibroblasts. Reduced serum levels of interferon g are found in some SSc patients. In vitro stimulation of T cells from SSc patients did not show an increased production of interferon g compared to normal individuals, suggesting an inability in SSc patients to suppress fibrosis normally.

Macrophages are present in increased numbers in the infiltrates ofSSclesions, including the pulmonary alveoli. Activated macrophages secrete several important products involved in the pathogenesis of SSc includingIL-1, IL-6, tumor necrosis factor (TNF) a,TGF-b, andPDGF. IL-1 has been shown to stimulate fibroblast proliferation and collagen synthesis. The important role for IL-6 may be in stimulating the local release of tissue inhibitor of metalloproteinase (TIMP) by fibroblasts and thereby limiting the breakdown of collagen. TNF-a, in conjunction with interferon g, can cause endothelial cell cytolysis and also induces the expression of endothelial cell adhesion molecules (see above), which are responsible for the binding of T cells and subsequent vascular injury. The role of TGF-b and PDGF secreted by macrophages and other cells is discussed below. In addition to the above cytokines, macrophages secrete *fibronectin*, a large matrix protein that is increased in SSc lesions. Fibronectin is also secreted by fibroblasts. Fibronectin interacts with collagen in the SSc lesions where it binds fibroblasts and mononuclear cells through receptors called *integrins*. Fibronectin functions as a chemoattractant and mitogen for fibroblasts.

Additional support for involvement of cell-mediated immunity in the pathogenesis ofSSc is the appearance of scleroderma-like lesions in patients with graft-versus-host disease (GVHD) after bone marrow transplantation and in a murine model of chronic GVHD, conditions known to be associated with activated T cells. GVHD and SSc are both associated with progressive skin induration, joint contractures, and gastrointestinal and pulmonary involvement and are frequently accompanied by Sjogren's syndrome. Antinuclear antibodies are present in both diseases. Raynaud's phenomenon and kidney involvement are infrequent in GVHD.

Mast cells may also be involved in the development of fibrosis. Increased numbers of mast cells are found in the dermis in both involved and uninvolved skin. Mast cell degranulation has been noted in skin that subsequently became fibrosed. Interaction with T cells may be one mechanism for mast cell degranulation resulting in release of products that stimulate fibroblast collagen synthesis. Release of histamine from mast cells may also contribute to edema observed in early disease.

Fibroblast growth and synthesis of collagen, fibronectin, and glycosaminoglycans are increased inSSc. Fibroblasts from SSc appear to have aberrant regulation of growth compared with fibroblasts from normal persons. When fibroblasts from affected SSc skin are removed and cultured in vitro, they continue to produce excessive quantities of collagen. The collagen is biochemically normal, and the proportion of type I to type III is the same as in normal skin. Fibroblasts from SSc patients appear to be in a state of permanent activation, most likely as a result of stimulation by cytokines. These activated cells are thought to represent an expanded subpopulation of fibroblasts that inherently express increased matrix genes. Studies have revealed a subpopulation of SSc fibroblasts that produces two to three times more collagen than other cells from the

same tissue. Fibroblasts expressing elevated levels of mRNA for types I and III collagen have been demonstrated by in situ hybridization, particularly around dermal blood vessels in affected SSc skin. Collagen deposition is also initially perivascular in other organs including myocardium, muscle, and kidney. A small number of fibroblasts express increased levels of mRNA for types VI and VII collagen. Type VII collagen is normally found at the dermal-epidermal basement membrane zone and is the major component of anchoring fibrils that act to stabilize the attachment of the basement membrane to the underlying dermis. In SSc patients, type VII collagen is found throughout the dermis and may account for the indurated, tightly bound skin in this disease.PDGFreceptors are expressed on SSc fibroblasts not only from affected areas but also from macroscopically normal-appearing skin. Fibroblasts from normal persons lack expression of these receptors.TGF-bhas been shown to upregulate the expression of these receptors in SSc fibroblasts but not in normal cells and, in conjunction with PDGF, stimulates SSc fibroblast proliferation. Macrophages and fibroblasts are capable of secreting PDGF and TGF-b, and activated T cells release TGF-b. TGF-b also induces the autocrine production of PDGF-related peptides, referred to as connective tissue growth factor (CTGF), by fibroblasts. TGF-b interacts with CTGF on fibroblasts to stimulate fibroblast proliferation and collagen synthesis. Serum levels of CTGF have been found to be elevated in SSc and correlate with the degree of dermal and pulmonary fibrosis.

Fibroblasts may activate T cells to release cytokines that stimulate fibrosis. Fibroblasts inSScpatients have been shown to have increased expression of an adhesion molecule,ICAM-1, which binds to specific integrins on T cells. This binding allows interaction between T cell antigen receptor and class II molecules and antigen on fibroblasts, resulting in T cell activation and cytokine release. T cells may also be activated by their interaction with extracellular matrix molecules including collagen, fibronectin, and laminin.

Recent studies have suggested that microchimerism may be involved in the pathogenesis ofSSc. Microchimerism in SSc is of interest because of the clinical similarities between SSc andGVHDafter allogeneic bone marrow transplantation. Also relevant are the predilection for women in SSc and the increased incidence of SSc in women after the childbearing years. Fetal progenitor cells can persist in the serum of normal women for many years after childbirth. Compared to normal controls, both the quantity and frequency of fetal cells have been found to be increased in the serum of SSc patients. Microchimerism can also occur in nulligravid women and in men with SSc as non-host cells may come from blood transfusion, engraftment of cells from a twin, or from maternal cells in utero. Two-directional traffic of cells occurs during pregnancy. The mechanism by which microchimerism is involved in the pathogenesis is not known, but it is conceivable that these small numbers of non-host cells interfere with immune regulation, leading to autoimmunity.

Chromosomal abnormalities have been noted in >90% ofSScpatients. These acquired abnormalities include chromatid breaks, acentric fragments, and ring chromosomes and are found in ~30% of mitotic cells. A chromosomal breakage factor has been found in the serum of SSc patients and their first-degree relatives. The significance of these chromosomal abnormalities is unknown.

PATHOLOGY

Skin In the skin, a thin epidermis overlies compact bundles of collagen that lie parallel to the epidermis. Fingerlike projections of collagen extend from the dermis into the subcutaneous tissue and bind the skin to the underlying tissue. Dermal appendages are atrophied, and rete pegs are lost. In early stages of disease, a mononuclear cell infiltrate of predominantly T cells surrounds small dermal blood vessels. Increased numbers of T cells, monocytes, plasma cells, and mast cells are found, particularly in the lower dermis of involved skin.

Gastrointestinal Tract In the lower two-thirds of the esophagus, the histologic findings consist of a thin mucosa and increased collagen in the lamina propria, submucosa, and serosa. The degree of fibrosis is less than in the skin. Atrophy of the muscularis in the esophagus and throughout the involved portions of the gastrointestinal tract is more prominent than the amount of fibrotic replacement of muscle. Ulceration of the mucosa is often present and may be due to eitherSSc or superimposed peptic esophagitis. Chronic esophageal reflux can lead to metaplasia of the lower esophagus (Barrett's esophagus), which is a premalignant lesion. Striated muscles in the upper third of the esophagus are relatively spared. Similar changes may be found throughout the gastrointestinal tract, especially in the second and third portions of the duodenum, in the jejunum, and in the large intestine. Atrophy of the muscularis of the large intestine may lead to the development of large-mouth diverticula. In the later stages of the disease, the involved portions of the gastrointestinal tract become dilated. Infiltration of lymphocytes and plasma cells in the lamina propria is also present.

Lung With pulmonary involvement, diffuse interstitial fibrosis, thickening of the alveolar membrane, and peribronchial and pleural fibrosis are observed. Bronchiolar epithelial proliferation accompanies the pulmonary fibrosis. Rupture of septa produces small cysts and areas of bullous emphysema. Small pulmonary arteries and arterioles show intimal thickening, fragmentation of the elastica, and muscular hypertrophy; this may occur without interstitial pulmonary fibrosis and produce pulmonary hypertension, particularly in a subset of patients with limited cutaneousSSc.

Musculoskeletal System The synovium in patients with arthritis is similar to that seen in early rheumatoid arthritis and shows edema with infiltration of lymphocytes and plasma cells. A characteristic finding is a thick layer of fibrin overlying and within the synovium. Later in the disease the synovium may become fibrotic. Fibrinous deposits appear on the surfaces of tendon sheaths and in the overlying fascia and may lead to audible creaking over moving tendons.

Histologic features of primary myopathy consist of interstitial and perivascular lymphocytic infiltrations, degeneration of muscle fibers, and interstitial fibrosis. Arterioles may be thickened, and capillaries may be decreased in number. Pathologic and electrophysiologic findings of polymyositis in proximal muscles are present in the few patients who are considered to have the overlap syndrome ofSSc and polymyositis.

Heart Cardiac involvement consists of degeneration of myocardial fibers and irregular areas of interstitial fibrosis that are most prominent around blood vessels. Intermittent spasm of blood vessels may result in contraction band necrosis, similar to change

observed in myocardial infarction in patients with atherosclerotic coronary artery disease. Fibrosis also involves the conduction system, leading to atrioventricular conduction defects and arrhythmias. The wall of smaller coronary arteries may be thickened. Fibrinous pericarditis and pericardial effusions are found in some patients.

Kidney Renal involvement is found in over half the patients and consists of intimal hyperplasia of the interlobular arteries; fibrinoid necrosis of the afferent arterioles, including the glomerular tuft; and thickening of the glomerular basement membrane. Small cortical infarctions and glomerulosclerosis may be present. The renal pathologic change is often indistinguishable from that observed in malignant hypertension. Renal vascular lesions, however, may be present in the absence of hypertension. Immunofluorescence studies of kidney have shown IgM, complement components, and fibrinogen in the walls of affected vessels. Angiographic renal studies in patients withSSc may show constriction of the intralobular arteries, a finding that simulates the vasospasm of the digital arteries observed in Raynaud's phenomenon. Cold-induced Raynaud's phenomenon has been shown to decrease renal blood flow.

Other Organs Primary liver involvement is not common. Primary biliary cirrhosis occurs in some patients, particularly in those with the limited cutaneous form ofSSc. Fibrosis of the thyroid gland may develop in the presence or absence of autoimmune thyroiditis.

Thickening of the periodontal membrane with replacement of the lamina dura is demonstrated radiographically as widening of the periodontal space and may cause gingivitis and loosening of the teeth. The decreased oral aperture and mucosal dryness make eating and oral hygiene difficult.

CLINICAL MANIFESTATIONS (See Table 313-3)

Raynaud's Phenomenon SScusually begins insidiously; the first symptoms are frequently Raynaud's phenomenon and puffy fingers. Some 95% of patients will experience Raynaud's phenomenon, which is defined as episodic vasoconstriction of small arteries and arterioles of fingers, toes, and sometimes the tip of the nose and earlobes. Episodes are brought on by cold exposure, vibration, or emotional stress. Patients experience pallor and/or cyanosis followed by rubor on rewarming. Pallor and/or cyanosis are usually associated with coldness and numbness of fingers and/or toes, and rubor with pain and tingling. Not all patients appreciate the three color phases. A history of digit pallor appears to be the most reliable symptom for the presence of Raynaud's phenomenon. Raynaud's phenomenon may precede skin changes by several months or even years in those patients who subsequently develop the limited cutaneous form of SSc. In diffuse cutaneous SSc, skin changes are seen typically within a year of the onset of Raynaud's phenomenon. After 2 or more years of Raynaud's phenomenon, few patients who have this as their only symptom will subsequently develop SSc.

Skin Features In early disease, fingers and hands are swollen. Swelling may also involve forearms, feet, lower legs, and face. However, lower extremities are relatively spared. This edematous phase may last for a few weeks, months, or even longer. The edema may be pitting or nonpitting and accompanied by erythema. The skin changes begin distally in the extremities and advance proximally. The skin gradually becomes

firm, thickened, and eventually tightly bound to underlying subcutaneous tissue (indurative phase). In patients with diffuse cutaneous scleroderma, skin changes will become generalized, involving initially the extremities, followed by the face and trunk over a period of time, varying from months to a few years. In some patients, the skin changes may develop gradually over several years. Rapid progression of these changes over a 1- to 3-year period is associated with a greater risk of visceral disease, particularly of the lungs, heart, or kidneys. Also in diffuse cutaneousSSc, the skin changes usually peak in 3 to 5 years and then slowly improve. On the other hand, patients with limited cutaneous scleroderma will usually have a more gradual progression of skin changes, which are restricted to fingers or distal extremity and face and may continue to worsen. In both subsets of SSc, skin thickening is usually greater in the distal extremity. After many years of disease, the skin may soften and return to normal thickness or become thin and atrophic.

In the extremities, the taut skin over fingers gradually limits full extension, and flexion contractures develop. Ulcers may appear on the volar pads of the fingertips and over bony prominences such as elbows, malleoli, and the extensor surface of the proximal interphalangeal joints of the hands. These ulcers may become secondarily infected. The volar pads of the fingertips develop pitting scars and lose soft tissue. In some instances, resorption of the terminal phalanges occurs. Skin over the extremities, face, and trunk may become darkly pigmented, even without exposure to the sun. Hyperpigmentation of the skin may occur over superficial blood vessels and tendons. Areas of hypopigmentation may also develop, similar to vitiligo, involving the eyebrows, scalp, and trunk. The sparing of pigment around hair follicles gives the skin a "salt-and-pepper" appearance. Other patients may develop a diffuse tanning of the skin. The skin loses hair, oil, and sweat glands and so becomes dry and coarse. Vaginal dryness occurs and may cause dyspareunia.

In some patients, particularly those with the limited cutaneous form of disease, calcific deposits develop in intracutaneous and subcutaneous tissue. The sites commonly involved are periarticular tissue, digital pads, olecranon and prepatellar bursae, and skin along the extensor surface of the forearms. The overlying skin may break down, with drainage of calcific material. Involvement of the face results in thinning of the lips, loss of skin wrinkles and facial expression, as well as microstomia, which may make eating and dental hygiene difficult. The nose takes on a pinched or beaklike appearance. Wrinkles appear around the mouth perpendicular to the lips. Small telangiectatic mats may appear on the fingers, face, lips, tongue, and buccal mucosa after several years. They are seen more frequently in patients with limited cutaneousSSc but are also observed in patients with long-standing diffuse cutaneous SSc. The capillary beds of nail folds of the fingers may show enlargement of capillaries with little or no capillary loss, usually indicative of limited cutaneous scleroderma. In diffuse cutaneous scleroderma, there is disorganization of the capillary beds with dilated capillaries interspersed with areas where capillaries have disappeared. These capillary changes, which are observed by wide-angle microscopy or with an ophthalmoscope used as a magnifier, are not found in patients who have only Raynaud's phenomenon.

Musculoskeletal Features More than half the patients withSSccomplain of pain, swelling, and stiffness of the fingers and knees. A symmetric polyarthritis resembling rheumatoid arthritis may be seen. In more advanced stages of the disease, leathery

crepitation can be palpated over moving joints, especially the knee. Extensive fibrotic thickening of the tendon sheaths in the wrist can produce a carpal tunnel syndrome. Muscle weakness is usually present in patients with severe skin involvement and, in most cases, is due to disuse atrophy. There is a distinctive histologic myopathy that accompanies SSc that is not associated with muscle enzyme abnormalities. A few patients develop a myositis characterized by proximal muscle weakness and muscle enzyme elevations that are identical to polymyositis (overlap syndrome). In addition to terminal phalanges, resorption of bone may involve ribs, clavicle, and angle of mandible.

Gastrointestinal Features The majority of patients from both subsets ofSSc have gastrointestinal involvement. Symptoms attributable to esophageal involvement are present in >50% of patients and include epigastric fullness, burning pain in the epigastric or retrosternal regions, and regurgitation of gastric contents. These symptoms, most noticeable when the patient is lying flat or bending over, are due to the reduced tone of the gastroesophageal sphincter and to dilatation of the distal esophagus. Peptic esophagitis frequently occurs and may lead to strictures and narrowing of the lower esophagus. However, it seldom results in bleeding. Barrett's metaplasia may develop, but transition to adenocarcinoma is uncommon. Dysphagia, particularly of solid foods, may occur independent of other esophageal symptoms and is caused by loss of esophageal motility due to neuromuscular dysfunction. Manometry or cineradiography reveals decreased amplitude or disappearance of peristaltic waves in the lower two-thirds of the esophagus. Raynaud's phenomenon in the absence of a connective tissue disease is also associated with esophageal dysmotility. Later in the course of the illness, dilatation and atony of the lower portion of the esophagus as well as reflux are seen. With gastric involvement, barium studies show dilatation, atony, and delayed gastric emptying. Patients may complain of early satiety. Gastric outlet obstruction can also occur.

Hypomotility of the small intestine produces symptoms of bloating and abdominal pain and may suggest an intestinal obstruction or paralytic ileus (pseudoobstruction). Malabsorption syndrome with weight loss, diarrhea, and anemia is due to bacterial overgrowth in the atonic intestine or possibly to obliteration of lymphatics by fibrosis. Roentgenographic features of the second and third portions of the duodenum and of the jejunum include dilatation, loss of the usual feathery pattern, and delayed disappearance of barium. Pneumatosis intestinalis occasionally occurs and appears as radiolucent cysts or linear streaks within the wall of the small intestine. Benign pneumoperitoneum may result from the rupture of these cysts. Involvement of the large intestine may cause chronic constipation and fecal impaction with episodes of bowel obstruction. A segment of atonic bowel may act as a fulcrum for intussuception to occur. Barium studies of the large intestine may show dilatation, atony, and large-mouth diverticula. Laxity of the anal sphincter may cause incontinence or rarely anal prolapse. Some patients may have gastrointestinal features ofSSc with little or no cutaneous or other organ involvement, referred to as *SSc sine scleroderma*. Vascular ectasia may develop in the stomach and intestine and can be the source of gastrointestinal bleeding. These dilated submucosal capillaries in the stomach appear on endoscopy as broad stripes -- hence the term "watermelon stomach."

Pulmonary Features Pulmonary involvement occurs in at least two-thirds ofSScpatients and is now the leading cause of death in SSc, replacing renal disease,

which can usually be treated effectively. The most common symptom is exertional dyspnea, often accompanied by a dry, nonproductive cough. Bilateral basilar rales may be present. In the majority of patients, symptoms usually correlate with radiologic evidence of pulmonary fibrosis and with restrictive lung disease on pulmonary function tests.

Pulmonary function tests are frequently abnormal and show a reduction in vital capacity and decreased lung compliance. Impairment of gas exchange is reflected by a low diffusing capacity and low P_{O2} with exercise. These abnormalities may be present even when the chest radiograph is normal. Chest film may show a pattern of linear densities, mottling, and honeycombing involving most prominently the lower two-thirds of the lung. Early interstitial pulmonary disease can be detected by high-resolution computed tomography (HRCT) and bronchoalveolar lavage (BAL). Active inflammatory alveolitis gives a "ground glass" appearance on HRCT. The recovery by BAL of increased numbers of cells, mostly alveolar macrophages accompanied by neutrophils or eosinophils, is evidence for alveolitis.

Both interstitial fibrosis and vascular lesions are found in the lungs of patients withSSc. Interstitial pulmonary fibrosis may be the predominant lesion in patients with diffuse or limited cutaneous SSc. Patients with diffuse cutaneous involvement who have antitopoisomerase 1 antibodies are particularly at risk of developing severe pulmonary fibrosis. In the absence of significant interstitial fibrosis, a severe form of pulmonary arterial hypertension may develop after many years of disease in a subset of patients with limited cutaneous SSc. Fewer than 10% of patients will develop this complication, which is caused by narrowing and obliteration of pulmonary arteries and arterioles by intimal fibrosis and medial hypertrophy. Pulmonary hypertension is manifested initially by exertional dyspnea and eventually by the appearance of right-sided heart failure. Pulmonary artery pressure can be measured noninvasively by two-dimensional echocardiography. The prognosis is extremely poor with the development of pulmonary hypertension; the mean duration of survival is approximately 2 years.

A less common pulmonary problem is aspiration pneumonia resulting from gastric reflux due to lower esophageal atony. Restriction of chest movement caused by extensive fibrotic skin involvement of the thorax rarely occurs. Superimposed bacterial or viral infection can be a serious complication in patients with pulmonary fibrosis. An increased frequency of alveolar cell and bronchogenic carcinoma is seen in patients with pulmonary fibrosis.

Cardiac Features Primary cardiac involvement inSScincludes pericarditis with or without effusions, heart failure, and varying degrees of heart block or arrhythmias. The majority of patients with diffuse cutaneous SSc have cardiac abnormalities. Cardiomyopathy attributable to myocardial fibrosis appears in <10% of patients and involves primarily those patients with diffuse cutaneous scleroderma. Radionuclide studies have shown abnormalities of left ventricular function due to myocardial fibrosis. Cold-induced vasospasm of the hands produces defects in myocardial thallium perfusion. The characteristic pathologic feature of contraction band necrosis results from cardiac muscle damage caused by intermittent vasospasm of coronary vessels. Patients may experience angina pectoris even though coronary angiograms are normal. Patients can also develop left ventricular failure secondary to systemic hypertension or

cor pulmonale secondary to pulmonary arterial hypertension.

Renal Features Renal failure was the leading cause of death inSScuntil the advent of effective treatment. Significant renal disease occurs mostly in those patients with diffuse cutaneous scleroderma. A high risk of renal crisis is present in those patients who have rapidly progressive widespread skin thickening in their first 2 to 3 years of disease. Renal crisis is characterized by malignant hypertension, which can progress rapidly to renal failure. These patients manifest hypertensive encephalopathy, severe headache, retinopathy, seizures, and left ventricular failure. Hematuria and proteinuria are followed by oliguria and renal failure. The mechanism for the hypertensive crisis is activation of the renin-angiotensin system. Before the advent of effective antihypertensive drugs, the majority of these patients died within 6 months. A small number of patients may develop renal crises in the absence of hypertension. Renal failure can also develop insidiously later in the course of disease in the setting of mild to moderate hypertension and proteinuria. In these patients or those with clinically unrecognized renal disease, reduction of renal plasma flow secondary to heart failure or volume depletion resulting from overdiuresis may precipitate renal crisis. An indicator of impending renal failure is microangiopathic anemia, which may occur in a normotensive patient. The presence of a large chronic pericardial effusion may also herald subsequent renal failure.

Other Features Symptoms of dry eyes and/or dry mouth are frequently present in patients withSSc. Lip biopsy may show lymphocytic infiltration of minor salivary glands characteristic of Sjogren's syndrome or intraglandular or periglandular fibrosis secondary to SSc. Antibodies to SS-A (Ro) and/or SS-B (La) are found in those patients with lip biopsies consistent with Sjogren's syndrome (overlap syndrome-SSc and Sjogren's syndrome) and not in those with salivary gland fibrosis.

Hypothyroidism occurs in a significant number of patients and may be associated with high levels of antithyroid antibodies. Fibrosis of the thyroid gland may be present but also occurs in the absence of autoimmune thyroiditis. Other manifestations ofSScinclude trigeminal neuralgia and male impotence secondary to decreased penile tumescence. These men have normal serum levels of testosterone and gonadotropins. Pathogenesis of this abnormality has been considered to be caused by vascular and/or autonomic nervous system abnormalities. Biliary cirrhosis is occasionally observed in patients with limited cutaneous SSc.

LABORATORY FINDINGS

The erythrocyte sedimentation rate may be elevated. Hypoproliferative anemia related to chronic inflammation is the most common cause of anemia inSSc. Anemia may also be caused by iron deficiency secondary to gastrointestinal bleeding. Bacterial overgrowth due to atony of the small bowel may lead to vitamin $B_{12}$and/or folic acid-deficiency anemia. Microangiopathic hemolytic anemia is most often associated with renal involvement and is caused by the presence of intravascular fibrin in renal arterioles. Polyclonal hypergammaglobulinemia, consisting mostly of IgG, is found in approximately half the patients. Rheumatoid factor, in low titer, is present in 25% of patients. Cryoglobulins may be present in the serum. Antinuclear antibodies detected by using a cultured human laryngeal carcinoma cell line (HEp-2) substrate are present in 95% of patients (Table 313-4). Antinuclear antibodies that have a high specificity for

SSc are antitopoisomerase 1 (Scl-70), antinucleolar, and anticentromere. Antitopoisomerase 1, originally called anti-Scl-70, recognizes the nuclear enzyme DNA topoisomerase 1, a nuclear enzyme involved in the unwinding of DNA for replication and RNA transcription. These antibodies are found in ~20% of all SSc patients and in ~40% of those with diffuse cutaneous SSc. They are associated with diffuse cutaneous involvement, interstitial pulmonary disease, and renal and other visceral organ involvement. A very high frequency of these antibodies has been reported in Choctaw Native Americans in association with diffuse cutaneous SSc. They are seldom present in other disorders or in conjunction with anticentromere antibodies. Anticentromere antibodies react with protein antigens located in the kinetochore region of chromosomes and are present in 40 to 80% of patients with limited cutaneous scleroderma or CREST syndrome. Anticentromere antibodies are found in only about 2 to 5% of patients with diffuse cutaneous scleroderma and rarely in other connective tissue diseases. They are found occasionally in patients with only Raynaud's phenomenon and may indicate subsequent development of limited cutaneous disease. Antinucleolar antibodies are relatively specific for SSc and are present in ~20 to 30% of patients. Several antinucleolar antibodies have been associated with SSc: Anti-RNA polymerases I, II, and III are found in patients with diffuse cutaneous SSc who have a higher prevalence of renal and cardiac involvement. Anti-ThRNP has been found in patients with limited cutaneous SSc, and anti-PM-Scl, formerly referred to as anti-PM1, along with anti-Ku, may be found in a subset of patients with overlapping features of limited cutaneous SSc and polymyositis. Anti-U_3RNP (anti-fibrillarin) is also highly specific for SSc and may be associated with skeletal muscle disease, bowel involvement, and pulmonary arterial hypertension. Anti-U_1RNP is found in ~5 to 10% of SSc patients and in 95 to 100% of those patients with the overlap syndrome ofMCTD. The titers in MCTD are usually high (see below). Anti-SS-A (Ro) and/or anti-SS-B (La) are present in those patients with overlap syndrome of SSc and Sjogren's syndrome.

DIAGNOSIS

The diagnosis ofSScpresents no difficulty in the presence of Raynaud's phenomenon, with typical skin lesions and visceral involvement. Although Raynaud's phenomenon may be the first symptom of SSc, most patients with Raynaud's phenomenon alone do not develop a connective tissue disease. Other causes of Raynaud's phenomenon include thoracic outlet (scalenus anticus and cervical rib) syndromes, shoulder-hand syndrome, trauma (jackhammer or vibratory machine operators), previous cold injury, vinyl chloride exposure, and circulating cryoglobulins or cold agglutinins. Linear scleroderma and morphea are localized forms of scleroderma that can usually be distinguished clinically. In early disease, SSc may initially be confused with rheumatoid arthritis,SLE, or polymyositis when articular or muscle involvement is prominent. SSc without cutaneous involvement should be considered in patients with unexplained pulmonary fibrosis, pulmonary hypertension, cardiomyopathies, heart block, dysphagia, or malabsorption syndrome. Several conditions have scleroderma-like features but lack the visceral involvement. Scleredema (scleredema adultorum of Buschke) occurs predominantly in children and is characterized by painless edematous induration involving the face, scalp, neck, trunk, and proximal portions of the extremities. Involvement of the hands and feet usually does not occur. Scleredema may be associated with previous streptococcal infection and is usually self-limited, resolving in 6 to 12 months. Histology reveals accumulation of mucopolysaccharides in the dermis

and skeletal muscle. A rare entity, scleromyxedema is manifested by yellowish or pale red papules in association with diffuse skin thickening that may involve the face and hands. Acid mucopolysaccharide deposits are found in the dermis. Monoclonal IgG may be detected in some of these patients. Patients with insulin-dependent diabetes mellitus may develop digital sclerosis and contractures (prayer hand deformity). Primary amyloidosis and amyloidosis associated with multiple myeloma may involve the skin of the extremities and face diffusely to give the appearance of scleroderma. Biopsy will clearly differentiate these entities.

COURSE AND PROGNOSIS

The course ofSSc is quite variable. Until the disease differentiates into recognizable subsets, prognosis in early disease is difficult to predict. Patients with limited cutaneous scleroderma, especially those with anticentromere antibodies, have a good prognosis, with the notable exception of those few patients,<10%, who after ³10 to 20 years develop pulmonary arterial hypertension. Malabsorption syndrome and primary biliary cirrhosis are the causes of morbidity and mortality in some patients with limited cutaneous disease. On the other hand, the prognosis is generally worse in patients with diffuse cutaneous disease, particularly when the onset occurs at an older age. In addition, males have a worse prognosis. Renal and other visceral organ disease may develop early in the course of those patients with rapidly progressive generalized skin thickening. Death occurs most often from pulmonary, cardiac, and renal involvement. With the advent of effective therapy for renal crisis along with renal dialysis for those patients with renal failure, survival has greatly improved. In patients with diffuse cutaneous disease, the 5-year cumulative survival rate is ~70% and the 10-year is ~55%. In limited cutaneous disease the 5-year is ~90% and the 10-year is ~75%.

Skin may spontaneously soften after years of disease. Softening occurs in the reverse order of original skin involvement, beginning with the trunk and followed by the proximal and then the distal extremities. Sclerodactyly and flexion contractures may persist. Skin thickness may eventually approach normal; however, the skin may be atrophic.

TREATMENT

Even thoughSScannot be cured, treatment of involved organ systems can relieve symptoms and improve function. The doctor-patient relationship is extremely important in caring for patients with this chronic debilitating illness. Once the diagnosis of SSc has been made, the patient and family should be instructed about this disorder. The patient will need repeated explanations and reassurances throughout his or her illness. Depending on the severity of illness, the patient will require monitoring of blood pressure, blood counts, urinalysis, and monitoring of renal and pulmonary function on a regular basis.

Effectiveness of drug therapy inSSc is difficult to evaluate because of the variable course and severity of the disease. Many drugs have been used in the treatment of SSc without any consistent or prolonged benefit. In uncontrolled studies, D-penicillamine has been reported to reduce skin thickening and prevent development of significant organ involvement when compared to similar historic controls. Five-year cumulative survival rates of 80% have been reported in D-penicillamine-treated patients. This drug

interferes with inter- and intramolecular cross-linking of collagen and is also immunosuppressive. Its immunosuppressive activity may also lead to decreased collagen production. Penicillamine is better tolerated when started at a low dose, usually 250 mg/d, and then increased at 1- to 3-month intervals up to 1.5 g/d as tolerated. Although a few patients can tolerate higher doses, most patients are maintained on a dose between 0.5 and 1 g/d. For optimal absorption, it is important to give this drug 1 h before or 2 h after a meal. This drug can be quite toxic; its more serious complications include glomerulonephritis with nephrotic syndrome, aplastic anemia, leukopenia, thrombocytopenia, and myasthenia gravis. Other side effects are fever, rash, anorexia, nausea, and loss of taste. Patients should have monthly complete blood counts (including platelet count) and urinalyses. The results of a 2-year double-blind randomized study comparing high-dose D-penicillamine (750 to 1000 mg/d) with low-dose D-penicillamine (125 mg every other day) in patients with early diffuse cutaneous SSc were recently reported. The degree of skin thickening and the occurrence of renal crises and other organ involvement as well as mortality were not significantly different between the high- and low-dose treated groups. This study suggested that there was no advantage in using doses >125 mg every other day. Azathioprine, methotrexate, cyclophosphamide, and other immunosuppressives have also been used in SSc and should be reserved for those patients with rapidly progressive disease. Control studies are lacking. Trials of treatment with recombinant interferon g, 5-fluorouracil, and extracorporeal photochemotherapy have shown improvement in some disease parameters. No therapy, however, has been clearly demonstrated in a controlled, prospective study to suppress or reverse the disease process of SSc. Because of the poor prognosis in SSc patients who have a rapid onset of diffuse cutaneous disease and early visceral organ involvement (pulmonary, cardiac, or renal), clinical trials are under way using high-dose immunosuppressive therapy followed by autologous stem cell transplantation. The rationale is that high doses of an immunosuppressive drug such as cyclophosphamide may reverse or modify the disease course. The autologous stem cell transplantation permits the rapid reconstitution of hematopoiesis.

Antiplatelet therapy may play a role in the treatment ofSSc, since the biologic products of platelets affect blood vessels. Low doses of aspirin block the formation of thromboxane A_2, a powerful vasoconstrictor and platelet aggregator. In addition, dipyridamole, 200 to 400 mg in divided daily doses, also decreases platelet adhesion to damaged vessel walls. While these drugs have a reasonable therapeutic rationale, a 2-year double-blind study did not show any benefit from their use. Reports of beneficial effects of colchicine or chlorambucil have not been documented in controlled studies.

Glucocorticoids are indicated in those patients with inflammatory myositis or pericarditis. The initial dose is 40 to 60 mg/d and is tapered based on clinical improvement (see below). They should not be used for the indolent primary form of muscle disease of SSc. Prednisone in the range of 20 to 40 mg/d may decrease edema associated with the edematous phase of early skin involvement. Glucocorticoids are not otherwise indicated in the long-term treatment of SSc. High doses of glucocorticoids may play a role in precipitating acute renal failure. A retrospective case-control study in patients with early diffuse cutaneous SSc showed a significant association between prior high-dose glucocorticoids (prednisone^3 15 mg/d) and the development of scleroderma renal crisis. Based on these observations, immunosuppressive drugs (e.g. methotrexate,

azathioprine, or cyclophosphamide) should be considered in treating the inflammatory myositis, pericarditis, or early inflammatory skin disease.

The management of Raynaud's phenomenon is directed at control of vasospasm. Patients should be advised to dress warmly and wear mittens and socks, not to smoke, to remove causes of external stress, and to avoid drugs such as amphetamine and ergotamine. Cold drafts should be avoided. Air-conditioned rooms in warm climates can also be a problem for patients with Raynaud's phenomenon. Beta-blocking drugs may make Raynaud's phenomenon worse. Warmth of the central body induces peripheral vasodilatation. Drugs that block sympathetic vasoconstriction, such as reserpine,a-methyldopa, phenoxybenzamine, and prazosin, may be useful in the treatment of Raynaud's phenomenon, but their side effects often curtail extended use. The calcium channel blockers nifedipine, diltiazem, and the longer acting amlodipine can be effective in alleviating Raynaud's phenomenon, but side effects of light-headedness and palpitations may limit their use. The sustained-release form of nifedipine is better tolerated; the dose is 30 mg/d up to 60 or 90 mg/d as required to control symptoms. Nitroglycerine paste, applied to an affected digit, may improve local blood flow. In a 12-week pilot study, losartan, a specific nonpeptide angiotensen II type 1 receptor antagonist, reduced the severity and frequency of Raynaud's phenomenon episodes. Ketanserin, an oral serotonin antagonist, also has been shown to be effective. Selective serotonin reuptake inhibitors (e.g., fluoxetine) may be beneficial in some patients. These drugs decrease platelet 5-hydroxytryptamine, which is thought to play a role in the pathogenesis of Raynaud's phenomenon. Studies with intravenous iloprost, a prostacyclin analogue, have shown a decrease in frequency and severity of Raynaud's phenomenon and healing of digital ulcers in some patients. Iloprost is still not available in the United States for general use. Intravenous alprostadil, a prostaglandin, can be effective in treating severe Raynaud's phenomenon with digital ulcers. Epoprostenol (prostacyclin), used in the treatment of pulmonary hypertension, also improves Raynaud's phenomenon. Pentoxifylline may also improve perfusion by increasing the deformability of the red cell plasma membranes. Techniques of biofeedback have also been used with variable success for teaching patients to control the temperature of their hands. Stellate ganglion blockage may be useful in temporarily alleviating severe ischemic pain in the fingers. Surgical sympathectomy usually provides only temporary improvement, and it, along with other forms of therapy, does not prevent progression of the vascular lesion. Digital sympathectomy can be effective in some patients. The response to any therapy for Raynaud's phenomenon is limited by the degree of existing structural narrowing of digital arteries. In patients with severe Raynaud's phenomenon and refractory digital ulcers, distal ulnar artery occlusion should be considered. A positive Allen test is suggestive, and the diagnosis is confirmed by angiography. When ulnar artery occlusion is present, revascularization and a digital sympathectomy may be beneficial. Gangrene of distal digits may occur and require surgical amputation.

Numerous drugs have been claimed to soften the hidebound skin, but documentation in controlled studies is lacking. These drugs include D-penicillamine, colchicine, *p*-aminobenzoic acid, and vitamin E. In a recent randomized, double-blind, placebo-controlled trial, recombinant human relaxin given by continuous subcutaneous infusion for 24 weeks was associated with reduced skin thickening and improved mobility in patients with moderate to severe diffuse cutaneous scleroderma. Relaxin, a hormone associated with pregnancy, has been shown to have antifibrotic properties.

Dryness of the skin may be reduced by avoiding frequent use of detergent soaps and by regularly applying hydrophilic ointments and bath oils. Regular exercise helps to maintain flexibility of extremities and pliability of skin. Massaging the skin several times a day may also be beneficial. Fingertip ulcerations can be protected by applying a guard or cage over the end of the finger. The use of an occlusive dressing, such as the hydrocolloid duo-DERM or other membranes, over a noninfected ulcer may promote healing and protect the finger. Skin ulcers should be kept clean by soaking or by surgical or chemical debridement. Sympatholytic drugs or local nitroglycerine paste applied to or adjacent to the ulcer may be beneficial in promoting healing. Infected ulcers can usually be treated with topical antibiotics but may require systemic antibiotics, especially when there is a question of underlying osteomyelitis. The development of calcinosis cannot be prevented, nor can deposits be dissolved. Warfarin has been reported to reduce calcinosis in a few patients.

In patients experiencing dry mouth, frequent sips of water help to relieve symptoms. Pilocarpine hydrochloride tablets may increase salivary secretions in some patients. Patients with dry eyes should use artificial tears regularly.

Patients with reflux esophagitis are treated with small, frequent meals, antacids between meals, and elevation of the head of the bed. Patients should be advised not to lie down for a few hours after a meal and to avoid coffee, tea, alcohol, peppermint, and chocolate, which reduce the pressure of the lower esophageal sphincter. Fatty foods and late-evening snacks should be avoided. Cimetidine, ranitidine or other newer H_2blockers may be beneficial. Gastric acid (proton) pump inhibitors are more effective in treating erosive esophagitis than are H_2blockers. Metoclopramide and cisapride increase gastrointestinal motility but do not significantly improve esophageal motility. They both increase lower esophageal sphincter tone and can be of help in some patients. Cisapride is no longer available (as of July 2000) because it caused life-threatening arrhythmias. Nifedipine and, to a lesser extent, diltiazem reduce lower esophageal sphincter tone resulting in esophageal reflux. Patients with dysphagia should be instructed to chew their food thoroughly and wash it down with fluids. Malabsorption syndrome due to duodenal hypomotility and bacterial overgrowth causes bloating and diarrhea, which may improve with intermittent use of appropriate antibiotics. Antibiotics are rotated every 2 weeks. Commonly used antibiotics are metronidazole, vancomycin, erythromycin, ciprofloxacin, neomycin, and tetracycline. Patients with severe debilitating malabsorption may benefit from parenteral hyperalimentation. Patients with chronic intestinal pseudoobstruction might respond to octreotide. Stool softeners and mild laxatives are usually adequate for treating constipation caused by hypomotility of the colon.

Articular symptoms are treated with nonsteroidal anti-inflammatory agents. Low-dose prednisone (£10 mg/d) may improve symptoms in those not responding to these agents. Physical therapy may help to reduce the loss of joint mobility that occurs in SSc.

In patients with diffuse cutaneous SSc, the early recognition of alveolitis as previously described (see "Pulmonary Features") may allow treatment that might slow or prevent the development of pulmonary fibrosis. Cyclophosphamide has been reported in uncontrolled studies to be beneficial, and a controlled study is presently being done. The role of glucocorticoids in preventing progression of interstitial lung disease is not

clear but may be of benefit in early disease. Pulmonary fibrosis is not reversible, and therefore treatment is directed at symptoms or complications. Pulmonary infection requires prompt treatment with antibiotics. Hypoxia necessitates giving low concentrations of oxygen. Patients should receive polyvalent pneumoccal vaccine (Pneumovax) and yearly influenza immunizations.

For patients with limited cutaneousSSc who develop isolated pulmonary arterial hypertension, treatment is limited. The usual treatment is supplemental oxygen, anticoagulation, and the administration of a vasodilator. A calcium channel blocker such as nifedipine lowers pulmonary arterial resistance and improves cardiac function, but in most patients this is only for a short period of time. Few patients survive more than 5 years. Heart-lung or single-lung transplantation may be a therapeutic option only in those patients without other significant systemic involvement. Current reports of intravenous epoprostenol (prostacyclin) in the treatment of SSc-associated pulmonary hypertension have been encouraging. Epoprostenol is infused continuously via a central line with a portable pump. Improvement in symptoms of right heart failure and exercise tolerance occurred. Also hemodynamic tests showed a decrease in the pulmonary vascular resistance and pulmonary artery pressure both in the short term and in a few patients after 1 or 2 years.

Recognition of early signs of renal hypertensive crisis is important in order to preserve renal function and prevent hypertensive encephalopathy. Renal involvement is often accompanied by hypertension and mild to moderate proteinuria. An occasional patient may be normotensive. Antihypertensive agents are often effective in lowering blood pressure and stabilizing or reversing renal failure. These drugs include propranolol, clonidine, and minoxidil. Particularly effective are the angiotensin-converting enzyme inhibitors, which include captopril, enalapril, and lisinopril. Dialysis may be required in patients with progressive renal failure. Some patients, however, have a slow return of renal function after several months and may no longer require dialysis. Patients are usually not candidates for kidney transplantation because of the other systemic manifestations ofSSc.

Patients with cardiac failure require careful monitoring of digitalis and diuretic administration. Noninflammatory pericardial effusions may also improve with diuretics. Care should be taken to avoid overdiuresis, which may lead to decreased renal blood flow, decreased cardiac output, and renal failure.

MIXED CONNECTIVE TISSUE DISEASE

MCTDis an overlap syndrome characterized by combinations of clinical features ofSLE(Chap. 311),SSc, polymyositis (Chap. 382), and rheumatoid arthritis (Chap. 312) and the presence of very high titers of circulating autoantibodies to nuclearRNPantigen. This antibody in high titer, now referred to as *anti-U_1RNP*, has been a justification for considering MCTD as a distinct clinical entity. MCTD has been challenged as a distinct disorder by those who consider it as a subset of SLE or scleroderma. Others prefer to classify MCTD as an undifferentiated connective tissue disease. MCTD occurs worldwide and in all races. The peak onset of disease is in the second and third decades, but MCTD is seen in children and the elderly. Women are predominantly affected. The pathogenic mechanisms in MCTD reflect the disorders making up this

syndrome.

Clinical Features The presenting symptoms ofMCTD are most often Raynaud's phenomenon, puffy hands, arthralgias, myalgias, and fatigue. Occasionally, patients may present with the acute onset of high fever, polymyositis, arthritis, and neurologic features such as trigeminal neuralgia and aseptic meningitis. The various features of the connective tissue disorders making up MCTD develop over months and years.

The fingers as well as the entire hand may be puffy, followed later by sclerodactyly. Sclerodermal changes are usually limited to the distal extremities and sometimes the face but spare the trunk. Telangiectasia and calcinosis may develop. Some patients have mucocutaneous features ofSLEincluding a classic malar rash, photosensitivity, discoid lesions, alopecia, and painful oral ulcerations. An erythematous rash over the knuckles, elbows, and knees and heliotropic eyelids, typical of dermatomyositis, are uncommon.

Joint pain, stiffness, and swelling involving the peripheral joints occur frequently. Deformities of the hands similar to those of rheumatoid arthritis may develop but usually without bony erosions. A destructive polyarthritis is occasionally observed. Myalgias are a frequent symptom. Some patients develop typical symptoms of polymyositis with proximal muscle weakness, abnormal electromyographic findings, elevated levels of muscle enzymes, and inflammatory changes on muscle biopsy.

Approximately 85% of patients have pulmonary involvement, which is often asymptomatic. Diffusing capacity for carbon monoxide may be the only abnormality. Pleurisy commonly occurs but is seldom associated with large pleural effusions. Some patients develop interstitial lung disease. Pulmonary arterial hypertension is the most common cause of death inMCTD.

Approximately 25% of patients develop renal disease. Membranous glomerulonephritis is most common and usually mild but can cause nephrotic syndrome. Diffuse proliferative glomerulonephritis is unusual inMCTD, perhaps because of the protective role believed to be played by the high titers of anti-U_1RNP. Renal crisis secondary to malignant renovasculature hypertension, as occurs in scleroderma, is seen in a few patients.

Gastrointestinal involvement is seen in ~70% of patients. The most common manifestations are esophageal dysmotility, lower esophageal sphincter laxity, and gastroesophageal reflux. Bowel manifestations mimic those of scleroderma bowel disease.

Pericarditis occurs in 30% of patients. Other cardiac features include myocarditis, arrhythmia, conduction disturbances, and mitral valve prolapse. Other clinical features ofMCTDinclude trigeminal neuropathy, peripheral neuropathy, aseptic meningitis, lymphadenopathy, and Sjogren's syndrome. The majority of patients have developed, or will develop within 5 years of presentation, diagnostic clinical criteria for one of the overlapping connective tissue diseases, most oftenSLE orSSc.

Laboratory Findings Anemia of chronic inflammation is seen in the majority of patients.

A positive direct Coombs' test is found in many patients, but hemolytic anemia is unusual. Leukopenia, thrombocytopenia, or both are present in some patients. Hypergammaglobulinemia is common, and rheumatoid factor is present in 50% of patients.

All patients, by definition ofMCTD, have antibodies to U_1RNP. The specificity of this antibody is to the 70-kDa protein complexed to small nuclear RNA. The anti-U_1RNP antibodies are associated with HLA-DR4 but not with -DR2 and -DR3 as found in SLE. Molecular mimicry has been demonstrated between U_1 RNP and retroviral antigens by some laboratories.

TREATMENT

The treatment ofMCTD is essentially the same as would be indicated for the respective connective tissue diseases defining this syndrome. More than half the patients have a favorable course. The 10-year survival rate overall is approximately 80% but varies depending on the connective tissue disease that may eventually develop.

EOSINOPHILIC FASCIITIS

Eosinophilic fasciitis is a scleroderma-like syndrome of unknown cause characterized by inflammation followed later by sclerosis of the dermis, subcutis, and deep fascia. The disease affects adults and often occurs after strenuous physical activity. Patients do not have Raynaud's phenomenon or internal organ involvement. Several immunologic abnormalities have been associated with eosinophilic fasciitis and include aplastic anemia, myelodysplastic syndrome, and thrombocytopenia. Patients usually have the abrupt onset of symmetric tenderness and swelling of the extremities, rapidly followed by induration of the skin and subcutaneous tissue. The skin takes on a cobblestone or puckered appearance. Carpal tunnel syndrome appears early in the course, and flexion contractures develop later. A low-grade myositis is often present, but creatinine kinase levels are usually normal. A marked eosinophilia is found in the early stage of disease and subsequently decreases. Increased levels of polyclonal IgG and immune complexes are often present in the serum. A full-thickness biopsy consisting of skin, fascia, and superficial muscle shows perivascular infiltration of histiocytes, eosinophils, lymphocytes, and plasma cells. Biopsies later in the course show sclerosis. Spontaneous improvement and occasionally complete remission may occur after 2 to 5 years of disease. Some patients have persistent disease, while others are left with flexion contractures. Administration of glucocorticoids may provide symptomatic improvement and will decrease the eosinophilia. Improvement has been reported with the use of the H_2blocker cimetidine.

EOSINOPHILIA-MYALGIA SYNDROME

In 1989, reports of patients with scleroderma-like skin changes, myalgias, and eosinophilia dramatically increased. Most, but not all, of these cases were associated with ingestion of L-tryptophan manufactured by a single Japanese company. Batches of L-tryptophan implicated inEMS were found to contain trace amounts of a contaminant identified as a dimer of L-tryptophan that appeared in 1988 after changes were made in the method of manufacturing this drug. It is not clear whether this chemical contaminant

is the etiologic agent or whether another unidentified substance is responsible. *L-Tryptophan products were taken off the market in 1990*. The onset of EMS can be either abrupt or insidious. In the early phases of the disease, clinical manifestations include low-grade fever, fatigue, dyspnea, cough, arthralgias/arthritis, evanescent erythematous rashes, muscle cramping, and severe myalgias. Pulmonary infiltrates may be present. Over the next 2 to 3 months, scleroderma-like skin changes appear. Some patients develop a peripheral neuropathy, which may persist. An ascending polyneuropathy may lead to paralysis and respiratory failure requiring ventilatory assistance. Cognitive dysfunction with impairment of memory and concentration has been recognized in this syndrome. Myocarditis and cardiac arrhythmias occur in some patients, and a few patients develop pulmonary hypertension. Approximately a third of patients have features of eosinophilic fasciitis. EMS most closely resembles toxic oil syndrome; however, Raynaud's phenomenon does not occur, and there is a lower prevalence of pulmonary hypertension and thromboembolic disease. The peripheral eosinophil count is >1000/uL in most patients. The histologic findings on biopsy of skin, fascia, and superficial muscle are similar to those found in eosinophilic fasciitis. The clinical features of EMS may persist after L-tryptophan has been discontinued. EMS may run a chronic course, and response to therapy has been variable. Treatment has included glucocorticoids, antimalarial drugs, immunosuppressive drugs, and plasmapheresis. Prednisone was beneficial during the acute inflammatory phase of the disease in the majority of patients and resulted in resolution of pulmonary infiltrates, peripheral edema, and eosinophilia. In the later phase of the illness, no treatment was found to be of particular value. The pathogenesis of this disease is not known. A follow-up of patients 2 years after their onset of illness showed that most symptoms and physical findings had resolved or improved except for cognitive dysfunction, which became worse in approximately one-third of the patients, and peripheral neuropathy, which remained unchanged (Chap. 382).

314. SJOGREN'S SYNDROME - *Haralampos M. Moutsopoulos*

DEFINITION

Sjogren's syndrome is a chronic, slowly progressive autoimmune disease characterized by lymphocytic infiltration of the exocrine glands resulting in xerostomia and dry eyes. Approximately one-third of patients present with systemic manifestations. A small but significant number of the patients may develop malignant lymphoma. The disease can be seen alone (primary Sjogren's syndrome) or in association with other autoimmune rheumatic diseases (secondary Sjogren's syndrome) (Table 314-1).

INCIDENCE AND PREVALENCE

The disease affects predominantly middle-aged women (female-to-male ratio 9:1), although it occurs in all ages, including childhood. The prevalence of primary Sjogren's syndrome is approximately 0.5 to 1.0%. In addition, 30% of patients with autoimmune rheumatic diseases suffer from secondary Sjogren's syndrome.

PATHOGENESIS

Sjogren's syndrome is characterized by lymphocytic infiltration of the exocrine glands and B lymphocyte hyperreactivity, as illustrated by circulating autoantibodies. The latter is accompanied by an oligomonoclonal B cell process, which is characterized by serum and urine monoclonal light chains and cryoprecipitable monoclonal immunoglobulins.

Sera of patients with Sjogren's syndrome often contain a number of autoantibodies directed against non-organ-specific antigens such as immunoglobulins (rheumatoid factors) and extractable nuclear and cytoplasmic antigens (Ro/SS-A, La/SS-B). Ro/SS-A autoantigen consists of three polypeptide chains (52, 54, and 60 kDa) in conjunction with RNAs, whereas the 48-kDa La/SS-B protein is bound to RNA III polymerase transcripts. The presence of autoantibodies to Ro/SS-A and La/SS-B antigens in Sjogren's syndrome is associated with earlier disease onset, longer disease duration, salivary gland enlargement, severity of lymphocytic infiltration of minor salivary glands, and certain extraglandular manifestations such as lymphadenopathy, purpura, and vasculitis. Antibodies toa-fordin (120 kDa), a salivary gland-specific protein, have recently been found in sera of patients with Sjogren's syndrome but not in sera of patients with other connective tissue diseases.

Phenotypic and functional studies have shown that the predominant cell infiltrating the affected exocrine glands is the helper/inducer T cell with characteristics of memory cells. Both B and T infiltrating lymphocytes are activated, as illustrated by production of immunoglobulins with autoantibody activity, spontaneous release of interleukin 2, and expression on the T cell surface of activation markers such as class II HLA as well as costimulatory molecules and lymphocyte function-associated antigen 1. Macrophages and natural killer cells are rarely detected in infiltrates, while epithelial cells of the affected glands inappropriately express class II molecules and possess messages for c-*myc* protooncogene and proinflammatory cytokines. All these phenomena suggest that the epithelial cell of the exocrine glands in Sjogren's syndrome may act as an antigen-presenting cell. In contrast to infiltrating lymphocytes, these cells undergo

apoptotic death, resulting in exocrine gland dysfunction.

Immunogenetic studies have demonstrated that HLA-B8, -DR3, and -DRw52 are prevalent in patients with primary Sjogren's syndrome as compared with the normal control population. Molecular analysis of HLA class II genes has revealed that patients with Sjogren's syndrome, regardless of their ethnic origin, are highly associated with the HLA DQA1*0501 allele.

CLINICAL MANIFESTATIONS

The majority of the patients with Sjogren's syndrome have symptoms related to diminished lacrimal and salivary gland function. In most patients, the primary syndrome runs a slow and benign course. The initial manifestations can be mucosal dryness or nonspecific, and 8 to 10 years elapse from the initial symptoms to full-blown development of the disease.

The principal oral symptom of Sjogren's syndrome is dryness (xerostomia). Patients complain of difficulty in swallowing dry food, inability to speak continuously, a burning sensation, increase in dental caries, and problems in wearing complete dentures. Physical examination shows a dry, erythematous, sticky oral mucosa. There is atrophy of the filiform papillae on the dorsum of the tongue, and saliva from the major glands is either not expressible or is cloudy. Enlargement of the parotid or other major salivary glands occurs in two-thirds of patients with primary Sjogren's syndrome but is uncommon in those with the secondary syndrome. Diagnostic tests include sialometry, sialography, and scintigraphy. The labial minor salivary gland biopsy permits histopathologic confirmation of the focal lymphocytic infiltrates.

Ocular involvement is the other major manifestation of Sjogren's syndrome. Patients usually complain of dry eyes, with a sandy or gritty feeling under the eyelids. Other symptoms include burning, accumulation of thick strands at the inner canthi, decreased tearing, redness, itching, eye fatigue, and increased photosensitivity. These symptoms are attributed to the destruction of corneal and bulbar conjunctival epithelium, defined as keratoconjunctivitis sicca. Diagnostic evaluation of keratoconjunctivitis sicca includes measurement of tear flow by Schirmer's I test and tear composition as assessed by the tear breakup time or tear lysozyme content. Slit-lamp examination of the cornea and conjunctiva after rose Bengal staining reveals punctate corneal ulcerations and attached filaments of corneal epithelium.

Involvement of other exocrine glands occurs less frequently and includes a decrease in mucous gland secretions of the upper and lower respiratory tree, resulting in dry nose, throat, and trachea (xerotrachea), and diminished secretion of the exocrine glands of the gastrointestinal tract, leading to esophageal mucosal atrophy, atrophic gastritis, and subclinical pancreatitis. Dyspareunia due to dryness of the external genitalia and dry skin also may occur.

Extraglandular (systemic) manifestations are seen in one-third of patients with Sjogren's syndrome (Table 314-2), while they are very rare in patients with Sjogren's syndrome associated with rheumatoid arthritis. These patients complain more often of easy fatigability, low-grade fever, Raynaud's phenomenon, myalgias, and arthralgias. Most

patients with primary Sjogren's syndrome experience at least one episode of nonerosive arthritis during the course of their disease. Manifestations of pulmonary involvement are frequent but rarely important clinically. Dry cough is the major manifestation that is attributed to small airway disease. Renal involvement includes interstitial nephritis, clinically manifested by hypostenuria and renal tubular dysfunction with or without acidosis. Untreated acidosis may lead to nephrocalcinosis. Glomerulonephritis is a rare finding that occurs in patients with systemic vasculitis, cryoglobulinemia, or systemic lupus erythematosus overlapping with Sjogren's syndrome. Vasculitis affects small and medium-sized vessels. The most common clinical features are purpura, recurrent urticaria, skin ulcerations, glomerulonephritis, and mononeuritis multiplex. Sensorineural hearing loss was found in one-half of patients with Sjogren's syndrome and correlated with the presence of anticardiolipin antibodies.

It has been suggested that primary Sjogren's syndrome with vasculitis also may present with multifocal, recurrent, and progressive nervous system disease, such as hemiparesis, transverse myelopathy, hemisensory deficits, seizures, and movement disorders. Aseptic meningitis and multiple sclerosis also have been reported in these patients.

Lymphoma is a well-known manifestation of Sjogren's syndrome that usually presents later in the illness. Persistent parotid gland enlargement, lymphadenopathy, cutaneous vasculitis, peripheral neuropathy, lymphopenia, and cryoglobulinemia are manifestations suggesting the development of lymphoma. Most lymphomas are extranodal, marginal zone B cell, and low grade. Salivary glands are the most common site of involvement.

Routine laboratory tests reveal mild normochromic, normocytic anemia. An elevated erythrocyte sedimentation rate is found in approximately 70% of patients.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A European multicenter study has developed diagnostic criteria of Sjogren's syndrome (Table 314-3), which have been validated and present high specificity and sensitivity. A diagnostic algorithm is depicted inFig. 314-1.

The differential diagnosis of Sjogren's syndrome includes other conditions that may cause dry mouth or eyes or parotid salivary gland enlargement (Table 314-4). Infections with HIV and hepatitis C virus (Chap. 309) and sarcoidosis (Chap. 318) appear to produce a clinical picture indistinguishable from that of Sjogren's syndrome (Table 314-5).

TREATMENT

Sjogren's syndrome remains fundamentally an incurable disease. Hence treatment is aimed at symptomatic relief and limiting the damaging local effects of chronic xerostomia and keratoconjunctivitis sicca by substitution of the missing secretions.

The sicca complex is treated with fluid replacement supplied as often as necessary. To replace deficient tears, there are several readily available ophthalmic preparations (Tearisol; Liquifilm; 0.5% methylcellulose; Hypo Tears). It may be necessary for

severely affected patients to use these preparations as often as every 30 min. If corneal ulceration is present, eye patching and boric acid ointments are recommended. Certain drugs that may increase lacrimal and salivary hypofunction such as diuretics, antihypertensive drugs, and antidepressants should be avoided. Propionic acid gels may be used to treat vaginal dryness.

Pilocarpine (5 mg thrice daily) given orally appears to improve sicca manifestations. Hydroxychloroquine (200 mg/day) is helpful for arthralgias. Glucocorticoids (1 mg/kg per day) or other immunosuppressive agents (i.e., cyclophosphamide) are indicated for the treatment of extraglandular manifestations, particularly when renal or severe pulmonary involvement and systemic vasculitis have been documented.

315. ANKYLOSING SPONDYLITIS, REACTIVE ARTHRITIS, AND UNDIFFERENTIATED SPONDYLOARTHROPATHY - *Joel D. Taurog, Peter E. Lipsky*

The spondyloarthropathies are a group of disorders that share certain clinical features and an association with the HLA-B27 allele. These disorders include ankylosing spondylitis, Reiter's syndrome, reactive arthritis, psoriatic arthritis and spondylitis, enteropathic arthritis and spondylitis, juvenile-onset spondyloarthropathy, and undifferentiated spondyloarthropathy. The similarities in clinical manifestations and genetic predisposition suggest that these disorders share pathogenic mechanisms. Specific definitions and diagnostic criteria for the individual conditions will be provided in subsequent sections of this chapter.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is an inflammatory disorder of unknown cause that primarily affects the axial skeleton; peripheral joints and extraarticular structures may also be involved. The disease usually begins in the second or third decade; the prevalence in men is approximately three times that in women. It is considered the prototype of the spondyloarthropathies. Older names include *Marie-Strumpell disease* or *Bechterew's disease*.

EPIDEMIOLOGY

ASshows a striking correlation with the histocompatibility antigen HLA-B27 and occurs worldwide roughly in proportion to the prevalence of this antigen (Chap. 306). In North American Caucasians, the general prevalence of B27 is 7%, whereas over 90% of patients with AS have inherited this antigen. The association with B27 is independent of disease severity.

In population surveys, 1 to 6% of adults inheriting B27 have been found to haveAS. In contrast, in families of patients with AS, the prevalence is 10 to 30% among adult first-degree relatives inheriting B27. The concordance rate in identical twins is estimated to exceed 65%. It is currently believed that susceptibility to AS is determined almost entirely by genetic factors, with as yet unidentified allelic genes in addition to B27 comprising about two-thirds of the genetic component and B27 itself comprising about one-third. AS is strongly associated with inflammatory bowel disease (IBD), including both ulcerative colitis and Crohn's disease. IBD is a risk factor for AS independent of HLA-B27, although 50 to 75% of patients with both AS and IBD are B27 positive.*See also Chap. 287.*

PATHOLOGY

The *enthesis*, the site of ligamentous attachment to bone, is thought to be the primary site of pathology inAS, particularly in the lesions around the pelvis and spine. Enthesitis is associated with prominent edema of the adjacent bone marrow and is often characterized by erosive lesions that eventually undergo ossification.

Sacroiliitis is usually one of the earliest manifestations ofAS, with features of both

enthesitis and synovitis. The early lesions consist of subchondral granulation tissue containing lymphocytes, plasma cells, mast cells, macrophages, and chondrocytes; infiltrates of lymphocytes and macrophages in ligamentous and periosteal zones; and subchondral bone marrow edema. Synovitis follows and may progress to pannus formation. Islands of new bone formation can be found within the inflammatory infiltrates. Usually, the thinner iliac cartilage is eroded before the thicker sacral cartilage. The irregularly eroded, sclerotic margins of the joint are gradually replaced by fibrocartilage regeneration and then by ossification. Ultimately, the joint may be totally obliterated. This progression is evident by imaging techniques (see below).

In the spine, early in the process there is inflammatory granulation tissue at the junction of the annulus fibrosus of the disk cartilage and the margin of vertebral bone. The outer annular fibers are eroded and eventually replaced by bone, forming the beginning of a bony excrescence called a *syndesmophyte*, which then grows by continued enchondral ossification, ultimately bridging the adjacent vertebral bodies. Ascending progression of this process leads to the "bamboo spine" observed radiographically. Other lesions in the spine include diffuse osteoporosis, erosion of vertebral bodies at the disk margin, "squaring" of vertebrae, and inflammation and destruction of the disk-bone border. Inflammatory arthritis of the apophyseal joints is common, with erosion of cartilage by pannus, often followed by bony ankylosis.

Bone mineral density is significantly diminished in the spine and proximal femur early in the course of the disease, before the advent of significant immobilization. The mechanism for this is not known.

Peripheral arthritis inAS can show synovial hyperplasia, lymphoid infiltration, and pannus formation, but the process lacks the exuberant synovial villi, fibrin deposits, ulcers, and accumulations of plasma cells seen in rheumatoid arthritis (Chap. 312). Central cartilaginous erosions caused by proliferation of subchondral granulation tissue are common in AS but rare in rheumatoid arthritis.

Acute anterior uveitis (iritis) occurs in at least 20% of patients withAS. Few cases have been studied histologically, none at an early stage. After recurrent attacks, the iris shows nonspecific inflammatory changes, scarring, increased vascularity, and pigment-laden macrophages. Pupillary synechiae and cataract formation are common sequelae.

Aortic insufficiency develops in a small percentage of cases. There is thickening of the aortic valve cusps and the aorta near the sinuses of Valsalva, with dense adventitial scar tissue and intimal fibrous proliferation. The scar tissue can extend into the ventricular septum with resultant heart block.

Microscopic inflammatory lesions of the colon and ileocecal valve have been found in 25 to 50% of patients withAS, even in those lacking any clinical evidence ofIBD. IgA nephropathy has been reported with increased frequency.

PATHOGENESIS

The pathogenesis ofAS is incompletely understood. A number of features of the disease

implicate immune-mediated mechanisms, including elevated serum levels of IgA and acute-phase reactants, inflammatory histology, and close association with HLA-B27. The inflamed sacroiliac joint is infiltrated with CD4+ and CD8+ T cells and macrophages and shows high levels of tumor necrosis factora. Transforming growth factorb is detectable near the sites of new bone formation. No specific event or exogenous agent that triggers the onset of disease has been identified, although overlapping features with reactive arthritis andIBDsuggest that enteric bacteria may play a role. Elevated serum titers of antibodies to certain enteric bacteria, particularly *Klebsiella pneumoniae*, are common in AS patients, but no role for these antibodies in the pathogenesis of AS has been identified. Evidence that B27 plays a direct role is provided by the finding that rats transgenic for B27 spontaneously develop spondylitis, along with colitis, peripheral arthritis, and other lesions characteristic of the spondyloarthropathies (see below).

Some evidence has accumulated for autoimmunity to the cartilage proteoglycan aggrecan, and particularly its G1 globulin domain and link protein.ASpatients have been found to have cellular immunity to these molecules, and mice immunized with the G1 domain develop spondylitis and discitis. Sharing of proteoglycan antigenic epitopes among the pathologic sites in the skeleton, uveal tract, and aorta in AS suggests a possible explanation for the distribution of pathologic sites in AS.

CLINICAL MANIFESTATIONS

The symptoms of the disease are usually first noticed in late adolescence or early adulthood; the median age in western countries is 23 in both genders. In 5% of patients, symptoms begin after age 40. The initial symptom is usually dull pain, insidious in onset, felt deep in the lower lumbar or gluteal region, accompanied by low-back morning stiffness of up to a few hours' duration that improves with activity and returns following periods of inactivity. Within a few months of onset, the pain has usually become persistent and bilateral. Nocturnal exacerbation of pain that forces the patient to rise and move around may be frequent.

In some patients bony tenderness may accompany back pain or stiffness, while in others it may be the predominant complaint. Common sites include the costosternal junctions, spinous processes, iliac crests, greater trochanters, ischial tuberosities, tibial tubercles, and heels. Occasionally, bony chest pain is the presenting complaint. Arthritis in the hips and shoulders ("root" joints) occurs in 25 to 35% of patients, in many cases early in the disease course. Arthritis of peripheral joints other than the hips and shoulders, usually asymmetric, occurs in up to 30% of patients and can occur at any stage of the disease. Neck pain and stiffness from involvement of the cervical spine are usually relatively late manifestations. Occasional patients, particularly in the older age group, present with predominantly constitutional symptoms such as fatigue, anorexia, fever, weight loss, or night sweats.

ASoften has a juvenile onset in developing countries. In these individuals, peripheral arthritis and enthesitis usually predominate, with axial symptoms supervening in late adolescence.

The most common extraarticular manifestation is acute anterior uveitis, which can antedate the spondylitis. Attacks are typically unilateral, causing pain, photophobia, and

increased lacrimation. These tend to recur, often in the opposite eye. Cataracts and secondary glaucoma are not uncommon sequelae. Aortic insufficiency, sometimes producing symptoms of congestive heart failure, occurs in a few percent of patients, occasionally early in the course of the spinal disease. Third-degree heart block may occur alone or together with aortic insufficiency. The block is in the atrioventricular node in 95% of cases. Up to half the patients have inflammation in the colon or ileum. This is usually asymptomatic, but in 5 to 10% of patients with AS, frankIBD will develop.

Initially, physical findings mirror the inflammatory process. The most specific findings involve loss of spinal mobility, with limitation of anterior and lateral flexion and extension of the lumbar spine and of chest expansion. Limitation of motion is usually out of proportion to the degree of bony ankylosis, reflecting muscle spasm secondary to pain and inflammation. Pain in the sacroiliac joints may be elicited either with direct pressure or with maneuvers that stress the joints, but these techniques are unreliable in discriminating inflammatory sacroiliitis. In addition, there is commonly tenderness upon palpation at the sites of symptomatic bony tenderness and paraspinous muscle spasm.

The Schober test is a useful measure of flexion of the lumbar spine. The patient stands erect, with heels together, and marks are made directly over the spine 5 cm below and 10 cm above the lumbosacral junction (identified by a horizontal line between the posterosuperior iliac spines.) The patient then bends forward maximally, and the distance between the two marks is measured. The distance between the two marks increases 5 cm or more in the case of normal mobility and less than 4 cm in the case of decreased mobility. Chest expansion is measured as the difference between maximal inspiration and maximal forced expiration in the fourth intercostal space in males or just below the breasts in females. Normal chest expansion is 5 cm or greater.

Limitation or pain with motion of the hips or shoulders is usually present if either of these joints is involved. Careful examination is also necessary to detect inflammatory disease of peripheral joints. It should be emphasized that early in the course of mild cases, symptoms may be subtle and nonspecific, and the physical examination may be completely normal.

The course of the disease is extremely variable, ranging from the individual with mild stiffness and radiographically equivocal sacroiliitis to the patient with a totally fused spine and severe bilateral hip arthritis, possibly accompanied by severe peripheral arthritis and extraarticular manifestations. Pain tends to be persistent early in the disease and then to become intermittent, with alternating exacerbations and quiescent periods. In a typical severe untreated case with progression of the spondylitis to syndesmophyte formation, the patient's posture undergoes characteristic changes. The lumbar lordosis is obliterated with accompanying atrophy of the buttocks. The thoracic kyphosis is accentuated. If the cervical spine is involved, there may be a forward stoop of the neck. Hip involvement with ankylosis may lead to flexion contractures, compensated by flexion at the knees. The progression of the disease may be followed by measuring the patient's height, chest expansion, Schober test, and occiput-to-wall distance when the patient stands erect with the heels and back flat against the wall. Occasional individuals are encountered with advanced physical findings suggestive of long-standingAS who report having never had significant symptoms.

In some but not all studies, onset of the disease in adolescence correlates with a worse prognosis, but there is general agreement that early severe hip involvement is an indication of progressive disease. The disease in women tends to progress less frequently to total spinal ankylosis, although there is some evidence for an increased prevalence of isolated cervical ankylosis and peripheral arthritis in women. In industrialized countries, peripheral arthritis (distal to hips and shoulders) occurs overall in about 25% of patients, usually as a late manifestation, whereas in developing countries, the prevalence is much higher, with onset typically early in the disease course. Pregnancy has no consistent effect onAS, with symptoms improving, remaining the same, or deteriorating in about one-third of pregnant patients, respectively.

The most serious complication of the spinal disease is spinal fracture, which can occur with even minor trauma to the rigid, osteoporotic spine. The cervical spine is most commonly involved. These fractures are often displaced and cause spinal cord injury. Cauda equina syndrome and slowly progressive upper pulmonary lobe fibrosis are rare complications of long-standingAS. The prevalence of aortic insufficiency and of cardiac conduction disturbances, including third-degree heart block, increases with prolonged disease. Subclinical pulmonary lesions and cardiac dysfunction may be relatively common. Prostatitis has been reported to have an increased prevalence in men with AS. Amyloidosis is only rarely associated (Chap. 319).

Several validated measures of disease activity and functional outcome have recently been developed forAS. Despite the persistence of the disease, most patients remain gainfully employed. The effect of AS on survival is controversial. Some, but not all, studies have suggested that AS shortens life span, compared with the general population. Mortality attributable to AS is largely the result of spinal trauma, aortic insufficiency, respiratory failure, amyloid nephropathy, or complications of therapy such as upper gastrointestinal hemorrhage.

LABORATORY FINDINGS

No laboratory test is diagnostic of AS. In most ethnic groups, the HLA-B27 gene is present in approximately 90% of patients with AS. Most, but not all, patients with active disease have an elevated erythrocyte sedimentation rate and an elevated level of C-reactive protein. A mild normochromic, normocytic anemia may be present. Patients with severe disease may show an elevated alkaline phosphatase level. Elevated serum IgA levels are common. Rheumatoid factor and antinuclear antibodies are largely absent unless caused by a coexistent disease. Synovial fluid from inflamed peripheral joints in AS is not distinctly different from that of other inflammatory joint diseases. In cases with restriction of chest wall motion, decreased vital capacity and increased functional residual capacity are common, but airflow measurements are normal and ventilatory function is usually well maintained.

RADIOGRAPHIC FINDINGS

Radiographically demonstrable sacroiliitis is usually present inAS. The earliest changes in the sacroiliac joints demonstrable by standard radiography are blurring of the cortical margins of the subchondral bone, followed by erosions and sclerosis. Progression of the erosions leads to "pseudowidening" of the joint space; as fibrous and then bony

ankylosis supervene, the joints may become obliterated radiographically. The changes and progression of the lesions are usually symmetric.

Roentgenographic abnormalities generally appear in the sacroiliac joints before appearing elsewhere in the spine. In the lumbar spine, progression of the disease leads to straightening, caused by loss of lordosis, and reactive sclerosis, caused by osteitis of the anterior corners of the vertebral bodies with subsequent erosion, leading to "squaring" of the vertebral bodies. Progressive ossification of the superficial layers of the annulus fibrosus leads to eventual formation of marginal syndesmophytes, visible on plain films as bony bridges connecting successive vertebral bodies anteriorly and laterally.

In mild cases, years may elapse before unequivocal sacroiliac abnormalities are evident on plain radiographs. Computed tomography (CT) and magnetic resonance imaging (MRI) can detect abnormalities reliably at an earlier stage than plain radiography. MRI has emerged as a highly sensitive and specific technique for identifying early intraarticular inflammation, cartilage changes, and underlying bone marrow edema in sacroiliitis (Fig. 315-1). In suspected cases in which conventional radiography does not reveal definite sacroiliac abnormalities or is undesirable (e.g., in young women or children), dynamic MRI is the procedure of choice for establishing a diagnosis of sacroiliitis.

Reduced bone mineral density can be detected by dual-energy x-ray absorptiometry of the femoral neck and the lumbar spine. Falsely elevated readings related to spinal ossification can be avoided by using a lateral projection of the L3 vertebral body.

DIAGNOSIS

The diagnosis of earlyASbefore the development of irreversible deformity can be difficult to establish. Currently, modified New York criteria (1984) are widely used for diagnosis. These consist of the following: (1) a history of inflammatory back pain (see below); (2) limitation of motion of the lumbar spine in both the sagittal and frontal planes; (3) limited chest expansion, relative to standard values for age and sex; and (4) definite radiographic sacroiliitis. Using these criteria, the presence of radiographic sacroiliitis plus any one of the other three criteria is sufficient for a diagnosis of definite AS. These criteria may need to be further modified to include sacroiliitis demonstrated byMRI to increase their sensitivity.

The presence of B27 is neither necessary nor sufficient for the diagnosis, but the B27 test can be helpful in patients with suggestive clinical findings who have not yet developed radiographic sacroiliitis. Moreover, the absence of B27 in a typical case ofASsignificantly increases the probability of coexistentIBD.

ASmust be differentiated from numerous other causes of low-back pain, some of which are far more common than AS. The inflammatory back pain of AS is usually distinguished by the following five features: (1) age of onset below 40, (2) insidious onset, (3) duration greater than 3 months before medical attention is sought, (4) morning stiffness, and (5) improvement with exercise or activity. The most common causes of back pain other than AS are primarily mechanical or degenerative rather than

inflammatory and do not show these features. Less common metabolic, infectious, and malignant causes of back pain also must be differentiated from AS. Ochronosis can produce a phenotype that is clinically and radiographically similar to AS.

Marked calcification and ossification of paraspinous ligaments occur in *diffuse idiopathic skeletal hyperostosis* (DISH). Although DISH is often categorized as a variant of osteoarthritis, diarthrodial joints are not involved. Ligamentous calcification and ossification are usually most prominent in the anterior spinal ligament and give the appearance of "flowing wax" on the anterior bodies of the vertebrae. However, a radiolucency may be seen between the newly deposited bone and the vertebral body, differentiating DISH from the marginal osteophytes in spondylosis. Intervertebral disk spaces are preserved, and sacroiliac and apophyseal joints appear normal, helping to differentiate DISH from spondylosis and fromAS, respectively.

DISHoccurs in the middle-aged and the elderly and is more common in men than in women. Patients are frequently asymptomatic but may have stiffness. Radiographic changes are generally much more severe than might be predicted from the mild symptoms caused by DISH.

TREATMENT

There is no definitive treatment forAS. The principal goal of management is the conscientious participation by the patient in an exercise program designed to maintain functional posture and to preserve range of motion. There is evidence that exercise increases mobility and improves function. The proportion of patients wtih severe deformity has decreased markedly in recent decades, probably because of earlier diagnosis and widespread use of physical therapy. Smoking has been associated with a poor outcome and should be emphatically discouraged. Most patients require anti-inflammatory agents to achieve sufficient symptomatic relief to be able to remain functional and carry out the exercise program. It is not known whether drug treatment alone can alter the progression of the disease.

Several nonsteroidal anti-inflammatory drugs (NSAIDs) have proved effective in reducing the pain and stiffness ofAS and are commonly used. Indomethacin is particularly effective as a 75-mg slow-release preparation taken once or twice daily. Although phenylbutazone, at doses of 200 to 400 mg/d, has been considered the most effective anti-inflammatory agent in AS, because of its greater potential for serious side effects such as aplastic anemia and agranulocytosis, its use in the United States is confined to patients with very severe disease whose symptoms do not respond at all to other agents. Recent controlled trials suggest that sulfasalazine, in doses of 2 to 3 g/d, is useful in reducing peripheral joint symptoms as well as reversing laboratory evidence of inflammation. Some studies have not shown it to benefit axial arthritis, and its effect on natural progression of the disease is unproven. The peripheral arthritis may also respond to the folic acid antagonist methotrexate.[1]No therapeutic role for gold, penicillamine, immunosuppressive drugs, or oral glucocorticoids has been documented in AS. Occasionally, intralesional or intraarticular glucocorticoid injections may be beneficial in patients with persistent enthesopathy or synovitis unresponsive to anti-inflammatory agents. Recent studies have suggested that symptomatic benefit can be achieved fromCT-guided glucocorticoid injections into the sacroiliac joints, but the

effects are not sustained. Anecdotal benefit has been reported for diverse agents such as pamidronate, thalidomide, pulse intravenous methylprednisolone, and tumor necrosis factor a antagonists. Controlled trials of these and other agents are needed, since for many patients current therapy is inadequate even for control of pain and stiffness.

The most common indication for surgery in patients withAS is severe hip joint arthritis, the pain and stiffness of which are usually dramatically relieved by total hip arthroplasty. A small number of patients may benefit from surgical correction of extreme flexion deformities of the spine or of atlantoaxial subluxation.

Attacks of iritis are usually effectively managed with local glucocorticoid administration in conjunction with mydriatic agents, although systemic glucocorticoids or even immunosuppressive drugs may be required in some cases. Coexistent cardiac disease may require pacemaker implantation and/or aortic valve replacement.

[1]Azathioprine, methotrexate, and sulfasalazine have not been approved for this purpose by the U.S. Food and Drug Administration at the time of publication.

REACTIVE ARTHRITIS AND UNDIFFERENTIATED SPONDYLOARTHROPATHY

Reactive arthritis (ReA) refers to acute nonpurulent arthritis complicating an infection elsewhere in the body. In recent years, the term has been used primarily to refer to spondyloarthropathies following enteric or urogenital infections and occurring predominantly in individuals with the histocompatibility antigen HLA-B27. Included in this category is the constellation of clinical findings formerly commonly called *Reiter's syndrome*.**Other forms of reactive and infection-related arthritis not associated with B27 and showing a different spectrum of clinical features, such as rheumatic fever or Lyme disease, are discussed in Chaps. 235 and 176.*

HISTORIC BACKGROUND

The association of acute arthritis with episodes of diarrhea or urethritis has been recognized for centuries. A large number of cases during World Wars I and II focused attention on the triad of arthritis, urethritis, and conjunctivitis, which became known as Reiter's syndrome, often occurring with additional mucocutaneous lesions.

The identification of bacterial species capable of triggering the clinical syndrome and the finding that up to 85% of the patients possess the B27 antigen have led to the unifying concept ofReA as a clinical syndrome triggered by specific etiologic agents in a genetically susceptible host. A similar spectrum of clinical manifestations can be triggered by enteric infection with any of several *Shigella*, *Salmonella*, *Yersinia*, and *Campylobacter* species, by genital infection with *Chlamydia trachomatis*; and possibly by other agents as well. Although Reiter's syndrome can be said to represent one part of the spectrum of the clinical manifestations ofReA, particularly that induced by *Shigella* or *Chlamydia*, the term is now largely of historic interest only. Since most patients with spondyloarthropathy do not have the classic features of Reiter's syndrome, it has become customary to employ the term *reactive arthritis*, regardless of whether or not there is evidence for a triggering infection. For the purposes of this chapter, the use of ReA will be restricted to those cases of spondyloarthropathy in which there is at least

presumptive evidence for a related antecedent infection. Patients with clinical features of ReA who lack both evidence of an antecedent infection and the classic findings of Reiter's syndrome (urethritis, arthritis, conjunctivitis) will be considered to have *undifferentiated spondyloarthropathy*, which is discussed at the end of this chapter.

EPIDEMIOLOGY

LikeAS,ReAoccurs predominantly in individuals who have inherited the B27 gene; in most series, 60 to 85% of patients are B27 positive. In epidemics of arthritogenic bacterial infection, e.g., *S. flexneri*, it has been estimated that ReA develops in ~20% of exposed B27-positive individuals. In families with multiple cases of AS or ReA, the two conditions have been said to "breed true," i.e., to be uncommonly found together within an individual family. Whether this is caused by genetic or environmental factors is not known. The disease is most common in individuals 18 to 40 years of age, but it can occur both in children over 5 years of age and in older adults.

The sex ratio inReAfollowing enteric infection is nearly 1:1, whereas venereally acquired ReA is predominantly confined to men. The overall prevalence and incidence of ReA are difficult to assess because of the variable prevalence of the triggering infections and genetic susceptibility factors in different populations. For example, in Olmsted County, MN, the incidence was estimated as 3.5 cases per 100,000 population per year. In contrast, in a population with a high rate of genitourinary and/or gastrointestinal infections such as urban homosexual and bisexual men, the prevalence may approach 1 per 1000.

A particularly severe form of peripheral spondyloarthropathy has been described in patients with AIDS (Chap. 309). Most of these patients are HLA-B27 positive, but HIV infection per se is not an independent risk factor for spondyloarthropathy.

PATHOLOGY

Synovial histology is similar to that of other inflammatory arthropathies. Enthesitis is a common clinical finding inReA; the histology of this lesion resembles that ofAS. Microscopic histopathologic evidence of inflammation has occasionally been noted in the colon and ileum of patients with postvenereal ReA, but much less commonly than in postenteric ReA. The skin lesions of keratoderma blenorrhagica, which is associated mainly with venereally acquired ReA, are histologically indistinguishable from psoriatic lesions.

ETIOLOGY AND PATHOGENESIS

The first bacterial infection noted to be causally related toReA was *S. flexneri*. An outbreak of shigellosis among Finnish troops in 1944 resulted in numerous cases of ReA. Of the four species *S. sonnei*, *S. boydii*, *S. flexneri*, and *S. dysenteriae*, *S. flexneri* has most often been implicated in cases of ReA, both sporadic and epidemic. *S. sonnei*, although responsible for the majority of cases of shigellosis in the United States, has only rarely been implicated in cases of ReA.

Other bacteria that have been definitively identified as triggers ofReAinclude several

Salmonella spp., *Y. enterocolitica*, *C. jejuni*, and *C. trachomatis*. There is suggestive evidence implicating several other microorganisms, including *Y. pseudotuberculosis*, *Clostridium difficile*, and *Ureaplasma urealyticum*. *Chlamydia pneumoniae*, a respiratory pathogen, has also recently been implicated in triggering ReA. There are also numerous isolated reports of acute arthritis preceded by other bacterial, viral, or parasitic infections, but whether the microorganisms involved are actual triggers of ReA remains to be determined.

It has not been determined whetherReAoccurs by the same pathogenic mechanism following infection with each of these microorganisms, nor has the mechanism been fully elucidated in the case of any one of the known bacterial triggers. Most, if not all, of the triggering organisms produce lipopolysaccharide (LPS) and share a capacity to attack mucosal surfaces, to invade host cells, and survive intracellularly. Antigens from *Chlamydia*, *Yersinia*, *Salmonella*, and *Shigella* have been shown to be present in the synovium and/or synovial fluid leukocytes of patients with ReA for long periods following the acute attack. In ReA triggered by *Y. enterocolitica*, bacterial LPS and heat shock protein antigens have been found in peripheral blood cells years after the triggering infection. In the case of *C. trachomatis*, synovial persistence of microbial DNA and RNA suggests the presence of viable organisms, despite uniform failure to culture the organism from these specimens. There is thus evidence that ReA, at least in some cases, may be a form of chronic infection, rather than solely "reactive." T cells that specifically respond to antigens of the inciting organism are typically found in inflamed synovium but not in peripheral blood of patients with ReA. These T cells are predominantly CD4+, but CD8+ B27-restricted bacteria-specific cytolytic T cells have also been isolated in *Yersinia*- and *C. trachomatis*-induced ReA. Specific peptide antigens from these organisms have been identified as dominant T cells epitopes. Unlike the synovial CD4 T cells in rheumatoid arthritis, which are predominantly of the T_H1 phenotype, those in ReA also show a T_H2 phenotype. It is likely that antigen-specific T cells play an important role in the pathogenesis of ReA, but the precise mechanisms remain to be determined.

The role of HLA-B27 inReA also remains to be determined. Transgenic rats with high expression of B27 spontaneously develop a multiple organ system inflammatory disease affecting the gut, peripheral and axial joints, male genital tract, and skin that resembles these human conditions clinically and histologically. When raised in a germ-free environment, the B27 rats do not develop gut or joint inflammation, but the skin and genital lesions are not prevented. These findings suggest that bacteria are necessary, and normal gut bacteria are sufficient, to induce B27-related joint inflammation. In both the rat and human diseases, it remains to be determined whether the primary process is an autoimmune response against host tissues or an immune response against antigens of the triggering organism that have disseminated to the target tissues, and the specific role of B27 itself remains to be determined. A potentially very informative converse observation, in which humans develop a disease process resembling one first described in rats, is the recent finding that 0.4 to 0.8% of individuals treated with intravesicular bacillus Calmette-Guerin for bladder cancer develop reactive arthritis, and 60% of these patients are B27 positive. The process closely mimics adjuvant-induced arthritis in rats given complete Freund's adjuvant, first described over 40 years ago, which is currently thought to be mediated by CD4+ T cells specific for mycobacterial heat shock protein.

An intriguing in vitro finding indicates that the presence of HLA-B27 significantly prolongs the intracellular survival of *Y. enterocolitica*, and *S. enteritides* in human and mouse cell lines. A unifying hypothesis suggests that prolonged intracellular bacterial survival, promoted by B27, other factors, or both, permits trafficking of infected leukocytes from the site of primary infection to joints, where a T cell response to persistent bacterial antigens promotes arthritis. Evidence exists supporting each step of this scheme.

CLINICAL FEATURES

The clinical manifestations ofReAconstitute a spectrum that ranges from an isolated, transient monarthritis to severe multisystem disease. In the majority of cases, a careful history will elicit some evidence of an antecedent infection 1 to 4 weeks before the onset of symptoms of the reactive disease. However, in a sizable minority, no clinical or laboratory evidence of an antecedent infection can be found. In many cases of presumed venereally acquired reactive disease, there is a history of a recent new sexual partner, even in the absence of laboratory evidence of infection.

Constitutional symptoms are common, including fatigue, malaise, fever, and weight loss. The musculoskeletal symptoms are usually acute in onset. Arthritis is usually asymmetric and additive, with involvement of new joints occurring over a period of a few days to 1 to 2 weeks. The joints of the lower extremities, especially the knee, ankle, and subtalar, metatarsophalangeal, and toe interphalangeal joints, are the most common sites of involvement, but the wrist and fingers can be involved as well. The arthritis is usually quite painful, and tense joint effusions are not uncommon, especially in the knee. Dactylitis, or "sausage digit," a diffuse swelling of a solitary finger or toe, is a distinctive feature of bothReA and psoriatic arthritis (Chap. 324). It is not specific, however, in that it is also seen in polyarticular gout and sarcoidosis. Tendinitis and fasciitis are particularly characteristic lesions, producing pain at multiple insertion sites, especially the Achilles insertion, the plantar fascia, and sites along the axial skeleton. Spinal and low-back pain are quite common and may be caused by insertional inflammation, muscle spasm, acute sacroiliitis, or, presumably, arthritis in intervertebral articulations.

Urogenital lesions may occur throughout the course of the disease. In males, urethritis may be marked or relatively asymptomatic and may be either an accompaniment of the triggering infection or a result of the reactive phase of the disease. Prostatitis is also common. Similarly, in females, cervicitis or salpingitis may be caused either by the infectious trigger or by the sterile reactive process.

Ocular disease is common, ranging from transient, asymptomatic conjunctivitis to an aggressive anterior uveitis that occasionally proves refractory to treatment and may result in blindness.

Mucocutaneous lesions are frequent. Oral ulcers tend to be superficial, transient, and often asymptomatic. The characteristic skin lesions, *keratoderma blenorrhagica*, consist of vesicles that become hyperkeratotic, ultimately forming a crust before disappearing. They are most common on the palms and soles but may occur elsewhere as well. In

patients with HIV infection, these lesions are often extremely severe and extensive, to the point of dominating the clinical picture (Chap. 309). Lesions on the glans penis, termed *circinate balanitis*, are common; these consist of vesicles that quickly rupture to form painless superficial erosions, which in circumcised individuals can form crusts similar to those of keratoderma blenorrhagica. Nail changes are common and consist of onycholysis, distal yellowish discoloration, and/or heaped-up hyperkeratosis.

Less frequent or rare manifestations ofReAinclude cardiac conduction defects, aortic insufficiency, central or peripheral nervous system lesions, and pleuropulmonary infiltrates.

Long-term follow-up studies suggest that some joint symptoms persist in 30 to 60% of patients withReA. Recurrences of the acute syndrome are common, and as many as 25% of patients either become unable to work or are forced to change occupations because of persistent joint symptoms. Chronic heel pain is often a particularly distressing symptom. Some aspects of ankylosing spondylitis are also common sequelae (see below). In some but not all studies, HLA-B27-positive patients have shown a worse outcome than B27-negative patients. The extent to which the long-term prognosis varies with different inciting agents is not known. However, patients with *Yersinia*-induced arthritis appear to have less chronic disease than those whose initial episode follows epidemic shigellosis.

LABORATORY AND RADIOGRAPHIC FINDINGS

The erythrocyte sedimentation rate is usually elevated during the acute phase of the disease. Mild anemia may be present, and acute-phase reactants tend to be increased. Synovial fluid is nonspecifically inflammatory, showing an elevated white cell count with a predominance of neutrophils. In most ethnic groups, 50 to 75% of the patients are B27 positive. It is unusual for the triggering infection to persist at the site of primary mucosal infection through the time of onset of the reactive disease, but it may occasionally be possible to culture the organism, e.g., in the case of *Yersinia*- or *Chlamydia*-induced disease. Serologic evidence of a recent infection may be present, such as a marked elevation of antibodies to *Yersinia*, *Salmonella*, or *Chlamydia*.

In early or mild disease, radiographic changes may be absent or confined to juxtaarticular osteoporosis. With long-standing persistent disease, marginal erosions and loss of joint space can be seen in affected joints. Periostitis with reactive new bone formation is characteristic of the disease, as it is with all the spondyloarthropathies. Spurs at the insertion of the plantar fascia are common.

Sacroiliitis and spondylitis may be seen as late sequelae. The sacroiliitis is more commonly asymmetric than inAS, and the spondylitis, rather than ascending symmetrically from the lower lumbar segments, can begin anywhere along the lumbar spine. The syndesmophytes may be coarse and nonmarginal, arising from the middle of a vertebral body, a pattern rarely seen in primary AS. Progression to spinal fusion as a sequela ofReA is uncommon.

DIAGNOSIS

ReAis a clinical diagnosis, there being no definitively diagnostic laboratory test or radiographic finding. The diagnosis should be entertained in any patient with an acute inflammatory, asymmetric, additive arthritis or tendinitis. The evaluation of such a patient should include careful questioning regarding possible antecedent triggering events such as an episode of diarrhea or dysuria. On physical examination, careful attention must be paid to the distribution of the joint and tendon involvement and to possible sites of extraarticular involvement, such as the eyes, mucous membranes, skin, nails, and genitalia. Synovial fluid aspiration and analysis may be helpful in excluding septic or crystal-induced arthritis. Culture or serology may help to identify a triggering infection. The role of molecular methods of microbial detection has not been established (see below).

Although typing for B27 is not needed to secure the diagnosis in clear-cut cases, it may have prognostic significance in terms of severity, chronicity, and the propensity for spondylitis and uveitis. Furthermore, it can be helpful diagnostically in atypical cases, a positive test increasing and a negative test decreasing the probability ofReA.

It is particularly important to differentiateReA from disseminated gonococcal disease, both of which can be venereally acquired and associated with urethritis (Chap. 147). Gonococcal arthritis and tenosynovitis tend to involve both upper and lower extremities equally, whereas in ReA lower extremity symptoms usually predominate. Back pain is common in ReA but is not a feature of gonococcal disease, whereas the vesicular skin lesions characteristic of disseminated gonococcal disease are not found in ReA. A positive gonococcal culture from the urethra or cervix does not exclude a diagnosis of ReA; however, culturing gonococci from blood, skin lesion, or synovium establishes the diagnosis of disseminated gonococcal disease. Polymerase chain reaction (PCR) technology has recently been used in the diagnosis of infections with *Neisseria gonorrheae* and with *C. trachomatis*. Occasionally, the only definitive way to distinguish the two is through a therapeutic trial of antibiotics.

ReAshares many features in common with psoriatic arthropathy, including the asymmetry of the arthritis, a propensity for "sausage digits" and nail involvement, an association with uveitis, and skin lesions of similar histology (Chap. 324). However, psoriatic arthritis is usually gradual in onset, the arthritis tends to affect primarily the upper extremities, and there is less associated periarthritis. Psoriatic arthritis is not associated with mouth ulcers or urethritis, or, usually, with bowel symptoms. Although psoriatic arthropathy shows some distinctive radiographic features that are not found in ReA, these occur only late in the disease and are of little help diagnostically. Only psoriatic spondylitis, not the peripheral arthritis, is associated with B27, about 50% of patients being positive. Occasional patients, usually B27 positive, following what appears to be a typical episode of ReA, will develop typical psoriasis and persistent arthritis such that the two entities become indistinguishable.

Undifferentiated spondyloarthropathy, or simply "spondyloarthropathy," is diagnosed in patients who lack evidence of an antecedent infection that might triggerReA and who do not meet criteria forAS but who show clinical features of these disorders.

TREATMENT

Most patients withReA are benefitted to some degree byNSAIDs, although rarely are symptoms of the acute arthritis completely ameliorated, and some patients fail to respond at all. Indomethacin, 75 to 150 mg/d in divided doses, is the initial treatment of choice. Other NSAIDs may be tried, with phenylbutazone, 100 mg tid or qid, being the NSAID of last resort, to be used only in severe, refractory cases because of its potentially serious side effects.

It is unclear whether antibiotics have a role in the therapy ofReA. One controlled study suggested that prolonged administration of a long-acting tetracycline may accelerate recovery from *Chlamydia*-induced ReA, but subsequent results have been less encouraging, and therapy for other bacterial triggers of ReA has shown little or no benefit. However, there is evidence that prompt, appropriate antibiotic treatment of acute chlamydial urethritis may prevent subsequent ReA. Currently, expert opinion supports the use of antibiotic therapy in established urogenital ReA but not in gastrointestinal ReA.

Two recent multicenter trials have suggested that sulfasalazine, up to 3 g/d in divided doses, may be beneficial to patients with persistentReA.[1]Patients with debilitating symptoms refractory toNSAIDand sulfasalazine therapy may respond to immunosuppressive agents such as azathioprine, 1 to 2 mg/kg per day, or to methotrexate, 7.5 to 15 mg per week. Systemic glucocorticoids are not generally recommended but in rare instances may be helpful in mobilizing a severely affected bedridden patient. Antimalarials, gold, and penicillamine are not useful in the treatment of ReA. Trials of new agents proven useful in rheumatoid arthritis, such as COX-2 inhibitors, leflunomide, and tumor necrosis factor a inhibitors, remain to be implemented.

Tendinitis and other enthesitic lesions occasionally may benefit from intralesional glucocorticoids. Uveitis may require aggressive treatment with glucocorticoids to prevent serious sequelae. Skin lesions ordinarily require only symptomatic treatment. In patients with HIV infection andReA, many of whom have severe skin lesions, the skin lesions in particular appear to respond to systemic treatment with anti-retroviral agents (Chap. 309). Cardiac complications are managed conventionally; management of neurologic complications is symptomatic.

Patients need to be educated about the nature of the disease and the factors that predispose to its recurrence. Comprehensive management includes counseling of patients in the avoidance of sexually transmitted disease and exposure to enteropathogens, as well as appropriate use of physical therapy, vocational counseling, and continued surveillance for long-term complications such as ankylosing spondylitis.

UNDIFFERENTIATED AND JUVENILE-ONSET SPONDYLOARTHROPATHY

It is not uncommon for clinicians to encounter patients, usually young adults, who do not haveIBD or psoriasis, lack evidence of an antecedent triggering infection, and do not have the classic triad of Reiter's syndrome or meet criteria for ankylosing spondylitis, who nonetheless present with some features of one or more of the spondyloarthropathies discussed above. For example, a patient may present with inflammatory synovitis of one knee, Achilles tendinitis, and dactylitis of one digit ("sausage digit"), or sacroiliitis in the absence of other criteria forAS. It is now common

to consider such patients as having *undifferentiated spondyloarthropathy*, or simply *spondyloarthropathy*. Other terms for this condition have included *seronegative oligoarthritis*, *undifferentiated oligoarthritis*, and the now-outmoded *incomplete Reiter's syndrome*. There is strong evidence that some, perhaps most, of these patients haveReA in which the triggering infection remains clinically silent. In some other cases, the patient subsequently develops IBD or psoriasis or the process eventually meets criteria for ankylosing spondylitis. Approximately half the patients with undifferentiated spondyloarthropathy are HLA-B27 positive, and thus the absence of B27 is not useful in establishing or excluding the diagnosis.

In *juvenile-onset spondyloarthropathy*, which begins most commonly in boys (60 to 80%) between ages 7 and 16, an asymmetric, predominantly lower extremity oligoarthritis and enthesitis without extraarticular features is the typical mode of presentation. The prevalence of B27 in this condition, which has been termed the *SEA syndrome* (*s*eronegative, *e*nthesopathy, *a*rthropathy), is approximately 80%. Many, but not all, of these patients go on to develop typical ankylosing spondylitis in late adolescence or adulthood.

Management of undifferentiated spondyloarthropathy is similar to that of the other spondyloarthropathies, withNSAIDsand physical therapy forming the mainstays of treatment. Textbooks of pediatrics should be consulted for information on management of juvenile-onset spondyloarthropathy. An algorithm for the diagnosis of the spondyloarthropathies in adults is presented in Fig. 315-2.

316. BEHCET'S SYNDROME - *Haralampos M. Moutsopoulos*

DEFINITION

Behcet's syndrome is a multisystem disorder presenting with recurrent oral and genital ulcerations as well as ocular involvement. Internationally agreed diagnostic criteria have been proposed (Table 316-1).

PREVALENCE, PATHOGENESIS, AND PATHOLOGY

The disease has a worldwide distribution. The prevalence of Behcet's syndrome ranges from 1:10,000 in Japan to 1:500,000 in North America and Europe. It affects mainly young adults, with males having more severe disease than females.

The etiology and pathogenesis of this syndrome remain obscure; vasculitis is the main pathologic lesion with a tendency to venous thrombus formation, and circulating autoantibodies to human oral mucous membrane are found in approximately 50% of the patients. Familial occurrence has been sporadically reported; and in patients from eastern Mediterranean countries and Japan, the disease appears to be linked to HLA-B5 (B51) alloantigens.

CLINICAL FEATURES

The recurrent aphthous ulcerations are a sine qua non for the diagnosis. The ulcers are usually painful, shallow or deep with a central yellowish necrotic base, appear singly or in crops, and are located anywhere in the oral cavity. The ulcers persist for 1 to 2 weeks and subside without leaving scars. The genital ulcers resemble the oral ones.

Skin involvement includes folliculitis, erythema nodosum, an acne-like exanthem, and infrequently vasculitis. Nonspecific skin inflammatory reactivity to any scratches or intradermal saline injection (pathergy test) is a common and specific manifestation.

Eye involvement is the most dreaded complication, since it occasionally progresses rapidly to blindness. The eye disease is usually present at the onset but also may develop within the first few years. In addition to iritis, posterior uveitis, retinal vessel occlusions, and optic neuritis can be seen in some patients with the syndrome. Hypopyon uveitis, which is considered the hallmark of Behcet's syndrome, is in fact a rare manifestation.

The arthritis of Behcet's syndrome is not deforming and affects the knees and ankles.

Superficial or deep peripheral vein thrombosis is seen in one-fourth of the patients. Pulmonary emboli are a rare complication. The superior vena cava is obstructed occasionally, producing a dramatic clinical picture. Arterial involvement occurs infrequently and presents with aortitis or peripheral arterial aneurysm and arterial thrombosis. Pulmonary artery vasculitis presenting with dyspnea, cough, chest pain, hemoptysis, and infiltrates on chest roentgenograms has been reported recently in 5% of patients.

Central nervous system involvement is found more frequently in patients from northern Europe and the United States. The most common lesions are benign intracranial hypertension, a multiple sclerosis-like picture, pyramidal involvement, and psychiatric disturbances.

Gastrointestinal involvement is reported in patients from Japan and includes mucosal ulcerations of the gut.

Laboratory findings are mainly nonspecific indices of inflammation such as leukocytosis and elevated erythrocyte sedimentation rate as well as C-reactive protein levels; antibodies to human oral mucosa are also found.

TREATMENT

The severity of the syndrome usually abates with time. Apart from the patients with neurologic complications, the life expectancy seems to be normal, and the only serious complication is blindness.

Mucous membrane involvement may respond to topical glucocorticoids in the form of mouthwash or paste. In more serious cases thalidomide (100 mg/d) is effective. Thrombophlebitis is treated with aspirin, 325 mg/d. Colchicine or interferona can be beneficial for the arthritis of the syndrome. Uveitis and central nervous system involvement require systemic glucocorticoid therapy (prednisone, 1 mg/kg per day) and azathioprine, 2 to 3 mg/kg per day, or cyclosporine, 5 to 10 mg/kg per day. Early initiation of azathioprine tends to favorably affect the long-term prognosis of Behcet's syndrome.

317. THE VASCULITIS SYNDROMES - *Anthony S. Fauci*

DEFINITION

Vasculitis is a clinicopathologic process characterized by inflammation of and damage to blood vessels. The vessel lumen is usually compromised, and this is associated with ischemia of the tissues supplied by the involved vessel. A broad and heterogeneous group of syndromes may result from this process, since any type, size, and location of blood vessel may be involved. Vasculitis and its consequences may be the primary or sole manifestation of a disease; alternatively, vasculitis may be a secondary component of another primary disease. Vasculitis may be confined to a single organ such as the skin, or it may simultaneously involve several organ systems.

CLASSIFICATION OF VASCULITIC SYNDROMES

A major feature of the vasculitic syndromes as a group is the fact that there is a great deal of heterogeneity at the same time as there is considerable overlap among them. This has led to both difficulty and confusion with regard to the categorization of these diseases. The classification scheme listed inTable 317-1 takes into account this heterogeneity and overlap and will serve as a matrix to emphasize the fact that certain syndromes are predominantly systemic in nature and almost invariably lead to irreversible organ system dysfunction and even death if untreated, while others are usually localized to the skin and rarely result in irreversible dysfunction of vital organs. The distinguishing and overlapping features of the diseases listed inTable 317-1, which justify this classification scheme, will be discussed below.

PATHOPHYSIOLOGY AND PATHOGENESIS

Generally, most of the vasculitic syndromes are assumed to be mediated at least in part by immunopathogenic mechanisms (Table 317-2). However, evidence to this effect is for the most part indirect and may reflect epiphenomena as opposed to true causality.

Pathogenic Immune-Complex Formation Vasculitis is generally considered within the broader category of *immune-complex diseases* that include serum sickness and certain of the connective tissue diseases of which systemic lupus erythematosus (Chap. 311) is the prototype. Although deposition of immune complexes in vessel walls is the most widely accepted pathogenic mechanism of vasculitis, the causal role of immune complexes has not been clearly established in most of the vasculitic syndromes. Circulating immune complexes need not result in deposition of the complexes in blood vessels with ensuing vasculitis, and many patients with active vasculitis do not have demonstrable circulating or deposited immune complexes. The actual antigen contained in the immune complex has only rarely been identified in vasculitic syndromes. In this regard, hepatitis B antigen has been identified in both the circulating and deposited immune complexes in a subset of patients with systemic vasculitis, most notably within the polyarteritis nodosa group (see below). Essential mixed cryoglobulinemia has been associated with hepatitis C virus infection; hepatitis C virions and hepatitis C virus antigen-antibody complexes have been identified in the cryoprecipitates of these patients. An association between persistent parvovirus B19 infection and certain vasculitides has been reported; however, the pathogenic mechanisms related to this

association are unclear.

The mechanisms of tissue damage in immune complex-mediated vasculitis resemble those described for serum sickness. In this model, antigen-antibody complexes are formed in antigen excess and are deposited in vessel walls whose permeability has been increased by vasoactive amines such as histamine, bradykinin, and leukotrienes released from platelets or from mast cells as a result of IgE-triggered mechanisms. The deposition of complexes results in activation of complement components, particularly C5a, which is strongly chemotactic for neutrophils. These cells then infiltrate the vessel wall, phagocytose the immune complexes, and release their intracytoplasmic enzymes, which damage the vessel wall. As the process becomes subacute or chronic, mononuclear cells infiltrate the vessel wall. The common denominator of the resulting syndrome is compromise of the vessel lumen with ischemic changes in the tissues supplied by the involved vessel.

Antineutrophil Cytoplasmic Antibodies (ANCA) ANCA are antibodies directed against certain proteins in the cytoplasm of neutrophils. They are present in a high percentage of patients with systemic vasculitis, particularly Wegener's granulomatosis, as well as in patients with microscopic polyangiitis and in patients with necrotizing and crescentic glomerulonephritis. There are two major categories of ANCA based on different targets for the antibodies. The terminology of *cytoplasmic* (c) *ANCA* refers to the diffuse, granular cytoplasmic staining pattern observed by immunofluorescence microscopy when serum antibodies bind to indicator neutrophils. Proteinase-3, the 29-kDa neutral serine proteinase present in neutrophil azurophilic granules is the major c-ANCA antigen. More than 90% of patients with typical Wegener's granulomatosis and active glomerulonephritis have a positive c-ANCA titer. The terminology of *perinuclear* (p) *ANCA* refers to the more localized perinuclear or nuclear staining pattern of the indicator neutrophils. The major target for p-ANCA is the enzyme myeloperoxidase; other targets of p-ANCA include elastase, cathepsin G, lactoferrin, lysozyme, and bactericidal/permeability-increasing protein. p-ANCA have been reported to occur in variable percentages of patients with microscopic polyangiitis, polyarteritis nodosa, Churg-Strauss syndrome, crescentic glomerulonephritis, and Goodpasture's syndrome as well as in association with nonvasculitic entities such as certain rheumatic and nonrheumatic autoimmune diseases, inflammatory bowel disease, certain drugs, and infections such as endocarditis and bacterial airway infections in patients with cystic fibrosis.

It is unclear why patients with these vasculitis syndromes developANCA, whereas ANCA are rare in other inflammatory diseases. However, once ANCA are present, there are a number of in vitro observations that suggest feasible mechanisms whereby these antibodies can contribute to the pathogenesis of the vasculitis syndromes. When neutrophils are in the resting state, proteinase-3 exists in the azurophilic granules of the cytoplasm, apparently inaccessible to serum antibodies. However, when neutrophils are primed by tumor necrosis factor (TNF)a or interleukin (IL)1, proteinase-3 translocates to the cell membrane where it can interact with extracellular ANCA. The neutrophils then degranulate and produce reactive oxygen species that can cause tissue damage. Endothelial cells also translocate their cytoplasmic proteinase-3 to the cell membrane upon priming with TNF-a, IL-1, or interferon (IFN)g, thus rendering them susceptible to interaction with ANCA and leading possibly to tissue damage due to

complement-mediated cytotoxicity or antibody-dependent cellular cytotoxicity. Despite the attractiveness of these in vitro data, there is no conclusive evidence that ANCA are directly involved in the pathogenesis of the vasculitis syndromes, and they may represent merely an epiphenomenon; in fact, a number of clinical and laboratory observations argue against a primary pathogenic linkage. Patients may have vasculitis in the absence of ANCA; the absolute height of the antibody titers does not correlate well with disease activity; and patients with vasculitis, particularly Wegener's granulomatosis, in remission may continue to have high c-ANCA titers for years. Thus, their role in the pathogenesis of systemic vasculitis remains an open question.

Pathogenic T Lymphocyte Responses and Granuloma Formation In addition to the classic immune complex-mediated mechanisms of vasculitis as well asANCA, other immunopathogenic mechanisms may be involved in damage to vessels. The most prominent of these are delayed hypersensitivity and cell-mediated immune injury as reflected in the histopathologic feature of granulomatous vasculitis. However, immune complexes themselves may induce granulomatous responses. Vascular endothelial cells can express HLA class II molecules following activation by cytokines such as IFN-g. This allows these cells to participate in immunologic reactions such as interaction with CD4+ T lymphocytes in a manner similar to antigen-presenting macrophages. Endothelial cells can secreteIL-1 which may activate T lymphocytes and initiate or propagate in situ immunologic processes within the blood vessel. In addition, IL-1 andTNF-aare potent inducers of endothelial-leukocyte adhesion molecule 1 (ELAM-1) and vascular cell adhesion molecule 1 (VCAM-1), which may enhance the adhesion of leukocytes to endothelial cells in the blood vessel wall. Other mechanisms such as direct cellular cytotoxicity or antibody directed against vessel components or antibody-dependent cellular cytotoxicity have been suggested in certain types of vessel damage. However, there is no convincing evidence to support their causal contribution to the pathogenesis of any of the recognized vasculitic syndromes.

It is unknown why certain individuals develop vasculitis in response to certain antigenic stimuli, whereas others do not. However, it is likely that a number of factors are involved in the ultimate expression of a vasculitic syndrome. These include the genetic predisposition and the regulatory mechanisms associated with immune response to certain antigens. When immune complexes are involved in the pathogenic process, the ability of the reticuloendothelial system to clear circulating complexes from the blood, the size and physicochemical properties of immune complexes, the relative degree of turbulence of blood flow, the intravascular hydrostatic pressure in different vessels, and the preexisting integrity of the vessel endothelium likely explain why only certain types of immune complexes cause vasculitis and why the vasculitic process is selective for only certain vessels in individual patients.

Approach to the Patient

Given the heterogeneous nature of the vasculitis syndromes, workup of a patient with suspected vasculitis should follow a series of progressive steps that establish the diagnosis of vasculitis, determine where possible the category of the vasculitis syndrome (Table 317-1), and determine the pattern and extent of disease activity. This information should then be utilized to determine the choice of therapeutic options (Fig. 317-1). This approach is of considerable importance since several of the vasculitis

syndromes require aggressive therapy with glucocorticoids and immunosuppressive agents, while other syndromes usually resolve spontaneously and require symptomatic treatment only. Vasculitis is often suspected on clinical and laboratory grounds (see individual syndromes below). Depending on the individual category of vasculitis, measurement ofANCAtiters may be helpful in this regard. However, a diagnosis of a vasculitis syndrome should not be made nor should treatment be initiated on the basis of a positive ANCA titer alone. The definitive diagnosis of vasculitis is made upon biopsy of involved tissue. The yield of "blind" biopsies of organs with no subjective or objective evidence of involvement is very low and should be avoided. When syndromes such as classic polyarteritis nodosa, Takayasu's arteritis, or the polyangiitis overlap syndrome are suspected, angiogram of organs with suspected involvement should be performed. However, angiograms should not be performed routinely when patients present with localized cutaneous vasculitis with no clinical indication of visceral involvement.

The constellation of clinical, laboratory, biopsy, and radiographic findings usually allows proper categorization to a specific syndrome, and therapy where appropriate should be initiated according to this information (see individual syndromes below). If an offending antigen that precipitates the vasculitis is recognized, the antigen should be removed where possible. If the syndrome resolves, no further action should be taken. If disease activity continues, treatment should be initiated. If the vasculitis is associated with an underlying disease such as an infection, neoplasm, or connective tissue disease, the underlying disease should be treated. If the syndrome resolves, no further action should be taken. If the syndrome does not resolve or if there is no recognizable underlying disease and the vasculitis persists, treatment should be initiated according to the category of the vasculitis syndrome. Treatment options will be considered under the individual syndromes, and general principles of therapy will be considered at the end of the chapter.

SYSTEMIC NECROTIZING VASCULITIS

POLYARTERITIS NODOSA AND MICROSCOPIC POLYANGIITIS

Definition *Classic polyarteritis nodosa* (PAN) was described in 1866 by Kussmaul and Maier. It is a multisystem, necrotizing vasculitis of small and medium-sized muscular arteries in which involvement of the renal and visceral arteries is characteristic. Classic PAN does not involve pulmonary arteries, although bronchial vessels may be involved; granulomas, significant eosinophilia, and an allergic diathesis are not part of the classic syndrome. The term *microscopic polyangiitis* (microscopic polyarteritis) was introduced into the literature by Davson in 1948. The Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis held in 1992 officially adopted the term to connote a necrotizing vasculitis with few or no immune complexes (pauci-immune) affecting small vessels (capillaries, venules, or arterioles). Since necrotizing arteritis involving small and medium-sized arteries may also be present, it shares features with classic PAN except that glomerulonephritis is very common in microscopic polyangiitis, and pulmonary capillaritis often occurs.

Incidence and Prevalence It is difficult to establish an accurate incidence of these diseases because of the fact that many reports ofPANactually have included both classic PAN and microscopic polyangiitis as well as other related vasculitides. Both

diseases are uncommon, but classic PAN is felt to be more uncommon than microscopic polyangiitis. The mean age of onset of both PAN and microscopic polyangiitis is approximately 50 years of age, and males are slightly more frequently affected than females in both diseases.

Pathophysiology and Pathogenesis The vascular lesion in classicPAN is a necrotizing inflammation of small and medium-sized muscular arteries. The lesions are segmental and tend to involve bifurcations and branchings of arteries. They may spread circumferentially to involve adjacent veins. However, involvement of venules is not seen in classic PAN and, if present, suggests microscopic polyangiitis or the polyangiitis overlap syndrome (see below). In the acute stages of disease, polymorphonuclear neutrophils infiltrate all layers of the vessel wall and perivascular areas, which results in intimal proliferation and degeneration of the vessel wall. Mononuclear cells infiltrate the area as the lesions progress to the subacute and chronic stages. Fibrinoid necrosis of the vessels ensues with compromise of the lumen, thrombosis, infarction of the tissues supplied by the involved vessel, and, in some cases, hemorrhage. As the lesions heal, there is collagen deposition, which may lead to further occlusion of the vessel lumen. Aneurysmal dilatations up to 1 cm in size along the involved arteries are characteristic of classic PAN. Granulomas and substantial eosinophilia with eosinophilic tissue infiltrations are not characteristically found and suggest allergic angiitis and granulomatosis (see below).

Multiple organ systems are involved, and the clinicopathologic findings reflect the degree and location of vessel involvement and the resulting ischemic changes. As mentioned above, pulmonary arteries are not involved in classicPAN, and bronchial artery involvement is uncommon, whereas pulmonary capillaritis occurs frequently in microscopic polyangiitis. The pathology in the kidney in classic PAN is predominantly that of arteritis without glomerulonephritis. In contrast, glomerulonephritis is very common in microscopic polyangiitis. In patients with significant hypertension, typical pathologic features of glomerulosclerosis may be seen alone or superimposed on lesions of glomerulonephritis. In addition, pathologic sequelae of hypertension may be found elsewhere in the body.

The presence of hepatitis B antigenemia in approximately 20 to 30% of patients with systemic vasculitis, particularly of the classicPANtype, together with the isolation of circulating immune complexes composed of hepatitis B antigen and immunoglobulin, and the demonstration by immunofluorescence of hepatitis B antigen, IgM, and complement in the blood vessel walls, strongly suggest the role of immunologic phenomena in the pathogenesis of this disease. Hepatitis C infection has been reported in approximately 5% of patients with PAN; however, its pathogenic role in the vasculitis is unclear at present. Hairy cell leukemia can be associated with classic PAN; the pathogenic mechanisms of this association are unclear.

Clinical and Laboratory Manifestations Nonspecific signs and symptoms are the hallmarks of classicPAN. Fever, weight loss, and malaise are present in over one-half of cases. Patients usually present with vague symptoms such as weakness, malaise, headache, abdominal pain, and myalgias. Specific complaints related to the vascular involvement within a particular organ system may also dominate the presenting clinical picture as well as the entire course of the illness (Table 317-3). In classic PAN, renal

involvement most commonly manifests as hypertension, renal insufficiency, or hemorrhage due to microaneurysms. In microscopic polyangiitis acute glomerulonephritis is the characteristic renal lesion.

There are no diagnostic serologic tests for classicPAN. In over 75% of patients, the leukocyte count is elevated with a predominance of neutrophils. Eosinophilia is seen only rarely and, when present at high levels, suggests the diagnosis of allergic angiitis and granulomatosis. The anemia of chronic disease may be seen, and an elevated erythrocyte sedimentation rate (ESR) is almost always present. Other common laboratory findings reflect the particular organ involved. Hypergammaglobulinemia may be present, and up to 30% of patients have a positive test for hepatitis B surface antigen. PositiveANCAtiters (usually of the p-ANCA type) are found in a low percentage (<20%) of patients with classic PAN. Microscopic polyangiitis is strongly associated with ANCA that are usually of the p-ANCA type, but c-ANCA have also been reported. In contrast, the ANCA in Wegener's granulomatosis (see below) are almost always of the c-ANCA type. Arteriograms may demonstrate characteristic abnormalities such as aneurysms in the small and medium-sized muscular arteries of the kidneys and abdominal viscera in classic PAN.

Diagnosis The diagnosis of classicPAN is based on the demonstration of characteristic findings of vasculitis on biopsy material of involved organs. In the absence of easily accessible tissue for biopsy, the angiographic demonstration of involved vessels, particularly in the form of aneurysms of small and medium-sized arteries in the renal, hepatic, and visceral vasculature, is sufficient to make the diagnosis. Aneurysms of vessels are not pathognomonic of classic PAN; furthermore, aneurysms need not always be present, and angiographic findings may be limited to stenotic segments and obliteration of vessels. Biopsy of symptomatic organs such as nodular skin lesions, painful testes, and muscle groups provides the highest diagnostic yields, while blind biopsy of asymptomatic organs is frequently negative. The presence of small vessel vasculitis, particularly in the setting of glomerulonephritis and pulmonary capillaritis distinguishes microscopic polyangiitis from classic PAN. In this regard, biopsy of the kidney or lung may establish the diagnosis of microscopic polyangiitis.

Prognosis The prognosis of untreated classicPAN as well as that of microscopic polyangiitis is extremely poor. The usual clinical course is characterized either by fulminant deterioration or by relentless progression associated with intermittent acute flare-ups. In classic PAN, death usually results from renal failure; from gastrointestinal complications, particularly bowel infarcts and perforation; and from cardiovascular causes. In microscopic polyangiitis, death usually results from renal failure or pulmonary hemorrhage. Intractable hypertension often compounds dysfunction in other organ systems, such as the kidneys, heart, and central nervous system, leading to additional late morbidity and mortality in classic PAN. The 5-year survival rate of untreated patients has been reported to be between 10 and 20% for both diseases; this rate has increased substantially as a result of treatment (see below).

TREATMENT

Extremely favorable therapeutic results have been reported in classicPAN with the combination of prednisone, 1 mg/kg per day, and cyclophosphamide, 2 mg/kg per day

(see "Wegener's Granulomatosis" for a detailed description of this therapeutic regimen). This regimen has been reported to result in up to a 90% long-term remission rate even following the discontinuation of therapy. In less severe cases of classic PAN, glucocorticoids alone have resulted in disease remission. In addition, long-term remissions have been reported in PAN associated with hepatitis B virus antigenemia using the antiviral agent vidarabine in combination with plasma exchange with and without glucocorticoids. Favorable results have also been reported in the treatment of PAN related to hepatitis B virus withIFN-aand plasma exchange. Careful attention to the treatment of hypertension can lessen the acute and late morbidity and mortality associated with renal, cardiac, and central nervous system complications of PAN. The treatment regimen for microscopic polyangiitis is similar to that for Wegener's granulomatosis (see below), particularly if glomerulonephritis is present.

ALLERGIC ANGIITIS AND GRANULOMATOSIS (CHURG-STRAUSS DISEASE)

Definition *Allergic angiitis and granulomatosis* was described in 1951 by Churg and Strauss and is a disease characterized by granulomatous vasculitis of multiple organ systems, particularly the lung. It is characterized by vasculitis of blood vessels of various types or sizes (including veins and venules), intra- and extravascular granuloma formation together with eosinophilic tissue infiltration, and a strong association with severe asthma and peripheral eosinophilia.

Incidence and Prevalence Allergic angiitis and granulomatosis is an uncommon disease whose exact incidence, similar to classicPAN, is difficult to determine due to the grouping of multiple types of vasculitic syndromes in many reported series. The disease can occur at any age with the possible exception of infants. The mean age of onset is 44 years, with a male-to-female ratio of 1.3:1.

Pathophysiology and Pathogenesis The vasculitis of allergic angiitis and granulomatosis involves small and medium-sized muscular arteries, capillaries, veins, and venules. The characteristic histopathologic features of allergic angiitis and granulomatosis are granulomatous reactions that may be present in the tissues or even within the walls of the vessels themselves. These are usually associated with infiltration of the tissues with eosinophils. This process can occur in any organ in the body; lung involvement is predominant, with skin, cardiovascular system, kidney, peripheral nervous system, and gastrointestinal tract also commonly involved. Although the precise pathogenesis of this disease is uncertain, its strong association with asthma and its clinicopathologic manifestations including eosinophilia, granulomata, and vasculitis, which strongly suggest hypersensitivity phenomena, point to aberrant immunologic phenomena.

Clinical and Laboratory Manifestations Patients with allergic angiitis and granulomatosis exhibit nonspecific manifestations such as fever, malaise, anorexia, and weight loss, which are characteristic of a multisystem disease. The pulmonary findings in allergic angiitis and granulomatosis clearly dominate the clinical picture with severe asthmatic attacks and the presence of pulmonary infiltrates. Clinically recognizable heart disease occurs in approximately one-third of patients. Heart involvement is seen at autopsy in 62% of cases and is the cause of death in 23% of patients. Skin lesions occur in approximately 70% of patients and include purpura in addition to cutaneous

and subcutaneous nodules. The renal disease in allergic angiitis and granulomatosis is less common and generally less severe than that of classicPAN and microscopic polyangiitis.

The characteristic laboratory finding in virtually all patients with allergic angiitis and granulomatosis is a striking eosinophilia, which reaches levels greater than 1000 cells/uL in more than 80% of patients. The other laboratory findings are similar to those of classicPAN and microscopic polyangiitis and reflect the organ systems involved. Allergic angiitis and granulomatosis is associated with p-ANCA.

Diagnosis The diagnosis of allergic angiitis and granulomatosis is made by biopsy in a patient with the characteristic clinical manifestations (see above). Granulomatous vasculitis with eosinophilic tissue involvement together with peripheral eosinophilia are typical.

Prognosis The prognosis of untreated allergic angiitis and granulomatosis is poor, with a reported 5-year survival of 25%. The cause of death is likely to be related to pulmonary and cardiac disease.

TREATMENT

Glucocorticoid therapy has been reported to increase the 5-year survival to more than 50%. In certain patients, the disease may be quite mild and may remit spontaneously or with short courses of glucocorticoids. In glucocorticoid failures or in patients who present with fulminant multisystem disease, the treatment of choice is a combined regimen of cyclophosphamide and alternate-day prednisone, which has resulted in a high rate of complete remission (see "Wegener's Granulomatosis" for a detailed description of this therapeutic regimen).

POLYANGIITIS OVERLAP SYNDROME

Many patients with systemic vasculitis manifest clinicopathologic characteristics that do not fit precisely into any classification but have overlapping features of classicPAN, allergic angiitis and granulomatosis, Wegener's granulomatosis, Takayasu's arteritis, and the hypersensitivity group of vasculitides. This subgroup has been referred to as the *polyangiitis overlap syndrome* and is part of the major grouping of systemic necrotizing vasculitis. This entity has been designated with a distinct classification in order to avoid confusion in attempting to fit such overlap syndromes into one or other of the more classic vasculitic syndromes. This subgroup is truly a systemic vasculitis with the same potential for resulting in irreversible organ system dysfunction as the other systemic necrotizing vasculitides. The diagnostic and therapeutic considerations as well as the prognosis for this subgroup are the same as those for classic PAN, microscopic polyangiitis, and allergic angiitis and granulomatosis.

WEGENER'S GRANULOMATOSIS

DEFINITION

Wegener's granulomatosis is a distinct clinicopathologic entity characterized by

granulomatous vasculitis of the upper and lower respiratory tracts together with glomerulonephritis. In addition, variable degrees of disseminated vasculitis involving both small arteries and veins may occur.

INCIDENCE AND PREVALENCE

Wegener's granulomatosis is an uncommon disease whose true incidence is difficult to determine. It is extremely rare in blacks compared with whites; the male-to-female ratio is 1:1. The disease can be seen at any age; approximately 15% of patients are less than 19 years of age, but only rarely does the disease occur before adolescence; the mean age of onset is approximately 40 years.

PATHOPHYSIOLOGY AND PATHOGENESIS

The histopathologic hallmarks of Wegener's granulomatosis are necrotizing vasculitis of small arteries and veins together with granuloma formation, which may be either intravascular or extravascular (Fig. 317-2). Lung involvement typically appears as multiple, bilateral, nodular cavitary infiltrates (Fig. 317-3), which on biopsy almost invariably reveal the typical necrotizing granulomatous vasculitis. Endobronchial disease, either in its active form or as a result of fibrous scarring, may lead to obstruction with atelectasis. Upper airway lesions, particularly those in the sinuses and nasopharynx, typically reveal inflammation, necrosis, and granuloma formation with or without vasculitis.

In its earliest form, renal involvement is characterized by a focal and segmental glomerulitis that may evolve into a rapidly progressive crescentic glomerulonephritis. Granuloma formation is only rarely seen on renal biopsy. In addition to the classic triad of upper and lower respiratory tracts and kidney disease, virtually any organ can be involved with vasculitis, granuloma, or both.

The immunopathogenesis of this disease is unclear, although the involvement of upper airways and lungs with granulomatous vasculitis suggests an aberrant hypersensitivity response to an exogenous or even endogenous antigen that enters through or resides in the upper airway. Chronic nasal carriage of *Staphylococcus aureus* has been reported to be associated with a higher relapse rate of Wegener's granulomatosis; however, there is no evidence for a role of this organism in the pathogenesis of the disease.

Peripheral blood mononuclear cells obtained from patients with Wegener's granulomatosis manifest increased secretion ofIFN-gbut not ofIL-4, IL-5, or IL-10 compared to normal controls. The increased IFN-g production is inhibited by exogenous IL-10. In addition,TNF-aproduction from peripheral blood mononuclear cells and CD4+ T is elevated. Furthermore, monocytes from patients with Wegener's granulomatosis produce increased amounts of IL-12. These findings indicate an unbalanced Th1-type T cell cytokine pattern in this disease that may have pathogenic and perhaps ultimately therapeutic implications.

A high percentage of patients with Wegener's granulomatosis developANCA; c-ANCA are the predominant ANCA in this disease. As with the other categories of vasculitis,

there is no clear evidence that ANCA play a primary role in the pathogenesis of Wegener's granulomatosis.

CLINICAL AND LABORATORY MANIFESTATIONS

A typical patient presents with severe upper respiratory tract findings such as paranasal sinus pain and drainage and purulent or bloody nasal discharge with or without nasal mucosal ulceration (Table 317-4). Nasal septal perforation may follow, leading to saddle nose deformity. Serous otitis media may occur as a result of eustachian tube blockage.

Pulmonary involvement may be manifested as asymptomatic infiltrates or may be clinically expressed as cough, hemoptysis, dyspnea, and chest discomfort. It is present in 85 to 90% of patients. Subglottic stenosis resulting from active disease or scarring occurs in approximately 16% of patients and may result in severe airway obstruction.

Eye involvement (52% of patients) may range from a mild conjunctivitis to dacryocystitis, episcleritis, scleritis, granulomatous sclerouveitis, ciliary vessel vasculitis, and retroorbital mass lesions leading to proptosis.

Skin lesions (46% of patients) appear as papules, vesicles, palpable purpura, ulcers, or subcutaneous nodules; biopsy reveals vasculitis, granuloma, or both. Cardiac involvement (8% of patients) manifests as pericarditis, coronary vasculitis, or, rarely, cardiomyopathy. Nervous system manifestations (23% of patients) include cranial neuritis, mononeuritis multiplex, or, rarely, cerebral vasculitis and/or granuloma.

Renal disease (77% of patients) generally dominates the clinical picture and, if left untreated, accounts directly or indirectly for most of the mortality in this disease. Although it may smolder in some cases as a mild glomerulitis with proteinuria, hematuria, and red blood cell casts, it is clear that once clinically detectable renal functional impairment occurs, rapidly progressive renal failure usually ensues unless appropriate treatment is instituted.

While the disease is active, most patients have nonspecific symptoms and signs such as malaise, weakness, arthralgias, anorexia, and weight loss. Fever may indicate activity of the underlying disease but more often reflects secondary infection, usually of the upper airway.

Characteristic laboratory findings include a markedly elevatedESR, mild anemia and leukocytosis, mild hypergammaglobulinemia (particularly of the IgA class), and mildly elevated rheumatoid factor. Thrombocytosis may be seen as an acute-phase reactant. In typical Wegener's granulomatosis with granulomatous vasculitis of the respiratory tract and glomerulonephritis, approximately 90% of patients have a positive c-ANCA. However, in the absence of renal disease, the sensitivity drops to approximately 70%.

DIAGNOSIS

The diagnosis of Wegener's granulomatosis is a clinicopathologic one made by the demonstration of necrotizing granulomatous vasculitis on biopsy of appropriate tissue in a patient with the clinical findings of upper and lower respiratory tract disease together

with evidence of glomerulonephritis. Pulmonary tissue, preferably obtained by open thoracotomy, offers the highest diagnostic yield, almost invariably revealing granulomatous vasculitis. Biopsy of upper airway tissue usually reveals granulomatous inflammation with necrosis but may not show vasculitis. Renal biopsy confirms the presence of glomerulonephritis.

The specificity of a positive c-ANCAtiter for Wegener's granulomatosis is very high, especially if active glomerulonephritis is present. However, the presence of c-ANCA should be adjunctive and, with very rare exceptions, should not substitute for a tissue diagnosis. False-positive ANCA titers have been reported in certain infectious and neoplastic diseases.

In its typical presentation, the classic clinicopathologic complex of Wegener's granulomatosis usually provides ready differentiation from other disorders. However, if all the typical features are not present at once, it needs to be differentiated from the other vasculitides, particularly allergic angiitis and granulomatosis, Goodpasture's syndrome (Chap. 275), tumors of the upper airway or lung, and infectious diseases such as histoplasmosis (Chap. 201), mucocutaneous leishmaniasis (Chap. 215), and rhinoscleroma (Chap. 30) as well as noninfectious granulomatous diseases.

Of particular note is the differentiation from *midline granuloma* and *upper airway neoplasms*, which are part of the spectrum of *midline destructive diseases*. These diseases lead to extreme tissue destruction and mutilation localized to the midline upper airway structures including the sinuses; erosion through the skin of the face commonly occurs, a feature that is extremely rare in Wegener's granulomatosis. Although blood vessels may be involved in the intense inflammatory reaction and necrosis, primary vasculitis is seen rarely. When systemic involvement occurs, it usually declares itself as a neoplastic process. In this regard, it is likely that midline granuloma is part of the spectrum of *angiocentric immunoproliferative lesions* (AIL). The latter are considered to represent a spectrum of postthymic T cell proliferative lesions and should be treated as such (Chap. 112). The term *idiopathic* has been applied to midline granuloma when extensive diagnostic workup including multiple biopsies has failed to reveal anything other than inflammation and necrosis. Under these circumstances, it is possible that the tumor cells were masked by the intensive inflammatory response. Such cases have responded to local irradiation with 50 Gy (5000 rad). Upper airway lesions should never be irradiated in Wegener's granulomatosis.

Wegener's granulomatosis must also be differentiated from *lymphomatoid granulomatosis*, the latter also being a part of the spectrum ofAIL. Lymphomatoid granulomatosis is characterized by lung, skin, central nervous system, and kidney involvement in which atypical lymphocytoid and plasmacytoid cells infiltrate tissue in an angioinvasive manner. In this regard, it clearly differs from Wegener's granulomatosis in that it is not an inflammatory vasculitis in the classic sense but an infiltration of vessels with atypical mononuclear cells; granuloma may be present in involved tissues. Approximately 50% of patients develop a true malignant lymphoma. The presence of c-ANCAin Wegener's granulomatosis proves extremely helpful in the differentiation from all the preceding diseases.

TREATMENT

Wegener's granulomatosis was formerly universally fatal, usually within a few months after the onset of clinically apparent renal disease. Glucocorticoids alone led to some symptomatic improvement, with little effect on the ultimate course of the disease. It has been well established that the most effective therapy in this disease is cyclophosphamide given in doses of 2 mg/kg per day orally together with glucocorticoids. The leukocyte count should be monitored closely during therapy, and the dosage of cyclophosphamide should be adjusted in order to maintain the count above 3000/uL, which generally maintains the neutrophil count at approximately 1500/uL. With this approach, clinical remission can usually be induced and maintained without causing severe leukopenia with its associated risk of infection. Cyclophosphamide should be continued for 1 year following the induction of complete remission and gradually tapered and discontinued thereafter.

At the initiation of therapy, glucocorticoids should be administered together with cyclophosphamide. This can be given as prednisone, 1 mg/kg per day initially (for the first month of therapy) as a daily regimen, with gradual conversion to an alternate-day schedule followed by tapering and discontinuation after approximately 6 months.

Using the above regimen, the prognosis of this disease is excellent; marked improvement is seen in more than 90% of patients, and complete remissions are achieved in 75% of patients. A number of patients who developed irreversible renal failure but who achieved subsequent remission on appropriate therapy have undergone successful renal transplantation.

Despite the dramatic remissions induced by the therapeutic regimen described above, long-term follow-up of patients has revealed that approximately 50% of remissions are later associated with one or more relapses. Reinduction of remission is almost always achieved; however, a high percentage of patients ultimately have some degree of morbidity from irreversible features of their disease, such as varying degrees of renal insufficiency, hearing loss, tracheal stenosis, saddle nose deformity, and chronically impaired sinus function. In evaluating patients for relapse, the ANCA titer can be misleading. Many patients who achieve remission continue to have elevated titers for years. In addition, over 40% of patients who were in remission and had a fourfold increase in c-ANCA titer did not have a relapse in disease. In this regard, therapy should not be reinstituted or increased on the basis of a rise in the ANCA titer alone; however, such a finding should prompt the clinician to examine the patient carefully for any objective evidence of active disease and to monitor that patient more closely.

Certain types of morbidity are related to toxic side effects of treatment. Since the preceding therapeutic regimen calls for conversion to alternate-day glucocorticoid therapy within 3 months and ultimate discontinuation within 6 to 12 months, glucocorticoid-related side effects such as diabetes mellitus, cataracts, life-threatening infectious disease complications, serious osteoporosis, and severe cushingoid features are infrequently encountered except in those patients requiring prolonged courses of daily glucocorticoids. However, cyclophosphamide-related toxicities are more frequent and severe. Cystitis to varying degrees occurs in 50% of patients, bladder cancer in 6%, and myelodysplasia in 2%.

Some reports have indicated therapeutic success with less frequent and severe toxic side effects using intermittent boluses of intravenous cyclophosphamide (l g/m_2 per month) in place of daily drug administered orally. However, we and others have found an increased rate of relapse with bolus intravenous cyclophosphamide. We therefore strongly recommend that the drug be given as daily oral therapy.

Despite concerns regarding toxicity, a regimen of daily cyclophosphamide and glucocorticoids is clearly the treatment of choice in patients with immediately life-threatening disease such as rapidly progressive glomerulonephritis. However, methotrexate together with glucocorticoids may be considered as an alternative for initial therapy for certain patients whose disease is not immediately life-threatening or as a switch regimen in those patients who have experienced significant cyclophosphamide toxicity. In one study, patients in this category were given oral prednisone as described above, and methotrexate was administered orally starting at a dosage of 0.3 mg/kg, with a maximum of 15 mg/week. If the treatment was well tolerated after 1 to 2 weeks, the dosage was increased by 2.5 mg weekly up to a dosage of 20 to 25 mg/week and maintained at that level. Remissions were achieved in 33 of 42 patients (79%). Nineteen patients relapsed; 15 of these 19 relapses occurred when patients were receiving 15 mg or less of methotrexate per week; 13 of these 19 were treated with a second course of methotrexate and prednisone and 10 of 13 achieved a second remission. Toxicities of methotrexate included elevated transaminase levels (24%), leukopenia (7%), opportunistic infection (9.5%), methotrexate pneumonitis (7%), and stomatitis (2%).

Azathioprine, in doses of 1 to 2 mg/kg per day, has proven effective in some patients, particularly in maintaining remission in those in whom remission was induced by cyclophosphamide. The drug should be administered together with the glucocorticoid regimen described above. Although certain reports have indicated that trimethoprim-sulfamethoxazole may be of benefit in the treatment of Wegener's granulomatosis, there are no firm data to substantiate this, particularly in patients with serious renal and pulmonary disease. In a study examining the effect of trimethoprim-sulfamethoxazole on relapse, decreased relapses were shown only with regard to upper airway disease, and no differences in major organ relapses were observed. Trimethoprim-sulfamethoxazole alone should never be used to treat active Wegener's granulomatosis outside of the upper airway.

TEMPORAL ARTERITIS

DEFINITION

Temporal arteritis, also referred to as *cranial arteritis* or *giant cell arteritis*, is an inflammation of medium- and large-sized arteries. It characteristically involves one or more branches of the carotid artery, particularly the temporal artery; hence the name. However, it is a systemic disease that can involve arteries in multiple locations.

INCIDENCE AND PREVALENCE

The incidence of temporal arteritis varies widely in different studies and in different geographic regions. A high incidence has been found in Scandanavia and in regions of the United States with large Scandanavian populations, compared to a lower incidence

in southern Europe. The annual incidence rates in individuals 50 years of age and older range from 0.49 to 23.3 per 100,000 population. It occurs almost exclusively in individuals older than 55 years; however, well-documented cases have occurred in patients 40 years old or younger. It is more common in women than in men and is rare in blacks. Familial aggregation has been reported, as has an association with HLA-DR4. In addition, genetic linkage studies have demonstrated an association of temporal arteritis with alleles at the HLA-DRB1 locus, particularly HLA-DRB1*04 variants. The disease is closely associated with *polymyalgia rheumatica*, which is more common than temporal arteritis. In Olmsted County, Minnesota, the annual incidence of polymyalgia rheumatica in individuals 50 years of age and older is 52.5 per 100,000 population.

PATHOPHYSIOLOGY AND PATHOGENESIS

Although the temporal artery is most frequently involved in this disease, patients often have a systemic vasculitis of multiple medium- and large-sized arteries, which may go undetected. Histopathologically, the disease is a panarteritis with inflammatory mononuclear cell infiltrates within the vessel wall with frequent giant cell formation. There is proliferation of the intima and fragmentation of the internal elastic lamina. Pathophysiologic findings in organs result from the ischemia related to the involved vessels. Distinct cytokine patterns as well as T lymphocytes expressing specific antigen receptors have been described suggesting the involvement of immunopathogenic mechanisms in temporal arteritis.IL-6 and IL-1b expression has been detected in a majority of circulating monocytes of patients with temporal arteritis and polymyalgia rheumatica. T cells recruited to vasculitic lesions in patients with temporal arteritis produce predominantly IL-2 andIFN-g, and the latter has been suggested to be involved in the progression to overt arteritis. Sequence analysis of the T cell receptor of tissue-infiltrating T cells in lesions of temporal arteritis indicates restricted clonal expansion, suggesting that an antigen residing in the arterial wall is recognized by a small fraction of T cells.

CLINICAL AND LABORATORY MANIFESTATIONS

The disease is characterized clinically by the classic complex of fever, anemia, highESR, and headaches in an elderly patient. Other manifestations include malaise, fatigue, anorexia, weight loss, sweats, and arthralgias. The polymyalgia rheumatica syndrome is characterized by stiffness, aching, and pain in the muscles of the neck, shoulders, lower back, hips, and thighs.

In patients with involvement of the temporal artery, headache is the predominant symptom and may be associated with a tender, thickened, or nodular artery, which may pulsate early in the disease but become occluded later (Figs. 28-CD1 and28-CD2). Scalp pain and claudication of the jaw and tongue may occur. A well-recognized and dreaded complication of temporal arteritis, particularly in untreated patients, is ocular involvement due primarily to ischemic optic neuropathy, which may lead to serious visual symptoms, even sudden blindness in some patients. However, most patients have complaints relating to the head or eyes for months before objective eye involvement. Attention to such symptoms with institution of appropriate therapy (see below) will usually avoid this complication. Claudication of the extremities, strokes, myocardial infarctions, and infarctions of visceral organs have been reported. Of note,

temporal arteritis is associated with a markedly increased risk of aortic aneurysm, which is usually a late complication and may lead to dissection and death.

Characteristic laboratory findings in addition to the elevatedESRinclude a normochromic or slightly hypochromic anemia. Liver function abnormalities are common, particularly increased alkaline phosphatase levels. Increased levels of IgG and complement have been reported. Levels of enzymes indicative of muscle damage such as serum creatine kinase are not elevated.

DIAGNOSIS

The diagnosis of temporal arteritis and its associated clinicopathologic syndrome can often be made clinically by the demonstration of the classic picture of fever, anemia, and highESR with or without symptoms of polymyalgia rheumatica in an elderly patient. The diagnosis is confirmed by biopsy of the temporal artery. Since involvement of the vessel may be segmental, the diagnosis may be missed on routine biopsy; serial sectioning of biopsy specimens is recommended. When the temporal arteries appear clinically normal, but temporal arteritis is strongly suspected, a biopsy segment of a few centimeters may be required to establish the diagnosis. Ultrasonography of the temporal artery has been reported to be helpful in diagnosis. A temporal artery biopsy should be obtained as quickly as possible in the setting of ocular signs and symptoms, and under these circumstances therapy should not be delayed pending a biopsy. In this regard, it has been reported that temporal artery biopsies may show vasculitis even after more than 14 days of glucocorticoid therapy. A dramatic clinical response to a trial of glucocorticoid therapy can confirm the diagnosis.

TREATMENT

Temporal arteritis and its associated symptoms are exquisitely sensitive to glucocorticoid therapy. Treatment should begin with prednisone, 40 to 60 mg per day for approximately 1 month, followed by a gradual tapering to a maintenance dose of 7.5 to 10 mg per day. In order to lessen glucocorticoid side effects in elderly individuals, conversion to alternate-day therapy may be attempted, but only after the disease has been put into remission with daily therapy. When ocular signs and symptoms occur, it is important that therapy be initiated or adjusted to control them. Because of the possibility of relapse, therapy should be continued for at least 1 to 2 years. TheESR can serve as a useful indicator of inflammatory disease activity in monitoring and tapering therapy and can be used to judge the pace of the tapering schedule. However, minor increases in the ESR can occur as glucocorticoids are being tapered and do not necessarily reflect an exacerbation of arteritis, particularly if the patient remains symptom free. Under these circumstances, the tapering should continue with caution. If one attempts to maintain a normal ESR throughout the tapering period, glucocorticoid toxicity will almost surely occur. The prognosis is generally good, and most patients achieve complete remission that is often maintained after withdrawal of therapy.

TAKAYASU'S ARTERITIS

DEFINITION

Takayasu's arteritis is an inflammatory and stenotic disease of medium- and large-sized arteries characterized by a strong predilection for the aortic arch and its branches. For this reason, it is often referred to as the *aortic arch syndrome*.

INCIDENCE AND PREVALENCE

Takayasu's arteritis is an uncommon disease, much less common than temporal arteritis. It is most prevalent in adolescent girls and young women. Although it is more common in the Orient, it is neither racially nor geographically restricted.

PATHOPHYSIOLOGY AND PATHOGENESIS

The disease involves medium- and large-sized arteries, with a strong predilection for the aortic arch and its branches; the pulmonary artery may also be involved. The most commonly affected arteries seen by angiography are listed inTable 317-5. The involvement of the major branches of the aorta is much more marked at their origin than distally. The disease is a panarteritis with inflammatory mononuclear cell infiltrates and occasionally giant cells. There are marked intimal proliferation and fibrosis, scarring and vascularization of the media, and disruption and degeneration of the elastic lamina. Narrowing of the lumen occurs with or without thrombosis. The vasa vasorum are frequently involved. Pathologic changes in various organs reflect the compromise of blood flow through the involved vessels.

Immunopathogenic mechanisms, the precise nature of which is uncertain, are suspected in this disease. As with several of the vasculitis syndromes, circulating immune complexes have been demonstrated, but their pathogenic significance is unclear.

CLINICAL AND LABORATORY MANIFESTATIONS

Takayasu's arteritis is a systemic disease with generalized as well as local symptoms. The generalized symptoms include malaise, fever, night sweats, arthralgias, anorexia, and weight loss, which may occur months before vessel involvement is apparent. These symptoms may merge into those related to pain over the involved vessels, followed by symptoms of ischemia in organs supplied by the compromised vessels. Pulses are commonly absent in the involved vessels, particularly the subclavian artery. The frequency of arteriographic abnormalities and the potentially associated clinical manifestations are listed inTable 317-5.

The clinical course may be fulminant, may progress gradually, or may stabilize. Complications are related to the distribution of the involved vessels. Death usually occurs from congestive heart failure or cerebrovascular accidents.

Characteristic laboratory findings include an elevatedESR, mild anemia, and elevated immunoglobulin levels.

DIAGNOSIS

The diagnosis of Takayasu's arteritis should be suspected strongly in a young woman

who develops a decrease or absence of peripheral pulses, discrepancies in blood pressure, and arterial bruits. The diagnosis is confirmed by the characteristic pattern on arteriography, which includes irregular vessel walls, stenosis, poststenotic dilatation, aneurysm formation, occlusion, and evidence of increased collateral circulation. Complete aortic arteriography should be obtained, unless this is renally contraindicated, in order to fully delineate the distribution and degree of arterial disease. Histopathologic demonstration of inflamed vessels adds confirmatory data; however, tissue is rarely readily available for examination.

TREATMENT

The course of the disease is variable, and spontaneous remissions may occur. Reported mortality statistics range from less than 10 to 75%. Although glucocorticoid therapy in doses of 40 to 60 mg prednisone per day alleviates symptoms, there are no convincing studies that indicate that they alone increase survival. The combination of glucocorticoid therapy for acute signs and symptoms and an aggressive surgical and/or angioplastic approach to stenosed vessels has markedly improved survival and decreased morbidity by lessening the risk of stroke, correcting hypertension due to renal artery stenosis, and improving blood flow to ischemic viscera and limbs. Unless it is urgently required, surgical correction of stenosed arteries should be undertaken only when the vascular inflammatory process is well controlled with medical therapy. Most recent mortality figures using this therapeutic approach are less than 10%. In individuals who are refractory to glucocorticoids, methotrexate in doses up to 25 mg per week has yielded encouraging results; however, long-term studies will be needed to confirm this.

HENOCH-SCHONLEIN PURPURA

DEFINITION

Henoch-Schonlein purpura, also referred to as *anaphylactoid purpura*, is a distinct systemic vasculitis syndrome that is characterized by palpable purpura (most commonly distributed over the buttocks and lower extremities), arthralgias, gastrointestinal signs and symptoms, and glomerulonephritis. It is a small vessel vasculitis.

INCIDENCE AND PREVALENCE

Henoch-Schonlein purpura is usually seen in children; most patients range in age from 4 to 7 years; however, the disease may also be seen in infants and adults. It is not a rare disease; in one series it accounted for between 5 and 24 admissions per year at a pediatric hospital. The male-to-female ratio is 1.5:1. A seasonal variation with a peak incidence in spring has been noted.

PATHOPHYSIOLOGY AND PATHOGENESIS

The presumptive pathogenic mechanism for Henoch-Schonlein purpura is immune-complex deposition. A number of inciting antigens have been suggested including upper respiratory tract infections, various drugs, foods, insect bites, and immunizations. IgA is the antibody class most often seen in the immune complexes and has been demonstrated in the renal biopsies of these patients.

CLINICAL AND LABORATORY MANIFESTATIONS

In pediatric patients, presenting symptoms related to the skin, gut, and joints are present in 50% of cases. In adults, presenting symptoms related to the skin are seen in over 70% of patients, while initial complaints related to the gut or the joints are noted in fewer than 20% of cases. The typical palpable purpura is seen in virtually all patients; most patients develop polyarthralgias in the absence of frank arthritis. Gastrointestinal involvement, which is seen in almost 70% of pediatric patients, is characterized by colicky abdominal pain usually associated with nausea, vomiting, diarrhea, or constipation and is frequently accompanied by the passage of blood and mucus per rectum; bowel intussusception may occur rarely. The renal involvement is usually characterized by mild glomerulonephritis leading to proteinuria and microscopic hematuria, with red blood cell casts in the majority of patients (Chap. 275); it usually resolves spontaneously without therapy. Rarely, a progressive glomerulonephritis will develop. Renal failure is the most common cause of death in the rare patient who dies of Henoch-Schonlein purpura. Although certain studies have found that renal disease is more severe in adults, this has not been a consistent finding. However, the course of renal disease in adults may be more insidious and thus requires close follow-up. Myocardial involvement can occur in adults but is rare in children.

Routine laboratory studies generally show a mild leukocytosis, a normal platelet count, and occasionally eosinophilia. Serum complement components are normal, and IgA levels are elevated in about one-half of patients.

TREATMENT

The prognosis of Henoch-Schonlein purpura is excellent. Most patients recover completely, and some do not require therapy. Treatment is similar for adults and children. When glucocorticoid therapy is required, prednisone in doses of 1 mg/kg per day and tapered according to clinical response has been shown to be useful in decreasing tissue edema, arthralgias, and abdominal discomfort; however, it has not proven beneficial in the treatment of skin or renal disease and does not appear to shorten the duration of active disease or lessen the chance of recurrence. Patients with rapidly progressive glomerulonephritis have been anecdotally reported to benefit from intensive plasma exchange combined with immunosuppressive drugs.

PREDOMINANTLY CUTANEOUS VASCULITIS

DEFINITION

The term *predominantly cutaneous vasculitis* has been used interchangeably with the terms *hypersensitivity vasculitis* and *cutaneous leukocytoclastic vasculitis*. Due to the heterogeneity of this group of disorders, none of these terms is totally adequate. The common denominator of this group of diseases is the involvement of small vessels of the skin. The syndrome is presumed to be associated with an aberrant hypersensitivity reaction to an antigen such as an infectious agent, a drug, or other foreign or endogenous substances. In most instances, however, an antigen is never identified and the disease remains idiopathic. The term *hypersensitivity vasculitis* is a misleading term

since most of the other groups of vasculitis syndromes are probably also associated with some form of hypersensitivity or aberrant immunologic reaction to as yet unidentified antigens. The term *cutaneous leukocytoclastic vasculitis* is a better term; however, not all of these vasculitides are truly leukocytoclastic in nature. We have elected to use the term *"predominantly" cutaneous vasculitis* since skin involvement generally dominates the clinical picture, but the skin is not always the exclusive organ involved. Indeed, any organ system can be involved with this type of vasculitis; however, the extracutaneous involvement is usually much less severe than that of the systemic necrotizing vasculitides.

INCIDENCE AND PREVALENCE

Although the exact incidence of this group of vasculitis syndromes is uncertain, it is clearly more common than the systemic necrotizing vasculitis group. The disease can occur at any age and in both sexes; however, different subgroups have a higher incidence in certain age groups, and some are more common in males than females, or vice versa.

PATHOPHYSIOLOGY AND PATHOGENESIS

The typical histopathologic feature of the predominantly cutaneous vasculitides is the presence of vasculitis of small vessels. Postcapillary venules are the most commonly involved vessels; capillaries and arterioles may be involved less frequently. This vasculitis is characterized by a *leukocytoclasis*, a term that refers to the nuclear debris remaining from the neutrophils that have infiltrated in and around the vessels during the acute stages. In the subacute or chronic stages, mononuclear cells predominate; in certain subgroups, eosinophilic infiltration is seen. Erythrocytes often extravasate from the involved vessels, leading to palpable purpura.

Immune-complex deposition is generally considered to be the immunopathogenic mechanism of this type of vasculitis; however, formal proof that this is the case has not been established for all subgroups (see above). The predominantly cutaneous vasculitides can be broken down empirically into two major categories depending on the type of putative antigen involved in the hypersensitivity reaction. In the originally described group, the antigen was foreign to the host, i.e., a drug, microbe, or foreign protein. In this regard, essential mixed cryoglobulinemia has been associated with hepatitis C virus infection. In the second category, the antigen is felt to be endogenous to the host. Examples of these are the "self" proteins such as DNA or immunoglobulin, which form immune complexes with their respective antibodies and lead to vasculitic complications in systemic lupus erythematosus and rheumatoid arthritis, respectively; other examples are the recognized and putative tumor antigens that form immune complexes with antibody and lead to vasculitis associated with certain neoplasms. Certain lymphoid malignancies may also secrete cytokines that contribute to the pathogenic process.

CLINICAL AND LABORATORY MANIFESTATIONS

The hallmark of this broad group of vasculitides is the predominance of skin involvement. Skin lesions may appear typically as palpable purpura; however, other

cutaneous manifestations of the vasculitis may occur, including macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. Despite the fact that skin lesions predominate, other organ systems may be involved to varying degrees, and the extent to which this occurs may define a relatively distinct subgroup. Even in patients with isolated cutaneous involvement, the disease may be characterized by systemic signs and symptoms such as fever, malaise, myalgia, and anorexia. The skin lesions may be pruritic or even quite painful, with a burning or stinging sensation. Lesions most commonly occur in the lower extremities in ambulatory patients or in the sacral area in bedridden patients due to the effects of hydrostatic forces on the postcapillary venules. Edema may accompany certain lesions, and hyperpigmentation often occurs in areas of recurrent or chronic lesions.

There are no specific laboratory tests diagnostic of this category of vasculitis. A mild leukocytosis with or without eosinophilia is characteristic, as is an elevatedESR. Cryoglobulins and rheumatoid factor may be seen in certain cases, and serum complement levels follow no definite pattern. Laboratory abnormalities related to specific organ dysfunction reflect the involvement of these organs in the particular syndrome in question.

Drug-Induced Vasculitis Cutaneous drug reactions take a number of forms, and vasculitis is only one of these (Chaps. 57 and59). Vasculitis associated with drug reactions usually presents as palpable purpura that may be generalized or limited to the lower extremities or other dependent areas; however, urticarial lesions, ulcers, and hemorrhagic blisters may also occur (Chap. 59). Signs and symptoms may be limited to the skin, although systemic manifestations such as fever, malaise, and polyarthralgias may occur. Although the skin is the predominant organ involved, systemic vasculitis may result from drug reactions. Drugs that have been implicated in vasculitis include allopurinol, thiazides, gold, sulfonamides, phenytoin, and penicillin (Chap. 59).

Serum Sickness and Serum Sickness-Like Reactions These reactions are characterized by the occurrence of fever, urticaria, polyarthralgias, and lymphadenopathy 7 to 10 days after primary exposure and 2 to 4 days after secondary exposure to a heterologous protein (classic serum sickness) or a nonprotein drug such as penicillin or sulfa (serum sickness-like reaction). Most of the manifestations are not due to a vasculitis; however, occasional patients will have typical cutaneous venulitis that may progress rarely to a systemic vasculitis.

Vasculitis Associated with Other Underlying Primary Diseases A number of diseases have vasculitis as a secondary manifestation of the underlying primary process. Foremost among these are the connective tissue diseases, particularly *systemic lupus erythematosus* (Chap. 311), *rheumatoid arthritis* (Chap. 312), and *Sjogren's syndrome* (Chap. 314). The most common form of vasculitis in these conditions is the small vessel venulitis isolated to the skin and clinically indistinguishable from the predominantly cutaneous vasculitides noted in response to an exogenous antigen. However, certain patients may develop a fulminant systemic necrotizing vasculitis indistinguishable from thePANgroup.

Cryoglobulinemia may be seen in a number of the diverse vasculitic syndromes. *Essential mixed cryoglobulinemia* (Chap. 275) may present as a predominantly

cutaneous vasculitis. However, typically, it is associated with glomerulonephritis, arthralgias, hepatosplenomegaly, and lymphadenopathy in addition to skin involvement.

Vasculitis can be associated with certain *malignancies*, particularly lymphoid or reticuloendothelial neoplasms. Leukocytoclastic venulitis confined to the skin is the most common finding; however, widespread systemic vasculitis may occur. Of particular note is the association of *hairy cell leukemia* (Chap. 112) with classicPAN.

A leukocytoclastic vasculitis predominantly involving the skin with occasional involvement of other organ systems may be a minor component of many other diseases. These include *subacute bacterial endocarditis*, *Epstein-Barr virus infection*, *HIV infection*, *chronic active hepatitis*, as well as a number of other infections; *ulcerative colitis*, *congenital deficiencies of various complement components*, *retroperitoneal fibrosis*, and *primary biliary cirrhosis*. Association of predominantly cutaneous vasculitis witha_1*-antitrypsin deficiency*, *intestinal bypass surgery*, and *relapsing polychondritis* has been reported.

DIAGNOSIS

The diagnosis of this category of vasculitis is made by the demonstration of vasculitis on biopsy. Given the predominance of cutaneous involvement, biopsy material is generally readily available. An important principle in the diagnostic approach to patients with presumed isolated cutaneous vasculitis is to search for an etiology of the vasculitis -- be it an exogenous agent such as a drug or an infection or an endogenous condition such as an underlying disease (Fig. 317-1). In addition, a careful physical and laboratory examination should be performed to rule out the possibility of systemic disease. This should start with the least invasive diagnostic approach and proceed to the more invasive only if clinically indicated.

TREATMENT

Most cases of predominantly cutaneous vasculitis resolve spontaneously, and others remit and relapse before finally remitting completely. In those patients in whom persistent cutaneous disease evolves or in whom extracutaneous organ system involvement occurs, a variety of therapeutic regimens have been tried with variable results. In general, the treatment of this type of vasculitis has not been satisfactory. Fortunately, since the disease is generally limited to the skin, this lack of consistent response to therapy usually does not lead to a life-threatening situation. When an antigenic stimulus is recognized as the precipitating factor in the vasculitis, it should be removed; if this is a microbe, appropriate antimicrobial therapy should be instituted. If the vasculitis is associated with another underlying disease, treatment of the latter often results in resolution of the former. In situations where disease is apparently self-limited, no therapy, except possibly symptomatic therapy, is indicated. When disease persists and when there is no evidence of an inciting agent, an associated disease, or an underlying systemic vasculitis, the decision to treat should be based on weighing the balance between the degree of symptoms and the risk of treatment. If the decision is made to treat, glucocorticoid therapy should be instituted, usually as prednisone, 1 mg/kg per day, in a regimen aimed at rapid tapering where possible, either directly to discontinuation or by conversion to an alternate-day regimen followed by ultimate

discontinuation. In cases that prove refractory to glucocorticoids, a trial of an immunosuppressive agent may be indicated. Patients with chronic vasculitis isolated to cutaneous venules rarely respond dramatically to any therapeutic regimen, and immunosuppressive agents should be used only as a last resort in these patients. Methotrexate and azathioprine have been used in such situations in anecdotal reports (see above for specific regimens). Although cyclophosphamide is the most effective therapy for the systemic vasculitides, it should almost never be used for predominantly cutaneous vasculitis because of the potential toxicity. Plasmapheresis has been used with some success in fulminant cases. Dapsone has been tried in a number of patients with isolated cutaneous vasculitis with rare anecdotal reports of success. However, this drug has been consistently beneficial as therapy for cutaneous vasculitis only in patients with erythema elevatum diutinum (see below).

KAWASAKI DISEASE

Kawasaki disease (mucocutaneous lymph node syndrome) is an acute, febrile, multisystem disease of children. It is characterized by unresponsiveness to antibiotics, nonsuppurative cervical adenitis, and changes in the skin and mucous membranes such as edema; congested conjunctivae; erythema of the oral cavity, lips, and palms; and desquamation of the skin of the fingertips. Although the disease is generally benign and self-limited, it is associated with coronary artery aneurysms in approximately 25% of cases, with an overall case fatality rate of 0.5 to 2.8%. These complications usually occur between the third and fourth weeks of illness during the convalescent stage. Vasculitis of the coronary arteries is seen in almost all the fatal cases that have been autopsied. There is typical intimal proliferation and infiltration of the vessel wall with mononuclear cells. Beadlike aneurysms and thromboses may be seen along the artery. Most investigators agree that many of the cases ofPANformerly reported in children were actually arteritic complications of unrecognized Kawasaki disease. Other manifestations include pericarditis, myocarditis, myocardial ischemia and infarction, and cardiomegaly.

It is likely that immune-mediated injury to blood vessel endothelium is involved in the pathogenesis of this disease. Patients with Kawasaki disease have been demonstrated to have evidence of increased immune activation characterized by increased activated helper T cells and monocytes, elevated serum-solubleIL-2 receptor levels, elevated levels of spontaneous IL-1 production by peripheral blood mononuclear cells, anti-endothelial cell antibodies, and increased cytokine-inducible activation antigens on their vascular endothelium. A strong association has been reported between a novel form of *S. aureus* that releases toxic shock syndrome toxin 1 and Kawasaki disease, suggesting that this was the causative organism and was acting as a superantigen similar to the superantigen effect in toxic shock syndrome. However, analysis of the T cell receptor repertoire of patients with Kawasaki disease has yielded conflicting data as to whether the T cell response is driven by a superantigen or by a conventional antigen.

Apart from the up to 2.8% of patients who develop fatal complications, the prognosis of this disease for uneventful recovery is excellent. High-dose intravenousg globulin (2 g/kg as a single infusion over 10 h) together with aspirin (100 mg/kg per day for 14 days followed by 3 to 5 mg/kg per day for several weeks) have been shown to be effective in reducing the prevalence of coronary artery abnormalities when administered early in the

course of the disease.

ISOLATED VASCULITIS OF THE CENTRAL NERVOUS SYSTEM

Isolated vasculitis of the central nervous system is an uncommon clinicopathologic entity characterized by vasculitis restricted to the vessels of the central nervous system without other apparent systemic vasculitis. Although the arteriole is most commonly affected, vessels of any size can be involved. The inflammatory process is usually composed of mononuclear cell infiltrates with or without granuloma formation. Cases have been associated with cytomegalovirus, syphilis, pyogenic bacterial, and varicella-zoster infections, as well as with Hodgkin's disease and amphetamine abuse; however, in most cases no underlying disease process has been identified.

Patients may present with severe headaches, altered mental function, and focal neurologic defects. Systemic symptoms are generally absent. Devastating neurologic abnormalities may occur depending on the extent of vessel involvement. The diagnosis is generally made by demonstration of characteristic vessel abnormalities on arteriography and confirmed by biopsy of the brain parenchyma and leptomeninges. In the absence of a brain biopsy, care should be taken not to misinterpret as true primary vasculitis angiographic abnormalities that might actually be vessel spasm related to another cause. The prognosis of this disease is poor; however, in certain patients the disease may remit spontaneously, and some reports indicate that glucocorticoid therapy alone or together with cyclophosphamide in steroid-resistant patients administered as described above for the systemic vasculitides has induced sustained clinical remissions in a small number of patients.

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Thromboangiitis obliterans is an inflammatory occlusive peripheral vascular disease of unknown etiology that affects arteries and veins. Thrombosis of the vessels is likely the primary event, and so this disease is not a classic vasculitis. However, it is considered among the vasculitides because of the intense inflammatory response within the thrombus and the fact that there is often a vasculitis of the vasa vasorum in the arterial wall.**The disease is discussed in detail in Chap. 248.*

BEHCET'S SYNDROME

Behcet's syndrome is a clinicopathologic entity characterized by recurrent episodes of oral and genital ulcers, iritis, and cutaneous lesions. The underlying pathologic process is a leukocytoclastic venulitis, although vessels of any size and in any organ can be involved.**This disorder is described in detail in Chap. 316.*

MISCELLANEOUS VASCULITIDES

A variety of disorders, many of which are uncommon, are characterized by varying degrees of inflammatory responses involving blood vessels. *Cogan's syndrome* is a disease characterized by nonsyphilitic interstitial keratitis together with vestibuloauditory symptoms. It may be associated with a systemic vasculitis involving vessels of different sizes as well as the aortic valve.

Erythema elevatum diutinum is a rare chronic skin disorder of unknown etiology characterized by persistent red, purple, and yellowish papules, plaques, and nodules usually distributed symmetrically over the extensor surface of the limbs; on biopsy, they demonstrate a leukocytoclastic venulitis together with a marked dermal inflammatory infiltrate. An association with streptococcal infections has been reported. The disease responds dramatically to dapsone therapy.

Certain *infections* may directly trigger an inflammatory vasculitic process. For example, rickettsias can invade and proliferate in the endothelial cells of small blood vessels causing a vasculitis (Chap. 177). In addition, the inflammatory response around blood vessels associated with certain systemic fungal diseases such as histoplasmosis (Chap. 201) may mimic a primary vasculitic process.

PRINCIPLES OF TREATMENT

Once a diagnosis of vasculitis has been established, a decision regarding therapeutic strategy must be made (Fig. 317-1). The vasculitis syndromes represent a wide spectrum of diseases with varying degrees of severity. Some require immediate and aggressive therapy with glucocorticoids and immunosuppressive agents, while others should be treated conservatively and symptomatically, usually with nonsteroidal anti-inflammatory drugs. Since the potential toxic side effects of certain therapeutic regimens may be substantial, the risk-versus-benefit ratio of any therapeutic approach should be weighed carefully. Specific therapeutic regimens are discussed above for the individual vasculitis syndromes; however, certain general principles regarding therapy should be considered. On the one hand, glucocorticoids and/or immunosuppressive therapy should be instituted immediately in diseases where irreversible organ system dysfunction and high morbidity and mortality have been clearly established. Wegener's granulomatosis is the prototype of a severe systemic vasculitis requiring such a therapeutic approach (see above). On the other hand, when feasible, aggressive therapy should be avoided for vasculitic manifestations that rarely result in irreversible organ system dysfunction and that usually do not respond to such therapy. For example, isolated cutaneous vasculitis usually resolves with symptomatic treatment, and prolonged courses of glucocorticoids uncommonly result in clinical benefit. Immunosuppressive agents have not proven to be beneficial in isolated cutaneous vasculitis, and their toxic side effects generally outweigh any potential beneficial effects. Glucocorticoids should be initiated in those systemic vasculitides that cannot be specifically categorized or for which there is no established standard therapy; immunosuppressive therapy should be added in these diseases only if an adequate response does not result or if remission can only be achieved and maintained with an unacceptably toxic regimen of glucocorticoids. When remission is achieved, one should continually attempt to taper glucocorticoids to an alternate-day regimen and discontinue when possible. When using immunosuppressive regimens, one should taper and discontinue the drug as soon as is feasible upon induction of remission (see below).

When glucocorticoids are used, prednisone is generally the formulation of choice and is administered as 1 mg/kg per day orally, first in divided doses and then converted to a single daily dose. After clinical improvement is noted (usually within a month), the regimen is gradually converted to an alternate-day schedule, followed by tapering and

discontinuation after approximately 6 months or as the clinical response dictates. When an immunosuppressive agent is required, cyclophosphamide is the drug of choice and its efficacy has been clearly established in Wegener's granulomatosis and the severe systemic vasculitides (see above). It should be given in doses of 2 mg/kg per day orally. It is recommended that the drug be taken as a single dose in the morning together with large amounts of fluid. Dose adjustments should be based on the leukocyte count, which should be maintained above 3000/uL. Leukocyte counts at any given time will reflect the dosage of cyclophosphamide taken the previous week. Of note, neutropenia may become more pronounced as glucocorticoids are tapered. The regimen that has proven successful in Wegener's granulomatosis (see above) and that should be followed for the other severe systemic vasculitides has called for continuation of cyclophosphamide for approximately 1 year following the induction of complete remission, with gradual tapering (by 25-mg decrements of the daily dose) over several months until discontinuation. No other drug has proven to be as effective as cyclophosphamide for severe life-threatening vasculitis. However, immediate and long-range toxic side effects may be severe. Alternative immunosuppressive regimens may be instituted where indicated in those patients who cannot tolerate cyclophosphamide due to unacceptable side effects or who do not wish to take cyclophosphamide because of the potential side effects, particularly infertility or sterility in individuals of child-bearing age. Methotrexate has been shown to be an acceptable alternative to cyclophosphamide when the latter drug cannot be used. Methotrexate is administered as a single weekly dose initially at a dosage of 0.3 mg/kg, not to exceed 15 mg/week. If the treatment is well tolerated after 1 to 2 weeks, the dosage should be increased by 2.5 mg weekly up to a dosage of 20 to 25 mg/week and maintained at that level. Azathioprine at a dosage of 2 mg/kg per day orally has also been employed as an alternative to cyclophosphamide in severe systemic vasculitis with less favorable results. In unusual cases in which none of the above regimens have resulted in remission of the vasculitis, certain experimental approaches have been used, such as plasmapheresis together with immunosuppressive drugs, with anecdotal reports of limited success. In addition, other immunosuppressive agents such as cyclosporine have been employed with minimal success.

Physicians should be thoroughly aware of the toxic side effects of therapeutic agents employed (Table 317-6). Side effects of glucocorticoid therapy are markedly decreased in frequency and duration in patients on alternate-day regimens compared to daily regimens. When cyclophosphamide is administered chronically in doses of 2 mg/kg per day for substantial periods of time (one to several years), the incidence of cystitis as defined by nonglomerular hematuria is approximately 50% and the incidence of bladder cancer is 6%. Bladder cancer can occur several years after discontinuation of cyclophosphamide therapy; therefore, monitoring for bladder cancer should continue indefinitely in patients who have received prolonged courses of daily cyclophosphamide. Significant alopecia is unusual in the chronically administered, low-dose regimen. When patients are receiving low-dose cyclophosphamide, the white blood count (WBC) is maintained above 3000/uL, and the patient is not receiving daily glucocorticoids, the incidence of life-threatening opportunistic infections is very low. However, the WBC is not an accurate predictor of risk of opportunistic infections in patients receiving methotrexate; infections with *Pneumocystis carinii* and certain fungi can be seen in the face of WBC that are within normal limits. All vasculitis patients who are not allergic to sulfa and who are receiving daily glucocorticoids in combination with an

immunosuppressive drug should receive trimethoprim-sulfamethoxazole as prophylaxis against *P. carinii* infection.

Finally, it should be emphasized that each patient is unique and requires individual decision-making. The above outline should serve as a framework to guide therapeutic approaches; however, flexibility should be practiced in order to provide maximal therapeutic efficacy with minimal toxic side effects in each patient.

318. SARCOIDOSIS - *Ronald G. Crystal*

DEFINITION

Sarcoidosis is a chronic, multisystem disorder of unknown cause characterized in affected organs by an accumulation of T lymphocytes and mononuclear phagocytes, noncaseating epithelioid granulomas, and derangements of the normal tissue architecture. Although there are usually skin anergy and depressed cellular immune processes in the blood, sarcoidosis is characterized at the sites of disease by exaggerated T helper 1 (T_H1) lymphocyte immune processes. All parts of the body can be affected, but the organ most frequently affected is the lung. Involvement of the skin, eye, liver, and lymph nodes is also common. The disease is often acute or subacute and self-limiting, but in many individuals it is chronic, waxing and waning over many years.

ETIOLOGY

The cause of sarcoidosis is unknown. Various infectious and noninfectious agents have been implicated, but there is no proof that any specific agent is responsible. However, all available evidence is consistent with the concept that the disease results from an exaggerated cellular immune response (acquired, inherited, or both) to a limited class of persistent antigens or self-antigens.

INCIDENCE AND PREVALENCE

Sarcoidosis is a relatively common disease affecting individuals of both sexes and almost all ages, races, and geographic locations. Females appear to be slightly more susceptible than males. Cases of sarcoidosis have been described in all of the major races, and the disease is found throughout the world. It has been suggested that sarcoidosis is more common in certain geographic areas such as the southeastern part of the United States, but when case-matched controls have been used, these geographic differences are less convincing. There is a remarkable diversity of the prevalence of sarcoidosis among certain ethnic and racial groups, with a range of <1 to 64 per 100,000 worldwide. The prevalence of sarcoidosis is from 10 to 40 per 100,000 in the United States and Europe. In the United States, most patients are black, with a ratio of blacks to whites ranging from 10:1 to 17:1. In Europe, however, the disease affects mostly whites. Furthermore, while the prevalence per 100,000 in Sweden is 64, in France it is 10, in Poland 3, yet for Irish females living in London it is 200. In contrast, the disease is very rare among Inuit, Canadian Indians, New Zealand Maoris, and Southeast Asians.

Most patients present with sarcoidosis between the ages of 20 and 40, but the disease can occur in children and in the elderly. Several hundred kindred groups with familial sarcoidosis have been described, and the disease has been observed in twins, more commonly in monozygotic than in dizygotic pairs. There also have been several instances of husband-wife pairs identified, and geographic foci of sarcoidosis among unrelated individuals living closely within a community, arguing for some environmental factors in the pathogenesis of the disease. Although the disease is believed to result from exaggerated cellular immune responses to a limited class of antigens, no clear

patterns in any HLA locus have emerged. Unlike many diseases in which the lung is involved, sarcoidosis favors nonsmokers.

PATHOPHYSIOLOGY AND IMMUNOPATHOGENESIS

The first manifestation of the disease is an accumulation of mononuclear inflammatory cells, mostly CD4+ T_H1 lymphocytes and mononuclear phagocytes, in affected organs. This inflammatory process is followed by the formation of granulomas, aggregates of macrophages and their progeny, epithelioid cells, and multinucleated giant cells. The typical sarcoid granuloma is a compact structure composed of an aggregate of mononuclear phagocytes surrounded by a rim of CD4+ T lymphocytes and, to a far lesser extent, B lymphocytes. The overall structure is relatively discrete and is interspersed with fine collagen fibrils, presumably remnants of the underlying connective tissue matrix. The giant cells within the granuloma can be of the Langhans' or foreign-body variety and often contain inclusions such as Schaumann bodies (conchlike structures), asteroid bodies (stellate-like structures), and residual bodies (refractile calcium-containing inclusions).

Together the accumulated T cells, mononuclear phagocytes, and granulomas represent the active disease. Other than the fact that they take up space and thus their bulk modifies the local architecture, for all except late stage cases, there is no evidence that the mononuclear inflammatory cells dispersed in the tissue or in the granuloma injure the affected organ by releasing mediators that damage the normal parenchymal cells or the extracellular matrix. Rather, organ dysfunction in sarcoidosis results mostly from the accumulated inflammatory cells distorting the architecture of the affected tissue; if a sufficient number of structures vital to the function of the tissue are involved, the disease becomes clinically apparent in that organ. Thus, while autopsy series show that, to some extent, sarcoidosis involves most organs in the majority of patients, the disease manifests clinically only in organs where it affects function (such as the lung and eye) or in organs where it is readily observed (such as the skin or, by x-ray, the hilar nodes). For example, in the lung, the inflammatory cells and granulomas distort the walls of the alveoli, bronchi, and blood vessels (Fig. 318-1*A*), thus altering the intimate relationships between air and blood necessary for normal gas exchange. When a sufficient amount of pulmonary tissue is involved, it is sensed by the individual as dyspnea. In contrast, most individuals with sarcoidosis have granulomatous mononuclear cell inflammation in the liver but usually do not have symptoms or significant functional derangements referable to that organ, likely because the disease process does not modify the local structures sufficiently to affect function.

If the disease is suppressed, either spontaneously or with therapy, the mononuclear inflammation is reduced in intensity and the number of granulomas is reduced. The granulomas resolve either by dispersion of the cells or by centripetal proliferation of fibroblasts from the periphery of the granuloma inward, to form a small scar. In chronic cases, the mononuclear cell inflammation persists for years. If the intensity of the inflammation is sufficiently high for a sufficiently long period, the derangements to the affected tissues result in extensive damage, the development of fibrosis, and permanent loss of organ function.

All available evidence suggests that active sarcoidosis results from an exaggerated

cellular immune response to a variety of antigens or self-antigens, in which the process of T lymphocyte triggering, proliferation, and activation is skewed in the direction of CD4+ T_H1 lymphocyte processes (Fig. 318-1*B*). The result is an exaggerated T_H1 T lymphocyte response and thus the accumulation of large numbers of activated T_H1 cells in the affected organs. Since the activated T_H1 lymphocyte releases mediators that attract and activate mononuclear phagocytes, it is likely that the process of granuloma formation is a secondary phenomenon that is a consequence of the exaggerated T_H1 cell process. In this context, the current hypotheses of the cause of sarcoidosis, not mutually exclusive, include the following: (1) The disease is caused by a class of persistent antigens, nonself or self, that trigger only the T_H1 cell arm of the immune response; (2) the disease results from an inadequate suppressor arm of the immune response, such that T_H1 cell processes cannot be shut down in a normal fashion; or (3) the disease results from inherited (and/or acquired) differences in immune response genes, such that the response to a variety of antigens is an exaggerated, T_H1 cell process.

Independent of the inciting agent(s) or the reason why there is an exaggerated T_H1 cell response, there is a general understanding of the processes responsible for the maintenance of the inflammation and the development of the granuloma. The T_H1 lymphocytes accumulate at the sites of disease, at least in part, because they proliferate in these sites at an exaggerated rate. This T cell proliferation is maintained by the spontaneous release of interleukin (IL) 2, the T cell growth factor, by activated T_H1 cells in the local milieu. In this regard, sarcoidosis is a remarkable example of compartmentalization of the immune system and a dramatic illustration of why disease activity of sarcoidosis cannot be assessed by evaluating the immune system only in the blood. Whereas the T_H1 cells in the involved organs are releasing IL-2 and proliferating at an enhanced rate, the T cells in other sites, such as blood, are quiescent. Furthermore, while there is a marked enhancement of the number of T_H1 cells at the sites of disease, the numbers of T_H1 cells in the blood are normal or slightly reduced. In the involved organs, the ratio of CD4+ to CD8+ T cells may be as high as 10:1 compared to the ratio of 2:1 found in normal tissues or in the blood of affected individuals.

In addition to driving other T_H1 cells in the affected organs to proliferate, the T_H1 cells at the sites of disease are activated and release mediators that both recruit and activate mononuclear phagocytes. The activated T_H1 cells accomplish this by releasing a variety of mediators (lymphokines) including proteins capable of recruiting blood monocytes to the local milieu of the activated T cells and interferon g, a protein that, among its many actions, activates mononuclear phagocytes. Together with cytokines such as interleukin (IL)-12 and others released locally, these mediators recruit blood monocytes to the affected organs and activate them, providing the building blocks for the formation of the granuloma.

In addition to these exaggerated cellular immune processes, active sarcoidosis is also characterized by hyperglobulinemia. Included among the immunoglobulins are antibodies against a variety of infectious agents as well as IgM anti-T cell antibodies. However, there is no evidence that any of these antibodies plays a role in the pathogenesis of the disease, and they are thought to result from the nonspecific polyclonal stimulation of B cells by the activated T cells at the site of disease.

If the damage in the affected organs is sufficiently extensive that the remaining parenchymal cells cannot reestablish the normal tissue architecture, the usual result is fibrosis, the proliferation of mesenchymal cells, and deposition of their connective tissue products. There is convincing evidence that the fibroblast proliferation is directed by tissue macrophages spontaneously releasing growth signals for fibroblasts, including platelet-derived growth factor, fibronectin, and insulin-like growth factor 1. It is not known, however, why this fibrotic process occurs only in a relatively small proportion of individuals with sarcoidosis.

CLINICAL MANIFESTATIONS

Sarcoidosis is a systemic disease, and thus the clinical manifestations may be generalized or focused on one or more organs. However, because the lung is almost always involved, most patients have symptoms referable to the respiratory system. Independent of the site, the clinical manifestations of the disease relate directly to the exaggerated T_H1 lymphocyte-mononuclear phagocyte granulomatous inflammatory process itself or to the sequelae resulting from the permanent damage caused by this process.

Sarcoidosis is occasionally discovered in a completely asymptomatic individual, but more commonly it presents abruptly over 1 to 2 weeks or the affected individual develops symptoms insidiously over several months. Independent of the mode of presentation, ~75% of all cases present in individuals younger than 40 years.

The asymptomatic form is usually detected by a routine examination, such as a chest film. In the United States, this form represents about 10 to 20% of all cases, but in countries where chest films are mandatory in preemployment screening programs, the proportion of asymptomatic patients is higher.

So-called acute or subacute sarcoidosis develops abruptly over a period of a few weeks and represents 20 to 40% of all cases. These individuals usually have constitutional symptoms such as fever, fatigue, malaise, anorexia, or weight loss. These symptoms are usually mild, but in approximately 25% of the acute cases the constitutional complaints are extensive. Many patients have respiratory symptoms, including cough, dyspnea, a vague retrosternal chest discomfort and/or polyarthritis. Two syndromes have been identified in the acute group. Lofgren's syndrome, frequent in Scandinavian, Irish, and Puerto Rican females, includes the complex of erythema nodosum (Plate IIE-70) and x-ray findings of bilateral hilar adenopathy, often accompanied by joint symptoms, including arthritis at the ankles, knees, wrists, or elbows. The Heerfordt-Waldenstrom syndrome describes individuals with fever, parotid enlargement, anterior uveitis, and facial nerve palsy.

The insidious form of sarcoidosis develops over months and is associated usually with respiratory complaints without constitutional symptoms. In the United States, 40 to 70% of all patients with sarcoidosis patients are in this category. About 10% of these individuals have symptoms referable to organs other than the lung. It is the individuals who present with the insidious form of sarcoidosis who most commonly go on to develop chronic sarcoidosis, with permanent damage to the lung and other organs.

Despite the fact that sarcoidosis is a systemic disease and some evidence of inflammation can be detected in most organs in the majority of patients, sarcoidosis is important clinically because of the pulmonary abnormalities and, to a lesser extent, lymph node, skin, liver, and eye involvement. Far less commonly, other organs are involved significantly.

Lung Of individuals with sarcoidosis, 90% have abnormal findings on chest x-ray at some time during their course (Fig. 318-2*A*). Overall, ~50% develop permanent pulmonary abnormalities, and 5 to 15% have progressive fibrosis of the lung parenchyma. Sarcoidosis of the lung is primarily an interstitial lung disease (Chap. 259) in which the inflammatory process involves the alveoli, small bronchi, and small blood vessels. These individuals typically have symptoms of dyspnea, particularly with exercise, and a dry cough. In acute and subacute cases, physical examination usually reveals dry rales. Hemoptysis is rare, as is production of sputum. Occasionally, the large airways are involved to a degree sufficient to cause dysfunction. Distal atelectasis can result from endobronchial sarcoidosis or from external compression from enlarged intrathoracic nodes. Rarely, wheezing is heard, incorrectly suggesting asthma. Large-vessel pulmonary granulomatous arteritis is common, but it rarely causes major problems. If it dominates the pulmonary lesions, it is sometimes called *necrotizing sarcoidal granulomatosis*. The pleura is involved in 1 to 5% of cases, almost always manifesting as a unilateral pleural effusion with characteristics of an exudate containing lymphocytes. The effusions usually clear within a few weeks, but chronic pleural thickening can result. Pneumothorax is very rare.

Lymph Nodes Lymphadenopathy is very common in sarcoidosis. Intrathoracic nodes are enlarged in 75 to 90% of all patients; usually this involves the hilar nodes, but the paratracheal nodes are commonly involved (Fig. 318-2*A*). Less frequently, there is enlargement of subcarinal, anterior mediastinal, or posterior mediastinal nodes. Peripheral lymphadenopathy is very common, particularly involving the cervical, axillary, epitrochlear, and inguinal nodes. The nodes in the retroperitoneal area and in the mesenteric chain also can enlarge. All these nodes are nonadherent, with a firm, rubbery texture. Palpation causes no pain. Unlike nodes in tuberculosis, the nodes do not ulcerate. The lymphadenopathy rarely causes a problem for the affected individual; however, if it is massive, it can be disfiguring and can impinge on other organs and lead to functional impairment.

Skin Sarcoidosis involves the skin in ~25% of patients. The most common lesions are erythema nodosum (Plate IIE-70), plaques, maculopapular eruptions, subcutaneous nodules, and lupus pernio. Erythema nodosum, comprising bilateral, tender red nodules on the anterior surface of the legs, is not specific for sarcoidosis but is common, particularly in acute sarcoidosis, in combination with systemic symptoms and polyarthralgias. Treatment is not required, since the lesions resolve spontaneously in 2 to 4 weeks. Erythema nodosum is much more common among patients with sarcoidosis in Europe than in the United States. Skin plaques associated with sarcoidosis are purple, indolent lesions, often raised, and usually occur on the face, buttocks, and extremities. The maculopapular eruptions occur on the face around the eyes and nose, on the back, and on the extremities. These are elevated lesions <1 cm in diameter with a flat, waxy top. Subcutaneous nodules are most common on the trunk and extremities.

Lupus pernio is characterized by indurated blue-purple, swollen, shiny lesions on the nose, cheeks, lips, ears, fingers, and knees. The lesions on the tip of the nose cause a bulbous appearance, sometimes associated with varicosities. The nasal mucosa is usually involved, and underlying bone can be destroyed. Sarcoidosis also can involve old surgical scars and tattoos. Although it may be disfiguring, cutaneous sarcoidosis rarely causes major problems. Clubbing of the fingers is occasionally observed in sarcoidosis, usually in association with extensive pulmonary fibrosis.

Eye Eye involvement occurs in ~25% of patients with sarcoidosis, and it can cause blindness. The usual lesions involve the uveal tract, iris, ciliary body, and choroid. Of those patients with eye involvement, ~75% have anterior uveitis and 25 to 35% have posterior uveitis. There is blurred vision, tearing, and photophobia. The uveitis can develop rapidly and may clear spontaneously over a 6- to 12-month period. It also can develop insidiously and be chronic. Conjunctival involvement is also common, usually with small, yellow nodules. When the lacrimal gland is involved, a keratoconjunctivitis sicca syndrome, with dry, sore eyes, can result.

Upper Respiratory Tract The nasal mucosa is involved in up to 20% of patients, usually presenting with nasal stuffiness. Any of the structures of the mouth can be involved, particularly the tonsils. Sarcoidosis involves the larynx in ~5% of patients. The epiglottis and areas around the true vocal cords are usually involved, but the cords themselves are not. These individuals are usually hoarse, and they have dyspnea, wheezing, and stridor; complete obstruction can occur.

Bone Marrow and Spleen Sarcoidosis of the marrow is reported in 15 to 40% of patients, but it rarely causes hematologic abnormalities other than a mild anemia, neutropenia, eosinophilia, and occasionally, thrombocytopenia. Although splenomegaly occurs in only 5 to 10% of patients, celiac angiography or splenic biopsy reveals involvement in 50 to 60% of patients. The presentation and complications of splenomegaly in sarcoidosis are similar to those of splenomegaly in general.

Liver Although liver biopsy reveals liver involvement in 60 to 90% of patients, liver dysfunction is usually not important clinically. Sarcoidosis involves generally the periportal areas. Isolated granulomatous hepatitis can occur. Approximately 20 to 30% have hepatomegaly and/or biochemical evidence of liver involvement. Usually these changes reflect a cholestatic pattern and include an elevated alkaline phosphatase level; the bilirubin and aminotransferase levels are only mildly elevated, and jaundice is rare. Rarely, portal hypertension can develop, as can intrahepatic cholestasis with cirrhosis.

Kidney Clinically apparent primary renal involvement in sarcoidosis is rare, although tubular, glomerular, and renal artery diseases have been reported. More commonly, but still in only 1 to 2% of all patients, there is a disorder of calcium metabolism with hypercalciuria, with or without hypercalcemia. If chronic, nephrocalcinosis and nephrolithiasis can result. It is believed that the calcium abnormalities are associated with enhanced calcium absorption in the gut, which is related to an abnormally high level of circulating 1,25-dihydroxyvitamin D produced by mononuclear phagocytes in the granulomas.

Nervous System All components of the nervous system can be involved in sarcoidosis. Neurologic findings are observed in about 5% of patients. Seventh nerve involvement with unilateral facial paralysis is most common. It occurs suddenly and is usually transient. Other common manifestations of neurosarcoid include optic nerve dysfunction, papilledema, palate dysfunction, hearing abnormalities, hypothalamic and pituitary abnormalities, chronic meningitis, and, occasionally, space-occupying lesions. Psychiatric disturbances have been described, and seizures can occur. Rarely, multiple lesions occur that mimic multiple sclerosis, spinal cord abnormalities, and peripheral neuropathy.

Musculoskeletal System The bones, joints, and/or muscles can be involved in sarcoidosis. Bone lesions are observed in 5% of patients and include variable-sized cysts in areas of expanded bone; well-defined, round, punched-out lesions; or lattice-like changes. Hand and foot bones are the common sites, but most bones can be involved. Occasionally, the bone lesions are tender and painful. Joint involvement is more common, with an incidence of 25 to 50% in known cases of sarcoidosis. Arthralgias and frank arthritis occur mostly in large joints; they can be migratory and are usually transient, but they can be chronic and result in deformities. Although muscle biopsy frequently demonstrates granulomatous inflammation, muscle dysfunction is rare. However, nodules, polymyositis, and chronic myopathy have been described.

Heart Approximately 5% of patients have significant heart involvement, with clinical evidence of cardiac dysfunction. Left ventricular wall involvement is common. Arrhythmias are frequent, and serious conduction disturbances, including complete heart block, can occur. Papillary muscle dysfunction, pericarditis, and congestive heart failure are also observed. Cor pulmonale secondary to chronic pulmonary fibrosis may occur but is uncommon.

Endocrine and Reproductive System The hypothalamic-pituitary axis is the part of the endocrine system most commonly involved; this condition usually presents as diabetes insipidus. Anterior pituitary dysfunction is also seen, manifesting as a deficiency in one or more pituitary hormones. Complete hypopituitarism is rare. Much less frequently, sarcoidosis can cause primary dysfunction of other endocrine glands. Adrenal cortical involvement resulting in Addison's syndrome has been described. The reproductive organs may be involved, but infertility is rare. Pregnancy is not affected by sarcoidosis, and common with sarcoidosis who become pregnant usually improve during pregnancy. However, the disease may flare post partum; presumably this variation results from fluctuations in endogenous glucocorticoid production.

Exocrine Glands Parotid enlargement is a classic feature of sarcoidosis, but clinically apparent parotid involvement occurs in<10% of patients. Bilateral involvement is the rule. The gland is usually nontender, firm, and smooth. Xerostomia can occur; other exocrine glands are affected only rarely.

Gastrointestinal Tract Although sarcoidosis involvement of the gastrointestinal tract is found occasionally at autopsy, it rarely has clinical importance. Occasionally, patients have esophageal or gastric symptoms.

COMPLICATIONS

The respiratory tract abnormalities cause most of the morbidity and mortality associated with sarcoidosis. The major problems are those characteristic of interstitial lung disease (Chap. 259), particularly dyspnea and insufficient oxygen delivery to vital organs. Respiratory failure with carbon dioxide retention is rare. In some patients, lung destruction results in formation of bullae that may harbor mycetomas, which are usually aspergillomas; erosion into the parenchyma can result in massive bleeding. The most common complications apart from the lung are associated with the eye; however, with therapy, blindness is rare. Complications of other organs include a gamut of abnormalities. The most serious are central nervous system (CNS) lesions or cardiac involvement leading to congestive heart failure or sudden death.

LABORATORY ABNORMALITIES

Common abnormalities in the blood include lymphocytopenia, an occasional mild eosinophilia, an increased erythrocyte sedimentation rate, hyperglobulinemia, and an elevated level of angiotensin-converting enzyme (ACE). False-positive tests for rheumatoid factor or antinuclear antibodies can be observed. Hypercalcemia is rare. Other serum abnormalities relate to involvement of specific organs such as liver, kidney, or endocrine glands.

Because the lung is involved so commonly, the routine chest film is almost always abnormal (Fig. 318-2*A*). The three classic x-ray patterns of pulmonary sarcoidosis are type I -- bilateral hilar adenopathy with no parenchymal abnormalities; type II -- bilateral hilar adenopathy with diffuse parenchymal changes; and type III -- diffuse parenchymal changes without hilar adenopathy. The type III pattern is sometimes split into two categories, with films that show fibrosis and upper lobe retraction classified separately. Although patients with type I x-ray patterns tend to have the acute or subacute, reversible form of the disease while those with types II and III often have the chronic, progressive disease, these patterns do not represent consecutive "stages" of sarcoidosis. Thus, except for epidemiologic purposes, this x-ray categorization is mostly of historic interest. The hilar adenopathy is almost always bilateral, but unilateral node enlargement can be seen. Nodes are also common in the paratracheal region. The diffuse parenchymal changes are typically reticulonodular infiltrates, but an acinar pattern is observed occasionally. Large nodules, similar to those of metastatic disease, are unusual but can occur. When there is massive fibrosis, the hila are pulled upward and there are conglomerate masses in the midlung zones. Some of the unusual chest x-ray findings in sarcoidosis include "egg shell" calcification of hilar nodes, pleural effusions, cavitation, atelectasis, pulmonary hypertension, pneumothorax, and cardiomegaly. Computed tomography of the chest is rarely helpful for either diagnosis or prognosis but can identify early fibrosis, and a "ground-glass" appearance is thought to be consistent with an active alveolitis.

The lung function abnormalities of sarcoidosis are typical for interstitial lung disease (Chap. 259) and include decreased lung volumes and diffusing capacity with a normal or supernormal ratio of the forced expiratory volume in 1 s to the forced vital capacity. Occasionally there is evidence of airflow limitation. There is usually mild hypoxemia and a mild, compensated hypocarbia.

The gallium-67 lung scan is usually abnormal, showing a pattern of diffuse uptake. If present, enlarged nodes are detected in these scans, as is inflammation in a variety of extrathoracic sites that usually have no clinical importance (Fig. 318-2*B*). Bronchoalveolar lavage typically demonstrates an increased proportion of lymphocytes, most of which are members of the activated T_H1 subset of CD4+ T lymphocytes (Fig. 318-2*C*). The remaining cells are mostly alveolar macrophages. In patients with significant fibrosis, a few neutrophils are also found. Eosinophils are rare.

The other laboratory features of sarcoidosis depend on the specific organ involved.

DIAGNOSIS

For a typical case, the diagnosis of sarcoidosis is made by a combination of clinical, radiographic, and histologic findings (Fig. 318-3*A*). In a young adult with constitutional complaints, respiratory symptoms, erythema nodosum, blurred vision, and bilateral hilar adenopathy, the diagnosis is almost always sarcoidosis. Commonly, however, the findings are more subtle. Furthermore, because sarcoidosis can occur in almost any place in the body, like tuberculosis or syphilis, it can be confused with many other disorders. In this context, the differential diagnosis of sarcoidosis must cover a wide range. However, it is confused most commonly with neoplastic diseases such as lymphoma or with disorders characterized also by a mononuclear cell granulomatous inflammatory process, such as the mycobacterial and fungal disorders.

The presence of skin anergy is typical but not diagnostic of sarcoidosis. Individuals with sarcoidosis who develop active tuberculosis react strongly to skin tests with purified protein derivative. The Kveim-Siltzbach skin test, the intradermal injection of a heat-treated suspension of a sarcoidosis spleen extract which is biopsied 4 to 6 weeks later, yields sarcoidosis-like lesions in 70 to 80% of individuals with sarcoidosis, with <5% false-positive results. However, the material is not widely available, and with the use of the transbronchial biopsy to obtain lung parenchyma for diagnostic purposes, the Kveim-Siltzbach test is not in general use.

No blood findings are diagnostic of the disease. Serum levels ofACE are elevated in approximately two-thirds of patients with sarcoidosis. Approximately 5% of all positive tests are not sarcoidosis and are seen in a variety of disorders, including asbestosis, silicosis, berylliosis, fungal infection, granulomatous hepatitis, hypersensitivity pneumonitis, leprosy, lymphoma, and tuberculosis. Hypercalcemia or an elevated 24-h urine calcium level is consistent with the diagnosis but is not specific.

The chest x-ray cannot be used as the sole criterion for the diagnosis of sarcoidosis. While the finding of bilateral hilar adenopathy is the hallmark of this disease, a similar pattern is occasionally observed in lymphoma, tuberculosis, coccidioidomycosis, brucellosis, and bronchogenic carcinoma.

The pattern of the gallium-67 scan is not diagnostic for sarcoidosis, nor is the finding of an increased proportion of lymphocytes among the cells recovered by bronchoalveolar lavage. However, the typical patterns of these tests (Fig. 318-2*B* and *C*) put the diagnosis in the general category of granulomatous lung disorders.

Whether or not the presentation is "classic," biopsy evidence of a mononuclear cell granulomatous inflammatory process is mandatory to make a definitive diagnosis of sarcoidosis. Because the lung is involved so frequently, it is the most common site to be biopsied, usually through a fiberoptic bronchoscope. Less common, but acceptable, sites for biopsy are the hilar nodes (by mediastinoscopy), the skin, conjunctiva, or lip. Rarely, the spleen, intraabdominal nodes, muscle, parotid or other salivary glands, upper respiratory tract, or the heart is biopsied for diagnostic purposes. At any of these sites, the findings must include the typical noncaseating granulomas. However, although histologic evidence is mandatory for a definitive diagnosis of sarcoidosis, the histologic findings are not sufficiently specific to make the diagnosis by themselves, since noncaseating granulomas are found in a number of other diseases, including infections and malignancy. Furthermore, although the liver or scalene nodes often reveal "positive" biopsies in cases of sarcoidosis, noncaseating granulomas from other causes are so frequent in these sites that they are not considered acceptable sites for establishing the diagnosis. Thus the definitive diagnosis of sarcoidosis is based on the biopsy in the context of the history, physical examination, blood tests, x-ray, lung function, and, if available, gallium-67 scan and bronchoalveolar lavage. Patients with HIV infection commonly have lymphocytopenia, chest x-ray abnormalities, positive gallium-67 chest scans, and increased proportions of lavage lymphocytes (early in the course of the disease), and they can have lung granulomas; thus, serologic testing for HIV infection should always be done in individuals suspected of having sarcoidosis.

PROGNOSIS

Overall, the prognosis in sarcoidosis is good. Most individuals who present with the acute disease are left with no significant sequelae. Approximately half of all patients have some permanent organ dysfunction, but for most this is mild, stable, and progresses rarely. In ~15 to 20% of patients, the disease remains active or recurs intermittently. Death is attributable directly to the disease in ~10% of all those affected.

TREATMENT

The therapy of choice for sarcoidosis is glucocorticoids (Fig. 318-3*B*), Various other drugs have been tried, including indomethacin, oxyphenbutazone, chloroquine, hydroxychloroquine, methotrexate, *p*-aminobenzoate, allopurinol, levamisole, azothioprine, and cyclophosphamide; but there is no evidence, apart from anecdotal, uncontrolled reports, to support their efficacy. Cyclosporine is ineffective for the pulmonary manifestations of the disease; anecdotal reports suggest that it may be useful in extrathoracic sarcoid not responding to glucocorticoids.

The major problem in treating sarcoidosis is in deciding when to treat. Because the disease clears spontaneously in ~50% of patients, and because the permanent organ derangements often do not improve with glucocorticoid treatment, there is controversy among clinicians as to the criteria for treatment. However, there is no question that glucocorticoids suppress effectively the activated T_H1 lymphocyte processes occurring at the sites of disease. Thus, the major problem in making decisions concerning therapy in sarcoidosis is to determine the extent and activity of the inflammatory process in the organs at greatest risk, such as the lung, eye, heart, and CNS.

For the lung, this is based on a combination of history, physical findings, chest x-ray, and pulmonary function tests. Centers that see large numbers of these individuals sometimes use criteria based on gallium-67 lung scans and bronchoalveolar lavage findings. The serum level ofACE has been suggested as a criterion for disease activity, but it is not specific for the lung. Unless the respiratory impairment is devastating, active pulmonary sarcoidosis is observed usually without therapy for 2 to 3 months; if the inflammation does not subside spontaneously, therapy is instituted. For the eye, decisions concerning therapy are based on slit-lamp examination and tests for visual acuity. For the heart andCNS, decisions are based on an estimate of the severity of the involvement; patients with minor dysfunction are usually observed, while patients with significant cardiac or neurologic abnormalities are treated. Usually, it is not necessary to treat the systemic symptoms, but occasionally the extent of the fevers, fatigue, and/or weight loss necessitate therapy.

The usual therapy for sarcoidosis is prednisone, 1 mg/kg, for 4 to 6 weeks, followed by a slow taper over 2 to 3 months. This regimen is repeated if the disease again becomes active. Alternate-day therapy is used by some clinicians, but there is no evidence that it is as effective. High-dose bolus intravenous glucocorticoids are used occasionally but are probably not as effective as oral therapy. There is no evidence that inhaled glucocorticoids are efficacious. Mild ocular disease responds usually to local therapy, but suppression of the uveitis often requires systemic glucocorticoids.

319. AMYLOIDOSIS - *Jean D. Sipe, Alan S. Cohen*

DEFINITION AND CLASSIFICATION

Amyloidosis results from the deposition of insoluble, fibrous amyloid proteins, mainly in the extracellular spaces of organs and tissues. Named by Virchow in 1854 on the basis of color after staining with iodine and sulfuric acid, all amyloid fibrils share an identical secondary structure, the b-pleated sheet conformation, and a unique ultrastructure. All amyloid deposits contain an identical nonfibrillar component, the pentraxin serum amyloid P (SAP), and are associated with glycosaminoglycans. Abnormal protein folding and assembly can also result in protein deposition (e.g., in brain or kidney) that lacks the classic fibrillar morphology of amyloid and the presence of SAP. Depending upon the biochemical nature of the amyloid precursor protein, amyloid fibrils can be deposited locally or may involve virtually every organ system of the body. Amyloid fibril deposition may have no apparent clinical consequences or may lead to severe pathophysiologic changes. Often the disease falls between these two extremes. Regardless of etiology, the clinical diagnosis of amyloidosis is usually not made until the disease is far advanced.

Although the fibril precursors differ in their amino acid sequences, the polypeptide backbones of these protein precursors assume similar fibrillar morphologies that render them resistant to proteolysis.

The amyloidoses are classified according to the biochemical nature of the fibril-forming protein (Table 319-1). *Systemic amyloidoses* include biochemically distinct forms that are neoplastic, inflammatory, genetic, or iatrogenic in origin, while *localized* or *organ-limited amyloidoses* are associated with aging and diabetes and occur in isolated organs, often endocrine, without evidence of systemic involvement.

Despite their biochemical and clinical differences, the various amyloidoses share common pathophysiologic features: (1) an amyloidogenic precursor in appropriate concentration; (2) appropriate host genetic background; (3) abnormalities in proteolysis of fibril precursors and nascent amyloid fibrils; and (4) alterations in extracellular matrix constituents such as glycosaminoglycans, including the presence of amyloid-enhancing factor and Apo E. The guidelines for nomenclature and classification of amyloid and amyloidosis were updated in 1998 by the Nomenclature Committee of the International Society for Amyloidosis (Table 319-1). Amyloid deposits should be classified using the capital letter A as the first letter of designation followed by the protein designation without any open space; for example, AL for amyloidosis involving immunoglobulin light chains.

ETIOLOGY AND PATHOGENESIS

Light Chain Amyloidosis (AL) The most common form of systemic amyloidosis seen in current clinical practice is AL (primary idiopathic amyloidosis, or that associated with multiple myeloma) resulting from fibril formation by monoclonal antibody light chains in primary amyloidosis and in some cases of multiple myeloma (Chap. 113). Fewer than 20% of patients with AL have myeloma. The rest have other monoclonal gammopathies, light chain disease, or even agammaglobulinemia (producing light chains, but not intact

immunoglobulin). About 15 to 20% of patients with myeloma have amyloidosis. A monoclonal population of bone marrow plasma cells is present and consistently produces either small lambda or kappa fragments or immunoglobulins that are processed (cleaved) in an abnormal fashion by macrophage enzymes to produce the partially degraded light chains responsible for AL amyloidosis. Lambda chain class predominates over kappa in AL by a 2:1 ratio, whereas in multiple myeloma and normal immunoglobulin synthesis, the reverse is true. Indeed, almost all lambda VI family chains have been associated with amyloid. The primary structure of each amyloid-forming light chain is unique, reflecting the features of the B cell clone that produced it. In patients with multiple myeloma, light chains can be deposited as casts in kidney tubules or as punctate deposits on basement membranes. Also, nonfibrillar deposition diseases have been described; thus there are three forms of human light chain-associated renal and systemic diseases: AL amyloidosis, cast nephropathy, and light chain deposition disease. Rarely, heavy chain amyloid deposition has been reported.

Amyloid A Amyloidosis (AA) AA amyloidosis (secondary, reactive, or acquired amyloidosis) occurs most frequently as a complication of chronic inflammatory disease. Effective treatment of the underlying inflammatory condition has reduced incidence in developed countries. In the past in the United States, tuberculosis (Chap. 169), osteomyelitis (Chap. 129), and leprosy (Chap. 170) were the most common precipitating diseases, and they remain so in developing countries. During inflammation, proinflammatory cytokines such as interleukin (IL) 1, IL-6, and tumor necrosis factor (TNF) stimulate the synthesis in liver of serum amyloid A, an injury-specific component of high-density lipoprotein. Thus, effective treatment of the underlying inflammatory disorder blocks the stimulus for precursor synthesis. Familial deposition of the AA protein occurs in some groups of patients with familial Mediterranean fever (FMF) and Familial Hibernian Fever (FHF) (Chap. 289). Colchicine treatment has been very effective both in blocking attacks of FMF and in reducing the incidence of AA amyloidosis in association with FMF. FMF is an autosomal recessive disorder subdivided into phenotype I, with irregularly occurring fever and abdominal, chest, or joint pain, preceding or accompanying renal amyloid; and phenotype II, in which renal amyloidosis is the first or only manifestation of the disease (Chap. 289). FMF is caused by mutations (16 identified to date) in the gene designated *MEFV* that encodes a 781-amino-acid protein named *pyrin* that appears to be a transcription factor. There is a strong correlation between the M694V mutation in MEFV and development of amyloidosis. FHF is an autosomal dominant disorder characterized by missense mutations in the TNF receptor.

Heredofamilial Amyloidoses Heredofamilial amyloidoses other than the AA form associated withFMF andFHFprimarily involve the nervous system, and their mode of inheritance is autosomal dominant. Familial amyloid polyneuropathies (FAP) are dominant hereditary diseases affecting kinships originating in Portugal, Japan, Sweden, Finland, Greece, Italy, and elsewhere. FAP can be subclassified based on clinical symptoms and the biochemical nature of the fibrils; in nearly all cases the fibrils are variants of transthyretin (TTR), apolipoprotein AI, gelsolin, cystatin C, and rarely the a chain of fibrinogen A or lysozyme. The mutant proteins, although present from birth, are associated with a delayed onset of disease symptoms, usually after three to seven decades of life. The FAP transthyretin prototype is the lower limb neuropathy first

described in Portugal. It has a poor prognosis and is characterized by progressively severe neuropathy, including marked autonomic nervous system involvement. In some of these individuals, bilateral "scalloped" pupils are pathognomonic of the disease.

ATTR The most frequently occurring form ofFAPinvolvesTTR, a 14-kDa protein originally described as prealbumin, that transports thyroxine and retinol-binding protein in the blood. The first mutation to be identified in Portuguese families and in families of Swedish origin was a single amino acid substitution, methionine for valine at position 30. To date, more than 60 TTR variants have been defined, several of which are nonamyloidogenic. Variant TTR gene carriers exhibit clinically heterogeneous amyloidoses according to the position and nature of the amino acid substitution. Substitution of proline for leucine at position 55 results in an early onset and rapidly progressing disease, whereas substitution of methionine for threonine at position 119 appears to protect against amyloid fibril formation. In Denmark, patients with a methionine substitution for leucine at position 111 have a severe cardiopathy. Nonpathogenic TTR mutants such as the substitution of serine for glycine at position 6 also exist, and several are associated with changes in association with retinol-binding protein.

AApoAI Deposition of one of five apolipoprotein AI variants (G26R, W50R, L60R, L90P, and deletion of residues 61-7 with VT inserts) can be associated with peripheral neuropathy that is clinically similar to the type of familial amyloidosis that is caused by variants ofTTR. In some kindreds, the clinical presentation is renal failure without neurologic symptoms.

AGel A unique form of hereditary systemic amyloidosis has been reported primarily in Finland but also in patients of Japanese and Dutch backgrounds. Fibrils of gelsolin fragments, a calcium-binding protein that binds to and fragments actin filaments, are deposited in blood vessels and basement membranes, leading to clinical manifestations of lattice corneal dystrophy and cranial neuropathy, followed by peripheral neuropathy, dystrophic skin changes, and involvement of other organs. Two mutations at position 187, within the actin-binding domain of gelsolin, are associated with the disease.

ALys Hereditary nonneuropathic systemic amyloidosis has been described in English families in which lysozyme is the major fibril protein. Two mutations have been described -- I56T and D67H.

AFib Hereditary nonneuropathic renal amyloidosis has been described in families with one of three mutations in the fibrinogen A a chains, R524L, E526V, or R554L.

Ab$_2$M In long-term hemodialysis, amyloidosis is now well recognized as a serious bone and joint complication.b$_2$-microglobulin is the major constituent of the amyloid fibrils, and formation of advanced glycation end products ofb$_2$-microglobulin has been implicated in the pathogenesis of Ab$_2$M.

Localized or Organ-Limited Amyloidoses Depending upon the biochemical nature of the amyloid fibril protein, instead of systemic deposition involving the cardiovascular and gastrointestinal systems along with lymph nodes, spleen, liver, kidneys, and adrenals, amyloid deposition may be limited to a single organ such as the pancreas, brain, or

heart. Recently, lactoferrin has been found to occur as amyloid fibrils in a rare form of corneal amyloidosis, and amyloid fibrils of prolactin have been identified in the pituitary gland and in a prolactin-producing tumor.

Polypeptide Hormone-Derived Amyloidosis Amyloid deposits are common in polypeptide hormone-producing tissues and tumors. Calcitonin is deposited in the hereditary amyloid syndrome, medullary carcinoma of the thyroid (ACal) (Chap. 330). Also AANF (atrial natriuretic factor-derived) amyloid deposits are found in the sarcolemma of ~80% of persons over 80 years of age. AIAPP (islet amyloid polypeptide-derived, or amylin) is deposited as amyloid fibrils in 90% of individuals with type 2 diabetes (Chap. 333), in endocrine tumors (Chap. 93), and in insulinoma (Chap. 93). It is produced in bcells of the pancreas and stored and released together with insulin. Human insulin does not naturally form amyloid fibrils, although fibrils of porcine insulin, AIns, are sometimes found as subcutaneous nodules at sites of insulin injection in diabetic individuals.

Amyloidosis Associated with Alzheimer's Disease A novel protein, b-amyloid protein (Ab), is the major fibril protein in the amyloid deposits of the cerebrovascular walls and the cores of the neuritic plaques of Alzheimer's disease (AD) patients and also in individuals with Down's syndrome (Chap. 66). The intracellular neurofibrillary tangles are composed of paired helical filaments arranged in a twisted conformation and have as their major component an abnormally phosphorylatedt-protein, a microtubule-associated protein whose semantic relation to the Ab of AD is arguable. Ab varies in length from 39 to 43 amino acids and is derived from a large transmembrane glycoprotein called amyloidb-precursor protein (AbPP). Mutations in AbPP are associated with familial AD and also with a different type of amyloidosis, hereditary cerebral hemorrhage with amyloidosis (Dutch type). Other forms of familial AD are associated with mutations in genes that encode presenilin proteins.

Prion Diseases Prions are a unique class of infectious proteins associated with a group of neurodegenerative diseases, the transmissible spongiform encephalopathies. In humans, these diseases include kuru, Creutzfeldt-Jakob disease, Gerstmann-Straussler-Scheinker syndrome, and fatal familial insomnia (Chap. 373); in animals, scrapie and bovine spongiform encephalopathy (mad cow disease). PrP^{Sc} is a pathogenic, transmissible spongiform encephalopathy-specific form of the host-encoded prion protein (PrP); PrP^{Sc}differs from PrP in that it contains a high amount ofb-pleated sheet structure and is insoluble and resistant to proteolytic enzymes. PrP^{Sc}deposits either consist of or can be readily converted to amyloid fibrils. APrP is similar to Ab and ATTR in that both familial and sporadic forms occur. In addition, infectious prior diseases have resulted from the transmission of PrP^{Sc} by ritualistic cannibalism, corneal transplantation, treatment with cadaveric human growth hormone, and a variety of neurosurgical procedures. It has been suggested that the earlier onset familial forms of amyloidosis are due to accelerated fibril formation from mutant precursors, whereas in sporadic cases, amyloid fibrils are formed more slowly from normal precursor molecules. The mutant PrP molecules are nearer the threshold for transition to the amyloidogenic PrP^{Sc}than are the normal. The transition from normal to amyloidogenic PrP^{Sc} is irreversible but very slow. The disease progresses because, once formed, amyloidogenic PrP^{Sc}can seed the conversion of normal molecules into an amyloidogenic form.

CLINICAL MANIFESTATIONS

The clinical manifestations of amyloidosis are varied and depend entirely on the biochemical nature of the fibril protein and thus the area of the body that is involved (Table 319-2). The diagnosis of amyloidosis is usually not made until after the point of irreversible organ damage. Proteinuria is often the first symptom associated with systemic amyloidosis, particularly of the AA and AL type; peripheral neuropathies are associated withFAP, and dementia and cognitive dysfunction with amyloid deposits in brain. Organ enlargement, especially of the liver, kidney, spleen, and heart, may be prominent; however, this does not occur in FAP,AD, or PrP diseases.

Kidney Renal involvement may consist of mild proteinuria or frank nephrosis. In some cases, the urinary sediment may show a few red blood cells. The renal lesion is usually not reversible and in time leads to progressive azotemia and death. The prognosis does not appear to be related to the degree of the proteinuria; when azotemia finally develops, the prognosis is grave. Treatment by peritoneal or hemodialysis or kidney transplantation improves the prognosis considerably. Hypertension is rare, except in long-standing amyloidosis. Renal tubular acidosis or renal vein thrombosis may occur. Localized accumulation of amyloid may be noted in the ureter, bladder, or other parts of the genitourinary tract.

Heart Cardiac amyloidosis can present as intractable heart failure. Electrocardiographic abnormalities include a low-voltage QRS complex and abnormalities in atrioventricular and intraventricular conduction, often resulting in varying degrees of heart block. Owing to their propensity to develop conduction defects and arrhythmias, patients with cardiac amyloidosis appear to be especially sensitive to digitalis, and this drug should be used with caution.

With respect to systemic amyloidoses, cardiac amyloidosis is common in primary (AL) and heredofamilial amyloidosis and very rare in the secondary (AA) form. With respect to localized amyloidosis, cardiac amyloidosis of the wild type or nonvariantTTR type is common after 80 years of age; also atrial natriuretic factor may be present in the atria. In systemic amyloidosis, cardiac manifestations consist primarily of congestive failure and cardiomegaly (with or without murmurs) and a variety of arrhythmias and are comparable in AL andFAP, the predominant forms with cardiomyopathy (Chap. 238). Although these manifestations predominantly reflect diffuse myocardial amyloid, the endocardium, valves, and pericardium may also be involved. Pericarditis with effusion is rare, although the differential diagnosis of constrictive pericarditis versus restrictive cardiomyopathy frequently arises. Echocardiography has demonstrated symmetric thickening of the left ventricular wall, hypokinesia and decreased systolic contraction and thickening of the interventricular septum and left ventricular posterior wall, and left ventricular cavities of small to normal size. Two-dimensional echocardiography produces the characteristic findings of thickened right and left ventricles, a normal left ventricular cavity, and, especially, a diffuse hyperrefractile "granular sparkling" appearance. Hearts that are heavily infiltrated with amyloid may or may not show an enlarged silhouette. Fluoroscopy usually shows decreased mobility of the ventricular wall; angiographic studies usually demonstrate thickened ventricular wall, decreased ventricular mobility, and absence of rapid ventricular filling in early diastole.

Liver While hepatic involvement is common except in heredofamilial amyloidosis of theTTRtype, liver function abnormalities are minimal and occur late in the disease. Portal hypertension occurs but is uncommon. Intrahepatic cholestasis has been noted in about 5% of patients with AL (primary) amyloidosis. Hepatomegaly is common, and AL hepatic amyloid is usually accompanied by the nephrotic syndrome and congestive heart failure with poor prognosis. Amyloidosis of the spleen characteristically is not associated with leukopenia and anemia.

Skin Involvement of the skin is one of the most characteristic manifestations of primary (AL) amyloidosis (Chap. 57). Other forms of amyloidosis such as lichen amyloidosis are thought to involve forms of keratin. In AL amyloidosis, the usually nonpruritic lesions may consist of slightly raised, waxy papules or plaques that are usually clustered in the folds of the axillae, anal, or inguinal regions; the face and neck; or mucosal areas such as ear or tongue. Periorbital ecchymoses ("black eye" or "raccoon syndrome") have been reported.

Gastrointestinal Tract Gastrointestinal symptoms are common in all systemic types of amyloidosis either from direct involvement of the gastrointestinal tract at any level or from infiltration of the autonomic nervous system with amyloid. Symptoms include obstruction, ulceration, malabsorption, hemorrhage, protein loss, and diarrhea (Chap. 286). Infiltration of the tongue is characteristic of primary amyloidosis (AL) or amyloidosis accompanying multiple myeloma and occasionally leads to macroglossia (Fig. 319-CD1). When not enlarged, the tongue may become stiffened and firm to palpation. Gastrointestinal bleeding may occur from any of a number of sites, notably the esophagus, stomach, or large intestine, and may be severe. Amyloid infiltration of the esophagus may lead to an incompetent or nonrelaxing lower esophageal sphincter, nonspecific motility disorders of the esophageal body, or rarely achalasia. Small-bowel lesions may lead to clinical and x-ray changes of obstruction. A malabsorption syndrome is common. Amyloidosis (AA or secondary) may also develop in association with other entities involving the gastrointestinal tract, especially tuberculosis (Chap. 169), granulomatous enteritis (Chap. 287), lymphoma (Chap. 112), and Whipple's disease (Chap. 286); differentiation of these conditions, which give rise to secondary amyloidosis, from diffuse primary amyloidosis of the small bowel may be difficult. Similarly, amyloidosis of the stomach may closely mimic gastric carcinoma, with obstruction, achlorhydria, and the radiologic appearance of tumor masses.

Nervous System Neurologic manifestations, especially prominent in the heredofamilial amyloidoses may include peripheral neuropathy, postural hypotension, inability to sweat, Adies's pupil, hoarseness, and sphincter incompetence. The cranial nerves are generally spared, except in the Finnish hereditary amyloidosis. Carpal tunnel syndrome may be caused by several amyloidoses, especially primary (AL) and chronic hemodialysis (Ab_2M) amyloid. Peripheral neuropathy is frequent in the former type. Ab amyloid occurs in the central nervous system as a component of senile plaques and in blood vessels ("congophilic angiopathy"). The protein concentration in the cerebrospinal fluid may be increased. Infiltrates of the cornea or vitreous body may be present in hereditary amyloid syndromes. Certain of these syndromes (advancedFAP) are characterized by a bilateral scalloping appearance of the pupil.

Endocrine Amyloid may infiltrate the thyroid or other endocrine glands but rarely causes endocrine dysfunction. Local amyloid deposits almost invariably accompany medullary carcinoma of the thyroid. Amyloid is often found in the adrenal gland, pituitary gland, and pancreas. Pancreatic islet amyloid as a complication of type 2 diabetes is especially prominent and is caused by the b cell peptide islet amyloid polypeptide. Little if any clinical dysfunction is present unless there is massive replacement of the gland by amyloid.

Joints and Muscles Amyloid can directly, although rarely, involve articular structures by its presence in the synovial membrane and synovial fluid or in the articular cartilage. In these cases it is almost always of the AL type and associated with multiple myeloma. Amyloid arthritis can mimic a number of the rheumatic diseases because it can present as a symmetric arthritis of small joints with nodules, morning stiffness, and fatigue (Chap. 320). The synovial fluid usually has a low white blood cell count, a good to fair mucin clot, a predominance of mononuclear cells, and no crystals. Studies of surgical specimens suggest a significant incidence of amyloid in cartilage, capsule, and synovium in osteoarthritis (Chap. 321). Amyloid infiltration of muscle may lead to a pseudomyopathy. Shoulder muscle infiltration can produce the "shoulder pad" sign. Amyloid is found in muscle inclusion body disease, where Ab and/or PrP have been identified.

Deposition ofb_2-microglobulin as amyloid fibrils in the musculoskeletal systems is a serious complication of long-term hemodialysis. Ab_2M presents as the carpal tunnel syndrome, cystic bone lesions, and even destractive spondyloarthropathy.

Respiratory System The nasal sinuses, larynx, and trachea may be involved by accumulation of AL amyloid, which blocks the ducts, in the case of the sinuses, or the air passages. Amyloidosis of the lung involves the bronchi and alveolar septa diffusely. The lower respiratory tract is affected most frequently in primary (AL) amyloidosis and in the disease associated with dysproteinemia. Pulmonary symptoms attributable to amyloid are present in about 30% of cases. Amyloid may be localized in the bronchi or pulmonary parenchyma and may resemble a neoplasm. In these cases, local excision should be attempted and, when successful, may be followed by prolonged remissions.

Hematopoietic System Hematologic changes may include fibrinogenopenia, increased fibrinolysis, and selective deficiency of clotting factors. Deficient factor X seems to be due to nonspecific calcium-dependent binding to the polyanionic amyloid fibrils. Splenectomy in the patient with such a factor X deficiency can relieve the deficiency and the associated bleeding disorder, since factor X has been shown to bind to the large masses of splenic amyloid. Endothelial damage together with the clotting abnormalities lead to a propensity toward abnormal bleeding.

DIAGNOSIS

Amyloid fibrils are identified in biopsy or necropsy tissue sections (Table 319-3). The systemic amyloidoses offer a choice of biopsy sites; abdominal fat aspirates or renal or rectal biopsies are often performed. Microscopically, amyloid deposits stain pink with the hematoxylin-eosin stain and show metachromasia with crystal violet. The widely used and useful Congo red stain imparts a unique green birefringence when stained tissue

sections are viewed using the polarizing microscope (Fig. 319-1). Fluorescent dyes such as thioflavin are sensitive screening stains for amyloid deposits in brain and other tissues; however, specificity should be confirmed. After amyloid has been identified by staining, it can be chemically classified by genomic DNA and protein studies and by immunohistochemistry. In the case ofFAP, the presence of mutantTTR (or gelsolin, Apo AI, etc.) establishes the specific diagnosis of the disease. Isoelectric focusing is used as a simple screening test for variant transthyretins associated with familial TTR amyloidosis. In order to establish the relationship of immunoglobulin-related amyloid to multiple myeloma, electrophoretic and immunoelectrophoretic studies on serum and urine should be performed when the biopsy reveals amyloid deposition. Most of these patients will have only relatively small paraprotein components, and only a few will have frank multiple myeloma.

PROGNOSIS

Generalized amyloidosis is usually a slowly progressive disease that leads to death in several years, but in some instances, prognosis is improving. The average survival in most large series of AL amyloid is ~12 months and inFAP is ~7 to 15 years. A number of individuals with amyloid have been followed 5 to 10 years and longer. The course of amyloidosis is difficult to document, because dating the time of origin of the disease is rarely possible. When amyloidosis develops in patients with rheumatoid arthritis, it seldom becomes evident when the arthritis is of less than 2 years' duration. When amyloidosis develops in patients with multiple myeloma, manifestations leading to initial hospitalization are more apt to be related to amyloid disease than to myeloma. In these cases, prognosis is very poor, and life expectancy is usually less than 6 months.

TREATMENT

Rational therapy should be directed at (1) reducing precursor production, (2) inhibiting the synthesis and extracellular deposition of amyloid fibrils, and (3) promoting lysis or mobilization of existing amyloid deposits. There are new specific therapies for the various amyloidoses. In certain of the heredofamilial amyloidoses, genetic counseling is an important aspect of treatment, and the removal of the site of synthesis of the mutant protein by liver transplantation has proven remarkably successful. Liver transplantation has been carried out since 1990 forFAPpatients in Sweden, the United States, Portugal, Spain, and other countries. It appears that disease progression is halted and that there is some improvement in autonomic nervous system function. The utilization of chronic hemodialysis and of kidney transplantation has clearly improved the prognosis of renal amyloid.

In the case of AL amyloid, the fact that immunoglobulin light chain is made by plasma cells has led to the use of alkylating agents. However, these agents are toxic and not very effective. The most effective form of treatment currently is stem cell transplantation and immunosuppressive drugs (melphalan). Several long-term remissions have been reported, but serious complications, even death, can occur. A novel anthracycline, iododoxorubicin (IDOX), has been shown to bind to AL amyloid (similar to Congo red) in vivo and promote amyloid resorption. A subset of AL patients responds transiently to this experimental agent; and it is thought that IDOX may prove useful in combination with other forms of treatment. Cardiac tranplantation in selected cases of AL

orFAPamyloidosis has its advocates and has been successful.

Colchicine has been shown to be effective in preventing acute attacks and amyloidosis in patients withFMF(Chap. 289).

The major causes of death are heart disease and renal failure. Sudden death, presumably due to arrhythmias, is common. Occasionally, gastrointestinal hemorrhage, respiratory failure, intractable heart failure, and superimposed infections are the terminal events.

SECTION 3 -DISORDERS OF THE JOINTS

320. APPROACH TO ARTICULAR AND MUSCULOSKELETAL DISORDERS - *John J. Cush, Peter E. Lipsky*

Musculoskeletal complaints account for more than 315,000,000 outpatient visits per year. Many of the musculoskeletal complaints that cause patients to seek medical attention are related to self-limited conditions requiring minimal evaluation and only symptomatic therapy and reassurance. However, some patients with similar symptoms have a more serious condition that requires further evaluation or additional laboratory testing to confirm the suspected diagnosis or determine the extent and nature of the pathologic process. A primary objective is to determine if a "red flag" or urgent rheumatologic condition is present and, if not, to formulate a differential diagnosis that leads to accurate diagnosis and timely therapy while avoiding excessive diagnostic testing and unnecessary treatment (Table 320-1) There are several urgent conditions that must be diagnosed promptly to avoid significant morbid or mortal sequelae. These red flag diagnoses include septic arthritis, acute crystal-induced arthritis (e.g., gout), and fracture. Each of these may be suspected by an acute onset with a monoarticular or focal presenting complaint (see below).

Individuals with musculoskeletal complaints should be evaluated in a uniform, logical manner by means of a thorough history, a comprehensive physical examination, and, if appropriate, laboratory testing. The goals of the initial encounter are to determine whether the musculoskeletal complaint is (1) *articular* or *nonarticular* in origin, (2) *inflammatory* or *noninflammatory* in nature, (3) *acute* or *chronic* in duration, and (4) *localized* or *widespread* (*systemic*) in distribution.

With such an approach and an understanding of the pathophysiologic processes that underlie musculoskeletal complaints, an adequate diagnosis can be made in the vast majority of individuals. However, some patients will not fit immediately into an established diagnostic category. Many musculoskeletal disorders resemble each other at the outset, and some take weeks or months to evolve into a readily recognizable diagnostic entity. This consideration should temper the desire always to establish a definitive diagnosis at the first encounter.

ARTICULAR VERSUS NONARTICULAR

The musculoskeletal evaluation must discriminate the anatomic site(s) of origin of the patient's complaint. For example, ankle pain can result from a variety of pathologic conditions involving disparate anatomic structures, including gonococcal arthritis, calcaneal fracture, Achilles tendinitis, cellulitis, and peripheral neuropathy. Articular structures include the synovium, synovial fluid, articular cartilage, intraarticular ligaments, joint capsule, and juxtaarticular bone. Nonarticular (or periarticular) structures, such as supportive extraarticular ligaments, tendons, bursae, muscle, fascia, bone, nerve, and overlying skin, may be involved in the pathologic process. Pain from nonarticular structures may mimic true articular pain because of their proximity to the joint. Distinguishing between articular and nonarticular disease requires a careful and detailed examination. Articular disorders may be characterized by deep or diffuse joint pain, limited range of motion on active and passive movement, swelling caused by

synovial proliferation or effusion or bony enlargement, crepitation, instability, locking, or deformity. By contrast, nonarticular disorders tend to be painful on active but not passive range of motion, demonstrate point or focal tenderness in regions distinct from articular structures, and have physical findings remote from the joint capsule. Moreover, nonarticular disorders seldom demonstrate crepitus, instability, deformity, or swelling.

INFLAMMATORY VERSUS NONINFLAMMATORY

In the course of a musculoskeletal evaluation, the examiner should elicit symptoms and signs that will narrow or establish the diagnosis. A primary objective is to identify the nature of the underlying pathologic process. Musculoskeletal disorders are generally classified as inflammatory or noninflammatory. Inflammatory disorders may be infectious (infection with *Neisseria gonorrhoea* or *Mycobacterium tuberculosis*), crystal-induced (gout, pseudogout), immune-related [rheumatoid arthritis (RA), systemic lupus erythematosus (SLE)], reactive (rheumatic fever, Reiter's syndrome), or idiopathic. Inflammatory disorders may be identified by the presence of some or all of the four cardinal signs of inflammation (erythema, warmth, pain, and swelling), by systemic symptoms (prolonged morning stiffness, fatigue, fever, weight loss), or by laboratory evidence of inflammation (elevated erythrocyte sedimentation rate or C-reactive protein level, thrombocytosis, anemia of chronic disease, or hypoalbuminemia). Articular stiffness is common in chronic musculoskeletal disorders. However, the chronology and magnitude of stiffness may be diagnostically important. Morning stiffness related to inflammatory disorders (such as RA) is precipitated by prolonged rest, often lasts several hours, and may improve with activity and anti-inflammatory medications. By contrast, intermittent stiffness associated with noninflammatory conditions, such as osteoarthritis, is precipitated by brief periods of rest, usually lasts less than 60 min, and is exacerbated by activity. Noninflammatory disorders may be related to trauma (rotator cuff tear), ineffective repair (osteoarthritis), cellular overgrowth (pigmented villonodular synovitis), or pain amplification (fibromyalgia). They are often characterized by pain without swelling or warmth, the absence of inflammatory or systemic features, little or no morning stiffness, and normal laboratory findings.

Identification of the nature of the underlying process and the site of the complaint will enable the examiner to narrow the diagnostic considerations and to assess the need for immediate diagnostic or therapeutic intervention or for continued observation.Figure 320-1 presents a logical approach to the evaluation of patients with musculoskeletal complaints.

CLINICAL HISTORY

Additional historic features may be helpful in establishing the nature and extent of the pathologic process and may provide important clues to the diagnosis. When evaluating patients with musculoskeletal complaints, the clinician should always consider the most common conditions (e.g., low back pain, osteoarthritis) seen in the general population (Fig. 320-2). Aspects of the patient profile, including age, sex, race, and family history, can provide important information. Certain diagnoses are more frequent in specific age groups.SLE, rheumatic fever, and Reiter's syndrome are more common in the young, whereas fibromyalgia andRA are most common in middle age, and osteoarthritis and

polymyalgia rheumatica in the elderly. Some diseases are more common in a particular gender or race. Gout and the spondyloarthropathies (e.g., ankylosing spondylitis, Reiter's syndrome) are more common in men, whereas SLE, RA, and fibromyalgia are more common in women. Polymyalgia rheumatica, giant cell arteritis, and Wegener's granulomatosis preferentially affect whites, whereas sarcoidosis and SLE are more common in blacks. *Familial aggregation* occurs in some disorders, such as ankylosing spondylitis, gout, RA, and Heberden's nodes of osteoarthritis.

The chronology of the complaint (*onset*, *evolution*, and *duration*) is an important diagnostic feature. The onset of disorders such as septic arthritis and gout tends to be abrupt, whereas osteoarthritis,RA, and fibromyalgia may develop more indolently. In terms of evolution, disorders are classified as acute (e.g., septic arthritis), chronic (e.g., osteoarthritis), intermittent (e.g., gout), migratory (e.g., rheumatic fever, gonococcal or viral arthritis), or additive (e.g., RA, Reiter's syndrome). Musculoskeletal disorders typically are called *acute* if they last less than 6 weeks and *chronic* if they last longer. Acute and intermittent arthropathies tend to be infectious, crystal-induced, or reactive. Noninflammatory and immune-related arthritides, such as osteoarthritis and RA, respectively, are often chronic. The duration of the patient's complaints may alter the diagnostic considerations. For example, the musculoskeletal signs and symptoms of hepatitis B virus infection may be identical with those of early RA at the onset but rarely persist beyond 3 weeks.

The *number and distribution* of involved articulations should be noted. Articular disorders are classified as *monarticular* (one joint involved), *oligoarticular* or *pauciarticular* (two to three joints involved), or *polyarticular* (more than three joints involved). Nonarticular disorders can be classified as either *focal* or *widespread*. Complaints secondary to trauma and gout are typically focal or monarticular, whereas polymyositis,RA, and fibromyalgia are more diffuse or polyarticular. Joint involvement tends to be symmetric in RA but is often asymmetric in the spondyloarthropathies and in gout. The upper extremities are frequently involved in RA, whereas lower extremity arthritis is characteristic of Reiter's syndrome and gout at their onset. Involvement of the axial skeleton is common in osteoarthritis and ankylosing spondylitis but infrequent in RA, with the notable exception of the cervical spine.

The clinical history should also identify *precipitating events*, such as trauma, drug administration (Table 320-2), or antecedent or intercurrent illnesses, that may have contributed to the patient's complaint. Last, a thorough *rheumatic review of systems* may disclose associated features outside the musculoskeletal system and provide useful diagnostic information. A variety of musculoskeletal disorders may be associated with systemic features such as fever (SLE, infection), rash (SLE, Reiter's syndrome, dermatomyositis), myalgias, weakness (polymyositis, polymyalgia rheumatica), and morning stiffness (inflammatory arthritis). In addition, some conditions are associated with involvement of other organ systems, including the eyes (Behcet's disease, sarcoidosis, Reiter's syndrome), gastrointestinal tract (scleroderma, inflammatory bowel disease), genitourinary tract (Reiter's syndrome, gonococcemia, Behcet's disease), and nervous system (Lyme disease, SLE, vasculitis).

PHYSICAL EXAMINATION

The goal of the physical examination is to ascertain the structures involved, the nature of the underlying pathology, the extent and functional consequences of the process, and the presence of systemic or extraarticular manifestations. A knowledge of topographic anatomy is necessary to identify the primary site(s) of involvement and differentiate articular from nonarticular disorders. The musculoskeletal examination depends largely on careful inspection, palpation, and a variety of specific physical maneuvers to elicit diagnostic signs (Table 320-3). Although most articulations of the appendicular skeleton can be examined in this manner, adequate inspection and palpation are not possible for many axial (e.g., zygapophyseal) and inaccessible (e.g., sacroiliac or hip) joints. For such joints, there is a greater reliance on specific maneuvers and imaging for assessment.

Examination of involved and uninvolved joints will determine whether *warmth*, *erythema*, or *swelling* is present. The examination should distinguish true articular swelling caused by synovial effusion or synovial proliferation from nonarticular or periarticular involvement, which usually extends beyond the normal joint margins or the full extent of the synovial space. Synovial effusion can be distinguished from synovial hypertrophy or bony hypertrophy by palpation or specific maneuvers. For example, small to moderate knee effusions may be identified by the "bulge sign" or "ballottement of the patella." Bursal effusions (e.g., effusions of the olecranon or prepatellar bursa) overlie bony prominences and are fluctuant with sharply defined borders. Joint *stability* can be assessed by palpation and by the application of manual stress to assess displacement in different planes. Subluxation or dislocation, which may be secondary to traumatic, mechanical, or inflammatory causes, can be assessed by inspection and palpation. Joint *volume* can be assessed by palpation. Distention of the articular capsule usually causes pain. The patient will attempt to minimize the pain by keeping the joint in the position of least intraarticular pressure and greatest volume, usually partial flexion. Clinically, joint distention may be detected as obvious swelling, voluntary or fixed flexion deformities, or diminished range of motion -- especially on extension, which decreases joint volume. Active and passive *range of motion* should be assessed in all planes, with contralateral comparison. Serial evaluations of joint motion may be made using a goniometer to quantify the arc of movement. Each joint should be passively manipulated through its full range of motion (including, as appropriate, flexion, extension, rotation, abduction, adduction, inversion, eversion, supination, pronation, and medial or lateral deviation or bending). Limitation of motion is frequently caused by effusion, pain, deformity, or contracture. *Contractures* may reflect antecedent synovial inflammation or trauma. Joint *crepitus* may be felt during palpation or maneuvers and may be prominent or coarse in osteoarthritis. Joint *deformity* usually indicates a long-standing or aggressive pathologic process. Deformities may result from ligamentous destruction, soft tissue contracture, bony enlargement, ankylosis, erosive disease, or subluxation. Examination of the musculature will permit assessment of strength and reveal atrophy, pain, or spasm. The examiner should look carefully for nonarticular or periarticular involvement, especially when articular complaints are not supported by objective findings referable to the joint capsule. The identification of musculoskeletal pain of soft tissue origin (nonarticular pain) will prevent unwarranted and often expensive additional evaluations. Specific maneuvers may reveal nonarticular abnormalities, such as a carpal tunnel syndrome (which can be identified by Tinel's or Phalen's sign). Other examples of soft tissue abnormalities include olecranon bursitis, epicondylitis (tennis elbow), enthesitis (e.g., Achilles tendinitis), and trigger points associated with

fibromyalgia.

LABORATORY INVESTIGATIONS

The vast majority of musculoskeletal disorders can be diagnosed easily by a complete history and physical examination. An additional objective of the initial encounter is to determine whether additional investigations or immediate therapy are required. A number of features indicate the need for additional evaluation. *Monarticular* conditions require additional evaluation, as do *traumatic* or *inflammatory* conditions and conditions accompanied by *neurologic changes* or *systemic manifestations* of serious disease. Finally, individuals with *chronic* symptoms (lasting more than 6 weeks), especially when there has been a lack of response to symptomatic measures, are candidates for additional evaluation. The extent and nature of the additional investigation should be dictated by the clinical features and suspected pathologic process. Laboratory tests should be used to confirm a specific clinical diagnosis and not be used as a tool to screen or evaluate patients with vague rheumatic complaints. Indiscriminate use of broad batteries of diagnostic tests and radiographic procedures are rarely useful or cost-effective.

Besides a complete blood count, including a white blood cell (WBC) and differential count, the routine evaluation should include determination of an acute-phase indicator, such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), which can be useful in discriminating inflammatory from noninflammatory musculoskeletal disorders. Both tests are inexpensive and easily performed; the resulting values may be elevated with infections, inflammatory arthritis, autoimmune disorders, neoplasia, pregnancy, and advanced age. Serum uric acid determinations are only useful when gout has been diagnosed and therapy contemplated.

Serologic tests for rheumatoid factor, antinuclear antibodies (ANA), complement levels, Lyme disease antibodies, or antistreptolysin O (ASO) titer should be carried out only when there is substantive clinical evidence suggesting a relevant associated diagnosis, as these tests have poor predictive value when used in a screening fashion, especially when the pretest probability is low. They should not be performed arbitrarily in patients with minimal or nonspecific musculoskeletal complaints. For example, 4 to 5% of the general population will have positive tests for rheumatoid factor and ANAs, yet only 1% or 0.04% will haveRA orSLE, respectively. IgM rheumatoid factor (autoantibodies against the Fc portion of IgG) is found in 80% of patients with RA and may also be seen in low titers in patients with chronic infections (tuberculosis, leprosy); other autoimmune diseases (SLE, Sjogren's syndrome); or chronic pulmonary, hepatic, or renal diseases. ANAs are found in nearly all patients with SLE and may also be seen in patients with other autoimmune diseases (polymyositis, scleroderma, antiphospholipid syndrome), drug-induced lupus (resulting from hydralazine, procainamide, or quinidine administration), or chronic hepatitic or renal disorders. The interpretation of a positive ANA determination may depend on the titer and on the pattern observed by immunofluorescence microscopy. Diffuse and speckled patterns are most common but least specific, whereas a peripheral, or rim, pattern is highly specific and is suggestive of autoantibodies against double-stranded (native) DNA. This pattern is seen only in patients with SLE.

Aspiration and analysis of synovial fluid are always indicated in acute monarthritis or when an infectious or crystal-induced arthropathy is suspected. Synovial fluid analysis may be crucial in distinguishing between noninflammatory and inflammatory processes. This distinction can be made on the basis of the appearance, viscosity, and cell count of the synovial fluid. Tests for synovial fluid glucose, protein, lactate dehydrogenase, lactic acid, or autoantibodies are not recommended, as they are insensitive or have little discriminatory value. Normal synovial fluid is clear or a pale straw color and is viscous, primarily because of the high levels of hyaluronate. Noninflammatory synovial fluid is clear, viscous, and amber-colored, with aWBCcount of <2000/uL and a predominance of mononuclear cells. The viscosity of synovial fluid is assessed by expressing fluid from the syringe one drop at a time. Normally there is a stringing effect, with a long tail behind each drop. Effusions due to osteoarthritis or trauma usually have normal viscosity. Inflammatory fluid is turbid and yellow, with an increased WBC (2000 to 50,000/uL) and a predominance of polymorphonuclear leukocytes. Inflammatory fluid has a reduced viscosity, diminished hyaluronate, and little or no tail following each drop of synovial fluid. Such effusions are found inRA, gout, other inflammatory arthritides, and septic arthritis. Infectious fluid is turbid and opaque, with a WBC count usually>50,000/uL, a predominance of polymorphonuclear leukocytes (>75%), and low viscosity. Such effusions are typical of septic arthritis, but they occur rarely with sterile inflammatory arthritides such as RA or gout. In addition, hemorrhagic synovial fluid may be seen with trauma, hemarthrosis, or neuropathic arthritis. An algorithm for synovial fluid aspiration and analysis is shown inFig. 320-3. Synovial fluid should be analyzed immediately for appearance, viscosity, and cell count. Cellularity and the presence of crystals may be assessed by light or polarizing microscopy, respectively. Monosodium urate crystals, seen in gouty effusions, are long, needle-shaped, negatively birefringent, and usually intracellular, whereas calcium pyrophosphate dihydrate crystals, found in chondrocalcinosis and pseudogout, are usually short, rhomboid-shaped, and positively birefringent. Whenever infection is suspected, synovial fluid should be Gram-stained and cultured appropriately. If gonococcal arthritis is suspected, immediate plating of the fluid on appropriate culture medium is indicated. Synovial fluid from chronic monarthritis patients should also be cultured for *M. tuberculosis* and fungi. Last, it should be noted that crystal-induced arthritis and infection occasionally occur together in the same joint.

DIAGNOSTIC IMAGING IN JOINT DISEASES

Conventional radiography has been a valuable tool in the diagnosis and staging of articular disorders. Plain x-rays are most appropriate when there is a history of trauma, suspected chronic infection, progressive disability, or monarticular involvement; when therapeutic alterations are considered; or when a baseline assessment is desired for what appears to be a chronic process. However, in most inflammatory disorders, early radiography is rarely helpful in establishing a diagnosis and may only reveal soft tissue swelling or juxtaarticular demineralization. As the disease progresses, calcification (of soft tissues, cartilage, or bone), joint space narrowing, erosions, bony ankylosis, new bone formation (sclerosis, osteophyte formation, or periostitis), or subchondral cysts may develop and suggest specific clinical entities. Consultation with a radiologist will help define proper technique and positioning and prevent the need for further studies.

Additional imaging techniques may possess greater diagnostic sensitivity and facilitate early diagnosis in a limited number of articular disorders and are indicated in selected

circumstances when conventional radiography is not adequate (Table 320-4). *Ultrasonography* is useful in the detection of soft tissue abnormalities that cannot be appreciated fully by clinical examination. Although ultrasonography is inexpensive and easily performed, only in a limited number of circumstances is it the preferred method of evaluation. The foremost application of ultrasound is in the diagnosis of synovial (Baker's) cysts, although rotator cuff tears and various tendon injuries may be evaluated with ultrasound by an experienced operator. *Radionuclide scintigraphy* provides useful information regarding the metabolic status of bone and, along with radiography, is well suited for total-body assessment of the extent and distribution of musculoskeletal involvement. It is a very sensitive but poorly specific means of detecting inflammatory or metabolic alterations in bone or periarticular soft tissue structures. The limited tissue resolution of scintigraphy may obscure the distinction between bony and periarticular processes and may necessitate the use of additional imaging modalities. Scintigraphy, using ^{99m}Tc, ^{67}Ga, or WBCs labeled with ^{111}In, has been applied to a variety of articular disorders with variable success (Table 320-4). [^{99m}Tc]pertechnetate or [^{99m}Tc]diphosphonate scintigraphy may be useful in identifying infection, neoplasia, inflammation, increased blood flow, bone remodeling, heterotopic bone formation, or avascular necrosis (Fig. 320-4). However, the poor specificity of ^{99m}Tc scanning has limited its use to investigational and serial assessments of joint or bone involvement, assessment of inflammatory or infectious processes, and surveys for bone metastases. ^{67}Ga binds to serum and cellular transferrin and lactoferrin and is preferentially taken up by neutrophils, macrophages, bacteria, and tumor tissue (e.g., lymphoma) and is useful in the identification of infection and malignancies. Scanning with ^{111}In-labeled WBCs has been used to detect both infectious and inflammatory arthritis. Although both have been used with success, ^{111}In-labeled WBC scanning is superior to ^{67}Ga in the early diagnosis of osteomyelitis and infected prosthetic joints. Prior treatment with antibiotics may reduce the diagnostic sensitivity of both ^{67}Ga and ^{111}In-labeled WBC scintigraphy.

Computed tomography (CT) provides rapid reconstruction of sagittal, coronal, and axial images and thus of the spatial relationships among anatomic structures. It has proved most useful in the assessment of the axial skeleton because of its ability to visualize in the axial plane. Articulations that are difficult to visualize by conventional radiography, such as the zygapophyseal, sacroiliac, sternoclavicular, and hip joints, can be evaluated effectively using CT. CT has been demonstrated to be useful in the diagnosis of low back pain syndromes, sacroiliitis, osteoid osteoma, tarsal coalition, osteomyelitis, intraarticular osteochondral fragments, and advanced osteonecrosis.

Magnetic resonance imaging (MRI) has significantly advanced the ability to image musculoskeletal structures. MRI can provide multiplanar images with fine anatomic detail and contrast resolution (Fig. 320-5). Other advantages are the absence of ionizing radiation and adverse effects and the superior ability to visualize bone marrow and soft tissue periarticular structures. However, the high cost and long procedural time of MRI limit its use in the evaluation of musculoskeletal disorders. MRI should be used only when it will provide necessary information that cannot be obtained by less expensive and noninvasive means.

MRI can image fascia, vessels, nerve, muscle, cartilage, ligaments, tendons, pannus, synovial effusions, cortical bone, and bone marrow. Visualization of particular structures

can be enhanced by altering the pulse sequence to produce either T1-weighted or T2-weighted spin echo, gradient echo, or inversion recovery [including short tau inversion recovery (STIR) images. Because of its sensitivity to changes in marrow fat, MRI is a sensitive although nonspecific means of detecting osteonecrosis and osteomyelitis (Fig. 320-5). Because of its enhanced soft tissue resolution, MRI is more sensitive than arthrography orCT for the diagnosis of soft tissue injuries (e.g., meniscal and rotator cuff tears), intraarticular derangements, and spinal cord damage following injury, subluxation, or synovitis of the vertebral facet joints.

RHEUMATOLOGIC EVALUATION OF THE ELDERLY

Musculoskeletal disorders in elderly patients are often not diagnosed because the signs and symptoms may be insidious or chronic in these patients. In addition, the nature of the problem is often obscured by the presence of multiple interacting factors, including other medical conditions and therapies. These difficulties are compounded by the diminished reliability of laboratory testing in the elderly, who often manifest nonpathologic abnormal results. For example, erythrocyte sedimentation rates may be misleadingly elevated and low titer positive tests for rheumatoid factor and ANAs may be seen in up to 15% of elderly patients. Although nearly all rheumatic disorders can afflict the elderly, certain diseases and drug-induced disorders (Table 320-2) are more common in this age group. The elderly should be approached in the same manner as other patients with musculoskeletal complaints but with additional inquiries to exclude common geriatric musculoskeletal disorders. An emphasis on identifying the rheumatic consequences of intercurrent medical conditions and therapies is extremely important. Osteoarthritis, gout, polymyalgia rheumatica, drug-induced lupus erythematosus, and chronic salicylate toxicity are all more common in the elderly than in other individuals. The physical examination should identify the nature of the musculoskeletal complaint, as well as coexisting diseases that may influence the diagnosis and choice of treatment.

Approach to the Patient

Regional Rheumatic Complaints Although all patients should be evaluated in a logical and thorough manner, many cases of focal musculoskeletal complaints are caused by commonly encountered disorders that exhibit a predictable pattern of onset, evolution, and localization and that can often be diagnosed immediately on the basis of limited historic information and selected maneuvers or tests. Although nearly every joint can be approached in this manner, the evaluation of four commonly involved anatomic regions -- the hand, shoulder, hip, and knee -- are reviewed here.

HAND PAIN Focal or unilateral hand pain may result from trauma, overuse, infection, or a reactive or crystal-induced arthritis. By contrast, bilateral hand complaints suggest a degenerative (e.g., osteoarthritis), systemic, or inflammatory/immune etiology. Patterns of joint involvement are highly suggestive of certain disorders. The distribution of affected joints in the hand may provide important diagnostic information (Fig. 320-6). Thus, osteoarthritis (or degenerative arthritis) may manifest as distal interphalangeal (DIP) and proximal interphalangeal (PIP) joint pain with bony hypertrophy sufficient to produce Heberden's and Bouchard's nodes, respectively. Pain, with or without bony swelling, involving the base of the thumb (first carpometacarpal joint) is also highly suggestive of osteoarthritis. By contrast,RA tends to involve the PIP,

metacarpophalangeal, intercarpal, and carpometacarpal joints (wrist) with pain, prolonged stiffness, and palpable synovial tissue hypertrophy. Psoriatic arthritis may also involve the DIP and PIP joints and the carpus with inflammatory pain, stiffness, and synovitis. Moreover, the diagnosis of psoriatic arthritis can be suggested by nail pitting or onycholysis. Soft tissue swelling may also be noted over the dorsum of the hand and wrist and may suggest an inflammatory extensor tendon tenosynovitis, possibly caused by gonococcal infection, gout, or inflammatory arthritis. The diagnosis of tenosynovitis may be suggested by local warmth and edema and is confirmed when pain is induced by maintaining the wrist in a fixed, neutral position and flexing the digits distal to the metacarpophalangeal joints to stretch the extensor tendon sheaths.

Focal wrist pain localized to the radial aspect may be caused by DeQuervain's tenosynovitis resulting from inflammation of the tendon sheath(s) involving the abductor pollicis longus or extensor pollicis brevis (Fig. 320-6). This condition commonly results from overuse or develops after pregnancy and may be diagnosed with Finkelstein's test. A positive result in Finkelstein's test is present when local wrist pain is induced after the thumb is flexed across the palm and placed inside a clenched fist and the patient actively moves the hand downward with ulnar deviation at the wrist. Carpal tunnel syndrome is another common disorder of the upper extremity and results from compression of the median nerve within the carpal tunnel. Manifestations include paresthesias in the thumb and the second, third, and radial half of the fourth fingers, and sometimes, atrophy of thenar musculature. Carpal tunnel syndrome is commonly associated with pregnancy, edema, trauma, osteoarthritis, inflammatory arthritis, and infiltrative disorders (e.g., amyloidosis). The diagnosis is suggested by a positive Tinel's or Phalen's sign. With each test, paresthesia in a median nerve distribution is induced or increased by either "thumping" the volar aspect of the wrist (Tinel's sign) or pressing the extensor surfaces of the two flexed wrists against each another (Phalen's sign).

SHOULDER PAIN During the evaluation of shoulder disorders, the examiner should carefully note any history of trauma, infection, inflammatory disease, occupational hazards, or previous cervical disease. In addition, the patient should be questioned as to the activities or movement(s) that elicit shoulder pain. Shoulder pain is frequently referred from the cervical spine, but it may also be referred from intrathoracic lesions (e.g., a Pancoast tumor) or from gallbladder, hepatic, or diaphragmatic disease. The shoulder should be put through its full range of motion both actively and passively (with examiner assistance): forward flexion, extension, abduction, adduction, and rotation. Manual inspection of the periarticular structures will often provide important diagnostic information. The examiner should apply direct manual pressure over the subacromial bursa, which lies lateral to and immediately beneath the acromion. Subacromial bursitis is a frequent cause of shoulder pain. Anterior to the subacromial bursa, the bicipital tendon traverses the bicipital groove. This tendon is best identified by palpating it in its groove as the patient rotates the humerus internally and externally. Direct pressure over the tendon may reveal pain indicative of bicipital tendinitis. Palpation of the acromioclavicular joint may disclose local pain, bony hypertrophy, or synovial swelling. Whereas osteoarthritis andRAcommonly affect the acromioclavicular joint, osteoarthritis seldom involves the glenohumeral joint, unless there is a traumatic or occupational cause. The glenohumeral joint is best palpated anteriorly by placing the thumb over the humeral head (just medial and inferior to the coracoid process) and having the patient rotate the humerus internally and externally. Pain localized to this region is indicative of

glenohumeral pathology. Synovial effusion or tissue is seldom palpable but, if present, may suggest infection, RA, or an acute tear of the rotator cuff.

Rotator cuff tendinitis or tear is a very common cause of shoulder pain. The rotator cuff is formed by the tendons of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles. Rotator cuff tendinitis is suggested by pain on active abduction (but not passive abduction), pain over the lateral deltoid muscle, night pain, and evidence of the impingement sign. This maneuver is performed by the examiner raising the patient's arm into forced flexion while stabilizing the scapula and preventing it from rotating. A positive sign is present if pain develops before 180° of forward flexion. A complete tear of the rotator cuff, which often results from trauma, may manifest in the same manner but is less common than tendinitis. The diagnosis is suggested by the drop arm test, in which the patient is asked to maintain the arm outstretched after it has been passively abducted. If the patient is unable to hold the arm up once 90° of abduction is reached, the test is positive. Tendinitis or tear of the rotator cuff can be confirmed byMRI or ultrasonography.

KNEE PAIN A careful history should delineate the chronology of the knee complaint and whether there are predisposing conditions, trauma, or medications that might underlie the complaint. Observation of the patient's gait is also important. The knee should be carefully inspected in the upright (weight-bearing) and prone positions for swelling, erythema, contusion, laceration, and malalignment. The most common form of malalignment in the knee is genu varum (bow-legs) and genu valgum (knock-knees). Bony swelling of the knee joint commonly results from hypertrophic osseous changes seen with disorders such as osteoarthritis and neuropathic arthropathy. Swelling caused by hypertrophy of intrasynovial structures (synovial enlargement or effusion) may manifest as a fluctuant, ballotable, or soft tissue enlargement in the suprapatellar pouch (superior reflection of the synovial cavity) or lateral and medial to the patella. Synovial effusions may also be detected by balloting the patella downward toward the femoral groove or by eliciting a bulge sign. To elicit this sign, the examiner positions the knee in extension and manually compresses or milks synovial fluid down from the suprapatellar pouch and lateral to the patellae. Manual pressure lateral to the patella may cause an observable shift in synovial fluid (bulge) to the medial aspect. This maneuver is only effective for detecting small to moderate effusions (<100 mL). Inflammatory disorders such asRA, gout, and Reiter's syndrome may involve the knee joint and produce significant pain, stiffness, swelling, or warmth. A popliteal or *Baker's cyst* is best palpated with the knee partially flexed and is best seen with the patient standing with knees fully extended to visualize popliteal swelling or fullness from a posterior view.

Anserine bursitis is an often missed cause of knee pain in adults. The pes anserine bursa underlies the semimembranosus tendon and may become inflamed or painful owing to trauma, overuse, or inflammation. Anserine bursitis manifests primarily as point tenderness inferior and medial to the patella and overlying the medial tibial plateau. Swelling and erythema may not be present. Other forms of bursitis may also present as knee pain. The prepatellar bursa is superficial and is located over the inferior portion of the patella. The infrapatellar bursa is deeper and lies beneath the patellar ligament before its insertion on the tibial tubercle.

Internal derangement of the knee may result from trauma or degenerative processes.

Damage to the meniscal cartilage (medial or lateral) frequently presents as chronic or intermittent knee pain. Such an injury should be suspected when there is a history of trauma or athletic activity and when the patient relates symptoms of locking, clicking, or "giving way" of the joint. Pain may be detected during direct palpation over the medial or lateral joint line. The diagnosis may also be suggested by ipsilateral joint-line pain when the knee is stressed laterally or medially. A positive McMurray test may indicate a meniscal tear. To perform this test, the knee is first flexed at 90°, and the leg is then extended while simultaneously the lower extremity is torqued medially or laterally. A painful click during inward rotation may indicate a lateral meniscus tear, and pain during outward rotation may indicate a tear in the medial meniscus. Finally, damage to the cruciate ligaments should be suspected if there is pain of acute onset, possibly with swelling, a history of trauma, or a synovial fluid aspirate that is grossly bloody. Examination of the cruciate ligaments is best accomplished by eliciting a drawer sign. With the patient recumbent, the knee should be partially flexed and the foot stabilized on the examining surface. The examiner should manually attempt to displace the tibia anteriorly or posteriorly with respect to the femur. If anterior movement is detected, then anterior cruciate ligament damage is likely. Conversely, significant posterior movement may indicate posterior cruciate damage. Contralateral comparison will assist the examiner in detecting significant anterior or posterior movement.

HIP PAIN The hip is best evaluated by observing the patient's gait and assessing range of motion. The vast majority of patients reporting "hip pain" localize their pain unilaterally to the posterior or gluteal musculature (Fig. 320-7). Such pain may or may not be associated with low back pain and tends to radiate down the posterolateral aspect of the thigh. This presentation frequently results from degenerative arthritis of the lumbosacral spine and commonly follows a dermatomal distribution with involvement of nerve roots between L5 and S1. Some individuals instead localize their "hip pain" laterally to the area overlying the trochanteric bursa. Because of the depth of this bursa, swelling and warmth are usually absent. Diagnosis of trochanteric bursitis can be confirmed by inducing point tenderness over the trochanteric bursa. Range of movement may be limited by pain. Pain in the hip joint is less common and tends to be located anteriorly, over the inguinal ligament; it may radiate medially to the groin or along the anteromedial thigh. Uncommonly, iliopsoas bursitis may mimic true hip joint pain. Diagnosis of iliopsoas bursitis may be suggested by a history of trauma or inflammatory arthritis. Pain associated with an iliopsoas bursitis is localized to the groin or anterior thigh and tends to worsen with hyperextension of the hip; many patients prefer to flex and externally rotate the hip to reduce the pain from a distended bursa.

Back to Table of Contents

321. OSTEOARTHRITIS - *Kenneth D. Brandt*

Osteoarthritis (OA), also erroneously called degenerative joint disease, represents failure of the diarthrodial (movable, synovial-lined) joint. In idiopathic (primary) OA, the most common form of the disease, no predisposing factor is apparent. Secondary OA is pathologically indistinguishable from idiopathic OA but is attributable to an underlying cause (Table 321-1).

EPIDEMIOLOGY AND RISK FACTORS

OAis the most common joint disease of humans. Among the elderly, knee OA is the leading cause of chronic disability in developed countries; some 100,000 people in the United States are unable to walk independently from bed to bathroom because of OA of the knee or hip.

Under the age of 55 years the joint distribution ofOA in men and women is similar; in older individuals, hip OA is more common in men, while OA of interphalangeal joints and the thumb base is more common in women. Similarly, radiographic evidence of knee OA and, especially *symptomatic* knee OA, is more common in women than in men (Table 321-2).

Racial differences exist in both the prevalence ofOA and the pattern of joint involvement. The Chinese in Hong Kong have a lower incidence of hip OA than whites; OA is more frequent in native Americans than in whites. Interphalangeal joint OA and, especially, hip OA are much less common in South African blacks than in whites in the same population. Whether these differences are genetic or are due to differences in joint usage related to life-style or occupation is unknown.

In some cases, the relation of heredity toOA is less ambiguous. Thus, the mother and sister of a woman with distal interphalangeal joint OA (Heberden's nodes) are, respectively, twice and thrice as likely to exhibit OA in these joints as the mother and sister of an unaffected woman. Point mutations in the cDNA coding for articular cartilage collagen have been identified in families with chondrodysplasia and polyarticular secondary OA.

Age is the most powerful risk factor forOA. In a radiographic survey of women less than 45 years old, only 2% had OA; between the ages of 45 to 64 years, however, the prevalence was 30%, and for those older than 65 years it was 68%. In males, the figures were similar but somewhat lower in the older age groups.

Major trauma and repetitive joint use are also important risk factors forOA. Anterior cruciate ligament insufficiency or meniscus damage (and meniscectomy) may lead to knee OA. Although damage to the articular cartilage may occur at the time of injury or subsequently, with use of the affected joint, even normal cartilage will degenerate if the joint is unstable. A person with a trimalleolar fracture will almost certainly develop ankle OA.

The pattern of joint involvement inOA is influenced by prior vocational or avocational overload. Thus, while ankle OA is common in ballet dancers, elbow OA in baseball

pitchers, and metacarpophalangeal joint OA in prize fighters, OA is not very common at any of these sites in the general population.

Given the growing participation of the population of this country in cardiovascular fitness programs, it is important to note that there are no convincing data to support an association between specific athletic activities and arthritis if major trauma is excluded. Neither long-distance running nor jogging has been shown to causeOA. This apparent lack of association may, however, be due to the lack of good long-term studies, the difficulty of retrospective assessment of activities, and selection bias, i.e., early discontinuation of the activity by those incurring joint damage. In contrast, vocational activities, such as those performed by jackhammer operators, cotton mill and shipyard workers, and coal miners, may lead to OA in the joints exposed to repetitive occupational use. Men whose jobs required knee bending and at least medium physical demands had a higher rate of radiographic evidence of knee OA, and more severe radiographic changes, than men whose jobs required neither.

Obesity is a risk factor for kneeOA and hand OA. For those in the highest quintile for body mass index at baseline examination, the relative risk for developing knee OA in the ensuing 36 years was 1.5 for men and 2.1 for women. For *severe* knee OA, the relative risk rose to 1.9 for men and 3.2 for women, suggesting that obesity plays an even larger role in the etiology of the most serious cases of knee OA. Furthermore, obese individuals who have not yet developed OA can reduce their risk: A weight loss of only 5 kg was found to be associated with a 50% reduction in the odds of developing symptomatic knee OA.

The correlation between the pathologic severity ofOA and symptoms is poor. Many individuals with radiographic changes of advanced OA have no symptoms. The risk factors for *pain* and *disability* in affected individuals are poorly understood. Disability in those with knee OA is more strongly associated with quadriceps muscle weakness than with either joint pain or radiographic severity of the disease. For the same degree of pathologic severity, women are more likely to be symptomatic than men, those on welfare more likely than those who are working, and those who are divorced more likely than those who are married. For individuals with OA who had poor social support, periodic telephone calls from a trained lay interviewer were as effective as a nonsteroidal anti-inflammatory drug (NSAID) in reducing joint pain, emphasizing the importance of psychosocial factors as determinants of pain.

PATHOLOGY

Although the cardinal pathologic feature ofOA is a progressive loss of articular cartilage, OA is not a disease of any single tissue but a disease of an *organ*, the synovial joint, in which all of the tissues are affected: the subchondral bone, synovium, meniscus, ligaments, and supporting neuromuscular apparatus as well as the cartilage.

The most striking morphologic changes inOA are usually seen in load-bearing areas of the articular cartilage. In the early stages the cartilage is thicker than normal, but with progression of OA the joint surface thins, the cartilage softens, the integrity of the surface is breached, and vertical clefts develop (fibrillation) (Fig. 321-1). Deep cartilage ulcers, extending to bone, may appear. Areas of fibrocartilaginous repair may develop,

but the repair tissue is inferior to pristine hyaline articular cartilage in its ability to withstand mechanical stress. All of the cartilage is metabolically active, and the chondrocytes replicate, forming clusters (clones). Later, however, the cartilage becomes hypocellular.

Remodeling and hypertrophy of bone are also major features ofOA. Appositional bone growth occurs in the subchondral region, leading to the bony "sclerosis" seen radiographically. The abraded bone under a cartilage ulcer may take on the appearance of ivory (eburnation). Growth of cartilage and bone at the joint margins leads to osteophytes (spurs), which alter the contour of the joint and may restrict movement. A patchy chronic synovitis and thickening of the joint capsule may further restrict movement. Periarticular muscle wasting is common and may play a major role in symptoms and, as indicated above, in disability.

PATHOGENESIS

The main load on articular cartilage -- the major target tissue inOA -- is produced by contraction of the muscles that stabilize or move the joint. Although cartilage is an excellent shock absorber in terms of its bulk properties, at most sites it is only 1 to 2 mm thick -- too thin to serve as the sole shock-absorbing structure in the joint. Additional protective mechanisms are provided by subchondral bone and periarticular muscles.

Articular cartilage serves two essential functions within the joint, both of which are mechanical. First, it provides a remarkably smooth bearing surface, so that, with joint movement, the bones glide effortlessly over each other. With synovial fluid as lubricant, the coefficient of friction for cartilage rubbed against cartilage, even under physiologic loading, is 15 times lower than that of two ice cubes passed across each other! Second, articular cartilage prevents the concentration of stresses, so the bones do not shatter when the joint is loaded.

OAdevelops in either of two settings: (1) the biomaterial properties of the articular cartilage and subchondral bone are normal, but excessive loading of the joint causes the tissues to fail, or (2) the applied load is reasonable, but the material properties of the cartilage or bone are inferior.

Although articular cartilage is highly resistant to wear under conditions of repeated oscillation, repetitive impact loading soon leads to joint failure. This fact accounts for the high prevalence ofOA at specific sites related to vocational or avocational overloading. In general, the earliest changes occur at the sites in the joint that are subject to the greatest compressive loads. Some cases of "idiopathic" OA of the hip may be due to subtle congenital or developmental defects, such as congenital subluxation/dislocation, acetabular dysplasia, Legg-Calve-Perthes disease, or slipped capital femoral epiphysis, which increase joint congruity and concentrate the dynamic load.

Clinical conditions that reduce the ability of the cartilage or subchondral bone to deform are associated with development ofOA. In ochronosis, for example, accumulation of homogentisic acid polymers leads to stiffening of the cartilage; in osteopetrosis, stiffness of the subchondral trabeculae occurs. In both conditions, severe generalized OA is usually apparent by the age of 40. If the subchondral bone is stiffened experimentally,

repetitive impact loading soon leads to breakdown of the overlying cartilage. Conversely, osteoporosis, in which the bone is abnormally soft, may protect against OA.

The Extracellular Matrix of Normal Articular Cartilage Articular cartilage is composed of two major macromolecular species: proteoglycans (PGs), which are responsible for the compressive stiffness of the tissue and its ability to withstand load, and collagen, which provides tensile strength and resistance to shear. Although lysomal proteases (cathepsins) have been demonstrated within the cells and matrix of normal articular cartilage, their low pH optimum makes it likely that the proteoglycanase activity of these enzymes will be confined to intracellular sites or the immediate pericellular area. However, cartilage also contains a family of matrix metalloproteinases (MMPs), including stromelysin, collagenase, and gelatinase, which can degrade all the components of the extracellular matrix at neutral pH. Each is secreted by the chondrocyte as a latent proenzyme that must be activated by proteolytic cleavage of its N-terminal sequence. The level of MMP activity in the cartilage at any given time represents the balance between activation of the proenzyme and inhibition of the active enzyme by tissue inhibitors. It has recently become apparent that much of the total tissue pool of aggrecan, the majorPG in articular cartilage, is degraded by a proteinase that cleaves the protein core of the molecule at a site distinct from that at which the MMPs are active. The enzyme responsible for this cleavage is referred to as "aggrecanase" but has not been clearly identified.

The turnover of normal cartilage is effected through a degradative cascade, for which many investigators consider the driving force to be interleukin (IL) 1, a cytokine produced by mononuclear cells (including synovial lining cells) and synthesized by chondrocytes. IL-1 stimulates the synthesis and secretion of the latentMMPs and of tissue plasminogen activator. Plasminogen, the substrate for the latter enzyme, may be synthesized by the chondrocyte or may enter the cartilage from the synovial fluid. Both plasminogen and stromelysin may play a role in activation of the latent MMPs. In addition to its catabolic effect on cartilage, IL-1, at concentrations even lower than those needed to stimulate cartilage degradation, suppressesPGsynthesis by the chondrocyte, inhibiting matrix repair (see below).

The balance of the system lies with at least two inhibitors, tissue inhibitor of metalloproteinase (TIMP) and plasminogen activator inhibitor-1 (PAI-1), which are synthesized by the chondrocyte and limit the degradative activity ofMMPs and plasminogen activator, respectively. If TIMP or PAI-1 is destroyed or is present in concentrations that are insufficient relative to those of active enzymes, stromelysin and plasmin are free to act on matrix substrates. Stromelysin can degrade the protein core of thePG and activate latent collagenase. Conversion of latent stromelysin to an active, highly destructive protease by plasmin provides a second mechanism for matrix degradation.

Polypeptide mediators, e.g., insulin-like growth factor-1 (IGF-1) and transforming growth factorb (TGF-b), stimulate biosynthesis ofPGs. They regulate matrix metabolism in normal cartilage and may play a role in matrix repair inOA. Notably, these growth factors modulate catabolic as well as anabolic pathways of chondrocyte metabolism; by down-regulating chondrocyte receptors forIL-1, they may decrease PG degradation.

In addition to its responsiveness to cytokines and a variety of other biologic mediators, chondrocyte metabolism in normal cartilage can be modulated directly by mechanical loading. Whereas static loading and prolonged cyclic loading inhibit synthesis ofPGs and protein, loads of relatively brief duration may stimulate matrix biosynthesis.

Pathophysiology of Cartilage Changes in OA Most investigators feel that the primary changes inOA begin in the cartilage. A change in the arrangement and size of the collagen fibers is apparent. Biochemical data are consistent with the presence of a defect in the collagen network of the matrix, perhaps due to disruption of the "glue" that binds adjacent fibers. This is among the earliest matrix changes observed and appears to be irreversible.

Although "wear" may be a factor in the loss of cartilage, strong evidence supports the concept that lysosomal enzymes andMMPsaccount for much of the loss of cartilage matrix inOA. Whether their synthesis and secretion are stimulated byIL-1 or by other factors (e.g., mechanical stimuli), MMPs, plasmin, and cathepsins all appear to be involved in the breakdown of articular cartilage in OA.TIMP andPAI-1may work to stabilize the system, at least temporarily, while growth factors, such asIGF-1,TGF-b, and basic fibroblast growth factor, are implicated in repair processes that may heal the lesion or, at least, stabilize the process. A stoichiometric imbalance exists between the levels of active enzyme and the level of TIMP, which may be only modestly increased.

Of current interest is the possible role of nitric oxide (NO) in articular cartilage damage inOA, since NO has been shown to stimulate synthesis ofMMPs by chrondrocytes. Chondrocytes are a major source of NO, the synthesis of which is stimulated byIL-1 and tumor necrosis factor and by shear stresses on the tissue. In an experimental model of OA, treatment with a selective inhibitor of inducible NO synthase reduced the severity of cartilage damage.

The chondrocytes inOAcartilage undergo active cell division and are very active metabolically, producing increased quantities of DNA, RNA collagen,PG, and noncollagenous proteins. (For this reason, it is inaccurate to call OA a *degenerative* joint disease). Prior to cartilage loss and PG depletion, this marked biosynthetic activity may lead to an increase in PG concentration, which may be associated with thickening of the cartilage and a stage of homeostasis referred to as "compensated" OA. These mechanisms may maintain the joint in a reasonably functional state for years. The repair tissue, however, often does not hold up as well under mechanical stresses as normal hyaline cartilage and eventually, at least in some cases, the rate of PG synthesis falls off and "end-stage" OA develops, with full-thickness loss of cartilage.

CLINICAL FEATURES

The joint pain ofOA is often described as a deep ache and is localized to the involved joint. Typically, the pain of OA is aggravated by joint use and relieved by rest, but, as the disease progresses, it may become persistent. Nocturnal pain, interfering with sleep, is seen particularly in advanced OA of the hip and may be enervating. Stiffness of the involved joint upon arising in the morning or after a period of inactivity (e.g., an automobile ride) may be prominent but usually lasts less than 20 min. Systemic manifestations are not a feature of primary OA.

Because articular cartilage is aneural, the joint pain inOA must arise from other structures (Table 321-3). In some cases it may be due to stretching of nerve endings in the periosteum covering osteophytes; in others, to microfractures in subchondral bone or from medullary hypertension caused by distortion of blood flow by thickened subchondral trabeculae. Joint instability, leading to stretching of the joint capsule, and muscle spasm may also be sources of pain.

In some patients withOA, joint pain may be due to synovitis. In advanced OA, histologic evidence of synovial inflammation may be as marked as that in the synovium of a patient with rheumatoid arthritis. Synovitis in OA may be due to phagocytosis of shards of cartilage and bone from the abraded joint surface (wear particles), to release from the cartilage of soluble matrix macromolecules, or to crystals of calcium pyrophosphate or hydroxyapatite. In other cases, immune complexes, containing antigens derived from cartilage matrix, may be sequestered in collagenous tissue of the joint, leading to low-grade chronic synovitis. In contrast, in the earlier stages of OA, even in the patient with chronic joint pain, synovial inflammation may be absent, suggesting that the joint pain is due to one of the other factors mentioned above.

Physical examination of theOA joint may reveal localized tenderness and bony or soft tissue swelling. Bony crepitus (the sensation of bone rubbing against bone, evoked by joint movement) is characteristic. Synovial effusions, if present, are usually not large. Palpation may reveal some warmth over the joint. Periarticular muscle atrophy may be due to disuse or to reflex inhibition of muscle contraction. In the advanced stages of OA, there may be gross deformity, bony hypertrophy, subluxation, and marked loss of joint motion. The notion that OA is inexorably progressive, however, is incorrect. In many patients the disease stabilizes; in some, regression of joint pain and even of radiographic changes occurs.

Although the diagnosis ofOA is often straightforward because of the high prevalence of radiographic changes of OA in asymptomatic individuals, it is important to ensure that joint pain in a patient with radiographic evidence of OA is not due to some other cause, such as soft tissue rheumatism (e.g., anserine bursitis at the knee, trochanteric bursitis at the hip), radiculopathy, referral of pain from another joint (e.g., 25% of patients with hip disease have pain referred to the knee), entrapment neuropathy, vascular disease (claudication), or some other type of arthritis (e.g., crystal-induced synovitis, septic arthritis). These are all common pitfalls in the diagnosis of OA. It is usually not difficult to differentiate OA from a systemic rheumatic disease, such as rheumatoid arthritis, because, in the latter diseases, joint involvement is usually symmetric and polyarticular, with arthritis in wrists and metacarpophalangeal joints (which are generally not involved in OA), and there are also constitutional features such as prolonged morning stiffness, fatigue, weight loss, or fever.

LABORATORY AND RADIOGRAPHIC FINDINGS

The diagnosis ofOA is usually based on clinical and radiographic features. In the early stages, the radiograph may be normal, but joint space narrowing becomes evident as articular cartilage is lost. Other characteristic radiographic findings include subchondral bone sclerosis, subchondral cysts, and osteophytosis. A change in the contour of the

joint, due to bony remodeling, and subluxation may be seen. Although tibiofemoral joint space narrowing has been considered to be a radiographic surrogate for articular cartilage thinning, in patients with early OA who do not have radiographic evidence of bony changes (e.g., subchondral sclerosis or cysts, osteophytes), joint space narrowing alone does not accurately indicate the status of the articular cartilage. Similarly, osteophytosis alone, in the absence of other radiographic features of OA, may be due to aging rather than to OA.

As indicated above, there is often great disparity between the severity of radiographic findings, the severity of symptoms, and functional ability inOA. Thus, while more than 90% of persons over the age of 40 have some radiographic changes of OA in weight-bearing joints, only 30% of these persons are symptomatic.

No laboratory studies are diagnostic forOA, but specific laboratory testing may help in identifying one of the underlying causes of secondary OA (Table 321-1). Because primary OA is not systemic, the erythrocyte sedimentation rate, serum chemistry determinations, blood counts, and urinalysis are normal. Analysis of synovial fluid reveals mild leukocytosis (<2000 white blood cells per microliter), with a predominance of mononuclear cells. Synovial fluid analysis is of particular value in excluding other conditions, such as calcium pyrophosphate dihydrate deposition disease (Chap. 322), gout (Chap. 322), or septic arthritis (Chap. 323).

Prior to the appearance of radiographic changes, the ability to diagnoseOAclinically without an invasive procedure (e.g., arthroscopy) is limited. Approaches such as magnetic resonance imaging (MRI) and ultrasonography have not been sufficiently validated to justify their routine clinical use for diagnosis of OA or monitoring of disease progression.

OA AT SPECIFIC JOINT SITES

Interphalangeal Joints Heberden's nodes, bony enlargements of the distal interphalangeal joints, are the most common form of idiopathicOA(Fig. 321-2). A similar process at the proximal interphalangeal joints leads to Bouchard's nodes. Often, these nodes develop gradually, with little or no discomfort. However, they may present acutely with pain, redness, and swelling, sometimes triggered by minor trauma. Gelatinous dorsal cysts filled with hyaluronic acid may develop at the insertion of the digital extensor tendon into the base of the distal phalanx.

Erosive OA In erosiveOAdistal and/or proximal interphalangeal joints of the hands are most prominently affected. Erosive OA is more destructive than typical nodal OA; x-ray evidence of collapse of the subchondral plate is characteristic, and bony ankylosis may occur. Joint deformity and functional impairment may be severe. Pain and tenderness are commonly episodic. The synovium is much more extensively infiltrated with mononuclear cells than in other forms of OA.

Generalized OA GeneralizedOA is characterized by involvement of three or more joints or groups of joints (distal interphalangeal and proximal interphalangeal joints are counted as one group each). Heberden's and Bouchard's nodes are prominent. Symptoms may be episodic, with "flare-ups" of inflammation marked by soft tissue

swelling, redness, and warmth. The erythrocyte sedimentation rate may be elevated, but serum rheumatoid factor tests are negative.

Thumb Base The second most frequent area of involvement inOA is the thumb base. Swelling, tenderness, and crepitus on movement of the joint are typical. Osteophytes may lead to a "squared" appearance of the thumb base (Fig. 321-3). In contrast to Heberden's nodes, which usually do not interfere significantly with function, thumb base OA frequently causes loss of motion and strength. Pain with pinch leads to adduction of the thumb and contracture of the first web space, often resulting in compensatory hyperextension of the first metacarpophalangeal joint and swan-neck deformity of the thumb.

The Hip Congenital or developmental defects (e.g., acetabular dysplasia, Legg-Calve-Perthes disease, slipped capital epiphysis) can lead to cases of hipOA. Some 20% of patients will develop bilateral involvement. Pain from hip OA is generally referred to the inguinal area but may be referred to the buttock or proximal thigh. Less commonly, hip OA presents as knee pain. Pain can be evoked by putting the involved hip through its range of motion. Flexion may be painless initially, but internal rotation will exacerbate pain. Loss of internal rotation occurs early, followed by loss of extension, adduction, and flexion due to capsular fibrosis and/or buttressing osteophytes.

The Knee OA of the knee may involve the medial or lateral femorotibial compartment and/or the patellofemoral compartment. Palpation may reveal bony hypertrophy (osteophytes) and tenderness. Effusions, if present, are generally small. Joint movement commonly elicits bony crepitus. OA in the medial compartment may result in a varus (bow-leg) deformity; in the lateral compartment it may produce a valgus (knock-knee) deformity. A positive "shrug" sign (pain when the patella is compressed manually against the femur during quadriceps contraction) may be a sign of patellofemoral OA.

Chondromalacia patellae, which also is characterized by anterior knee pain and a positive shrug sign, is a syndrome of patellofemoral pain, often bilateral, in teenagers and young adults. It is more common in females than in males. It may be caused by a variety of factors (e.g., abnormal quadriceps angle, patella alta, trauma). Although exploration of the knee may reveal softening and fibrillation of cartilage on the posterior aspect of the patella, this change is usually not progressive; chondromalacia patellae is usually not a precursor ofOA. In most cases, analgesics orNSAIDsand physical therapy are effective; in some, pain may be relieved by surgical correction of patellar malalignment.

The Spine Degenerative disease of the spine can involve the apophyseal joint, intervertebral disks, and paraspinous ligaments. *Spondylosis* refers to degenerative *disk* disease. The diagnosis of spinalOAshould be reserved for patients with involvement of the apophyseal joints and not only disk degeneration. Symptoms of spinal OA include localized pain and stiffness. Nerve root compression by an osteophyte blocking a neural foramen, prolapse of a degenerated disk, or subluxation of an apophyseal joint may cause radicular pain and motor weakness.

Marked calcification and ossification of paraspinous ligaments occur in *diffuse idiopathic*

skeletal hyperostosis (DISH). Although DISH is often categorized as a variant ofOA, diarthrodial joints are not involved. Ligamentous calcification and ossification in the anterior spinal ligaments give the appearance of "flowing wax" on the anterior vertebral bodies. However, a radiolucency may be seen between the newly deposited bone and the vertebral body, differentiating DISH from the marginal osteophytes in spondylosis. Intervertebral disk spaces are preserved, and sacroiliac and apophyseal joints appear normal, helping to differentiate DISH from spondylosis and from ankylosing spondylitis, respectively. DISH occurs in the middle-aged and elderly and is more common in men than in women. Patients are frequently asymptomatic but may have musculoskeletal stiffness. The radiographic changes are generally much more severe than might be predicted from the mild symptoms.

TREATMENT

Treatment of OA is aimed at reducing pain, maintaining mobility, and minimizing disability. The vigor of the therapeutic intervention should be dictated by the severity of the condition in the individual patient. For those with only mild disease, reassurance, instruction in joint protection, and an occasional analgesic may be all that is required; for those with more severe OA, especially of the knee or hip, a comprehensive program comprising a spectrum of nonpharmacologic measures supplemented by an analgesic and/orNSAID is appropriate.

Nonpharmacologic Measures

Reduction of Joint Loading OA may be caused or aggravated by poor body mechanics. Correction of poor posture and a support for excessive lumbar lordosis can be helpful. Excessive loading of the involved joint should be avoided. Patients with OA of the knee or hip should avoid prolonged standing, kneeling, and squatting. Obese patients should be counseled to lose weight. In patients with medial-compartment knee OA, a wedged insole may decrease joint pain.

Rest periods during the day may be of benefit, but complete immobilization of the painful joint is rarely indicated. In patients with unilateralOA of the hip or knee, a cane, held in the contralateral hand, may reduce joint pain by reducing the joint contact force. Bilateral disease may necessitate use of crutches or a walker.

Physical Therapy Application of heat to theOA joint may reduce pain and stiffness. A variety of modalities are available; often, the least expensive and most convenient is a hot shower or bath. Occasionally, better analgesia may be obtained with ice than with heat.

It is important to note that patients with OAof weight-bearing joints are less active and tend to be less fit with regard to musculoskeletal and cardiovascular status than normal controls. An exercise program should be designed to maintain range of motion, strengthen periarticular muscles, and improve physical fitness. The benefits of aerobic exercise include increases in aerobic capacity, muscle strength, and endurance; less exertion with a given workload; and weight loss. Those who exercise regularly live longer and are healthier than those who are sedentary. Patients with hip or knee OA can participate safely in conditioning exercises to improve fitness and health without

increasing their joint pain or need for analgesics orNSAIDs.

Disuse of theOA joint because of pain will lead to muscle atrophy. Because periarticular muscles play a major role in protecting the articular cartilage from stress, strengthening exercises are important. In individuals with knee OA, strengthening of the periarticular muscles may result, within weeks, in a decrease in joint pain as great as that seen withNSAIDs.

Drug Therapy of OA Therapy forOA today is palliative; no pharmacologic agent has been shown to prevent, delay the progression of, or reverse the pathologic changes of OA in humans. Although claims have been made that someNSAIDshave a "chondroprotective effect," adequately controlled clinical trials in humans with OA to support this view are lacking. In management of OA pain, pharmacologic agents should be used as adjuncts to nonpharmacologic measures, such as those described above, which are the keystone of OA treatment.

AlthoughNSAIDsoften decrease joint pain and improve mobility inOA, the magnitude of this improvement is generally modest -- on average, about 30% reduction in pain and 15% improvement in function. In a double-blinded, controlled trial in patients with symptomatic knee OA, an anti-inflammatory dose of ibuprofen (2400 mg/d) was no more effective than a low (i.e., essentially analgesic) dose of ibuprofen (1200 mg/d) or than acetaminophen (4000 mg/d), a drug with essentially no anti-inflammatory effect. Other studies confirm that an analgesic dose of ibuprofen may be as effective as anti-inflammatory doses of other NSAIDs, including the potent agent, phenylbutazone (400 mg/d), in symptomatic treatment of OA. Even in the presence of clinical signs of inflammation (e.g., synovial effusion, tenderness), relief of joint pain by acetaminophen may be as effective as that achieved with an NSAID. Nonetheless, if simple analgesics are inadequate, it is reasonable to cautiously prescribe an NSAID for a patient with OA.

It should be recognized that concern over the use ofNSAIDsin OAhas grown in recent years because of side effects of these agents, especially those related to the gastrointestinal (GI) tract. Those at greatest risk for OA, i.e., the elderly, appear also to be at greater risk than younger individuals for GI symptoms, ulceration, hemorrhage, and death as a result of NSAID use. The annual rate of hospitalization for peptic ulcer disease among elderly current NSAID users was 16 per 1000 -- four times greater than that for persons not taking an NSAID. Among those age 65 and older, as many as 30% of all hospitalizations and deaths related to peptic ulcer disease have been attributed to NSAID use. In addition to age, risk factors for hemorrhage and other ulcer complications associated with NSAID use include a history of peptic ulcer disease or of upper GI bleeding, concomitant use of glucocorticoids or anticoagulants, and, possibly, smoking and alcohol consumption (Table 321-4).

In patients who carry risk factors for anNSAID-associatedGIcatastrophe, a cyclooxygenase (Cox)-2-specific NSAID may be preferable to even a low dose of a nonselective Cox inhibitor. In contrast to the NSAIDs available to date -- all of which inhibit Cox-1 as well as Cox-2 -- two Cox-2-specific inhibitors (CSIs), celecoxib and rofecoxib, are now available. Both appear to be comparable in efficacy to the nonselective NSAIDs. Endoscopic studies have shown that both agents are associated with an incidence of gastroduodenal ulcer lower than that of comparator NSAIDs and

comparable to that of placebo. Of additional advantage with respect to the issue of upper GI bleeding, CSIs do not have a clinically significant effect on platelet aggregation or bleeding time, suggesting that CSIs may be especially advantageous in patients at high risk for incurring an NSAID-associated GI catastrophe. Long-term studies are now in progress that are designed to ascertain whether clinically important differences exist between CSIs and nonselective NSAIDs with respect to major GI clinical outcomes.

Systemic glucocorticoids have no place in the treatment ofOA. However, intra- or periarticular injection of a depot glucocorticoid preparation may provide marked symptomatic relief for weeks to months. Because studies in animal models have suggested that glucocorticoids may produce cartilage damage, and frequent injections of large amounts of steroids have been associated with joint breakdown in humans, the injection should generally not be repeated in a given joint more often than every 4 to 6 months.

Intraarticular injection of hyaluronic acid has been approved recently for treatment of patients with kneeOA who have failed a program of nonpharmacologic therapy and simple analgesics. Because the duration of benefit following treatment may exceed by months the synovial half-life of exogenous hyaluronic acid, the mechanism of action is unclear. The placebo response to intraarticular injection of hyaluronic acid is often large and sustained. Although relief of knee pain is achieved more slowly after hyaluronic acid injection than after intraarticular glucocorticoid injection, the effect may last much longer after hyaluronic acid injection than after glucocorticoid injection.

Capsaicin cream, which depletes local sensory nerve endings of substance P, a neuropeptide mediator of pain, may reduce joint pain and tenderness when applied topically by patients with hand or kneeOA, even when used as monotherapy, i.e., withoutNSAIDsor systemic analgesics.

A Rational Approach to the Nonsurgical Management of OA Nonpharmacologic management is the foundation of treatment ofOA pain and is as important as -- and often more important than -- drug treatment, which should play an adjunctive or complementary role in the management of this disease. Nonpharmacologic measures may comprise instruction of the patient in principles of joint protection; thermal modalities; exercises to strengthen periarticular muscles; weight reduction, if the patient is obese; avoidance of excessive loading of the arthritic hip or knee joint by use of shoes with well-cushioned soles and a cane or walker, when appropriate; and prescription of orthotics for the patient with varus or valgus knee deformity. Medial taping of the patella may reduce knee pain in patients with patellofemoral OA. In patients with painful knee OA, if the above measures are ineffective, tidal irrigation of the joint with a large quantity of saline or Ringer's lactate warrants consideration (see below). A health education program designed to assist the patient with self-management can reduce pain and decrease health care costs; the benefits may persist for years. At any point in the course of OA, if acute joint pain and effusion develop, intraarticular injection of glucocorticoids may be indicated once joint infection is excluded by synovial fluid analysis.

Figure 321-4 provides an algorithm that might be applied to treatment of a newly diagnosed patient with kneeOA. The progressive levels of treatment are associated with

increasing cost, decreasing convenience for the patient, and increasing risk of side effects. The scheme should not be interpreted dogmatically as a fixed progression of steps; rather, treatment of OA must be individualized. The treatment program should be flexible. For example, in some patients it may be reasonable to institute patellar taping or prescribe a wedged insole on the initial visit, or an intraarticular glucocorticoid injection on a later visit. As indicated above, maintaining regular contact with the patient, e.g., via periodic telephone calls, may reduce joint pain to a level beyond what can be achieved with anNSAIDalone, and this, or some surrogate measure, warrants incorporation into the treatment program (Fig. 321-4).

Because of its low cost, excellent safety profile, and an efficacy in many patients comparable to that ofNSAIDs, when an analgesic is required for treatment ofOA pain it is reasonable to prescribe acetaminophen initially, in a dose up to 4000 mg/d. If this does not control joint symptoms within a reasonable period of time, a *low dose* of NSAID (e.g., ibuprofen, 1200 mg/d; naproxen, 500 mg/d) may be substituted for, or added to, the acetaminophen. If a nonselective NSAID is used, even in a low dose, it is reasonable to recommend coadministration of a gastroprotective agent, such as misoprostol, or a proton pump inhibitor, such as famotidine or omeprazole, which have been shown by endoscopy to be effective in treating and preventing NSAID gastropathy. Because the risk of an NSAID-associatedGIcatastrophe is dose-dependent, the lowest effective dose of NSAID should be employed. Salsalate and other nonacetylated salicylates, which have only a minimal effect on prostaglandin synthase, are as effective as other NSAIDs and have a lower rate of serious GI side effects. However, phototoxicity and central nervous system toxicity may limit their use.

If the above approach does not provide adequate symptomatic relief, tramadol, a weak opioid, for which the risks of tolerance and addiction appear to be minimal, may be prescribed. Mean daily doses have typically been in the range of 200 to 300 mg. Side effects (e.g., nausea and vomiting, constipation, and drowsiness) are common, but their frequency may be reduced by initiating treatment with a dose of only 25 mg/d, which is then gradually increased over the next several days. If this is not effective or opioids are contraindicated, an anti-inflammatory dose of aCSI or of a nonselective NSAID may be prescribed, with coadministration of a gastroprotective agent in the latter instance.

WhenNSAIDsare required, they may be prescribed on an "as needed" basis, rather than in a fixed daily dose; pain control has been shown to be comparable and the risk of toxicity will be reduced. Once treatment with an NSAID or simple analgesic is initiated, the need for continuation of that treatment requires ongoing assessment. For many patients withOA, it will be possible eventually to reduce the dose of drug or to use the agent only intermittently, during exacerbations of joint pain.

Tidal Irrigation Copious irrigation of theOA knee to flush out fibrin, cartilage shards, and other debris may provide months of comfort for the patient whose joint pain has been refractory to analgesics,NSAIDs, and intraarticular glucocorticoid injections. It should be recognized, however, that invasive procedures such as this are accompanied by a large placebo effect, and studies that include a sham lavage control group have not yet been reported.

Orthopedic Surgery Joint replacement surgery should be reserved for patients with

advancedOA in whom aggressive medical management has failed. In such cases total joint arthroplasty may be remarkably effective in relieving pain and increasing mobility. Osteotomy, which is surgically more conservative, can eliminate concentrations of peak dynamic loading and may provide effective pain relief in patients with hip or knee OA. It is of greatest benefit when the disease is only moderately advanced. Arthroscopic removal of loose cartilage fragments can prevent locking and relieve pain. Chondroplasty (abrasion arthroplasty) has also had some popularity as treatment for OA, but well-controlled studies of its efficacy are lacking, and the fibrocartilage that resurfaces the abraded bone is inferior to normal hyaline cartilage in its ability to withstand mechanical loads. In patients who had undergone tibial osteotomy for medial compartment knee OA, knee pain and function were not related to the extent of cartilage regeneration 2 years later.

Autologous chondrocyte transplantation and attempts at cartilage repair using mesenchymal stem cells and autologous osteochondral plugs are currently being used experimentally for repair of focal chondral defects, but have not proved to be effective in treatment ofOA.

322. GOUT AND OTHER CRYSTAL ARTHROPATHIES - *Antonio J. Reginato*

"GOUT" CRYSTALLOGRAPHY AND ARTHRITIS

The use of polarizing microscopy during synovial fluid analysis and the application of other crystallographic techniques, such as electron microscopy, energy-dispersive elemental analysis, and x-ray diffraction, have established the role of different microcrystals, including monosodium urate (MSU), calcium pyrophosphate dihydrate (CPPD), calcium hydroxyapatite (HA), and calcium oxalate (CaOx), in inducing acute or chronic arthritis or periarthritis. In spite of differences in crystal morphology, chemistry, and physical properties, the clinical events that result from deposition of MSU, CPPD, HA, and CaOx may be indistinguishable (Table 322-1). Prior to the use of crystallographic techniques in rheumatology, much of what was considered to be MSU gouty arthritis in fact was not. Simkin has suggested that the generic term *gout* be used to describe the whole group of crystal-induced arthritides (MSU gout, CPPD gout, HA gout, and CaOx gout). This concept further emphasizes the identical clinical presentations of these entities (Table 322-1) and the need to perform synovial fluid analysis to distinguish the type of crystal involved. In the setting of acute articular or periarticular inflammation, aspiration and analysis of effusions are most important to assess the possibility of infection and to identify the type of crystals present. Polarization microscopy alone can identify most typical crystals and allow diagnosis. HA, however, is an exception. Apart from the identification of specific microcrystalline materials or organisms, synovial fluid characteristics are nonspecific, and synovial fluid can be inflammatory or noninflammatory.

MONOSODIUMURATE GOUT

MSUgout is a metabolic disease most often affecting middle-aged to elderly men. It is typically associated with an increased uric acid pool, hyperuricemia, episodic acute and chronic arthritis, and deposition of MSU crystals in connective tissue tophi and kidneys (Chap. 347).

Acute and Chronic Arthritis Acute arthritis is the most frequent early clinical manifestation ofMSUgout. Usually, only one joint is affected initially, but polyarticular acute gout is also seen in male hypertensive patients with ethanol abuse as well as in postmenopausal women. The metatarsophalangeal joint of the first toe is often involved, but tarsal joints, ankles, and knees are also commonly affected. In elderly patients, finger joints may be inflamed. Inflamed Heberden's or Bouchard's nodes may be a first manifestation of gouty arthritis. The first episode of acute gouty arthritis frequently begins at night with dramatic joint pain and swelling. Joints rapidly become warm, red, and tender, and the clinical appearance often mimics a cellulitis. Early attacks tend to subside spontaneously within 3 to 10 days, and most of the patients do not have residual symptoms until the next episode. Several events may precipitate acute gouty arthritis: dietary excess, trauma, surgery, excessive ethanol ingestion, adrenocorticotropic hormone (ACTH) and glucocorticoid withdrawal, hypouricemic therapy, and serious medical illnesses such as myocardial infarction and stroke.

After many acute mono- or oligoarticular attacks, a proportion of gouty patients may present with a chronic nonsymmetric synovitis, causing potential confusion with

rheumatoid arthritis (Chap. 312). Less commonly, chronic gouty arthritis will be the only manifestation and, more rarely, the disease will manifest as inflamed or noninflamed periarticular tophaceous deposits in the absence of chronic synovitis (Table 322-1). Women represent only 5 to 17% of all patients with gout. Premenopausal gout is a rare occurrence and accounts for only about 17% of all women with gout; it is seen mostly in individuals with a strong family history of gout. A few kindreds of precocious gout in young females caused by decreased renal urate clearance and renal insufficiency have been described. Most women with gouty arthritis are postmenopausal and elderly, have arterial hypertension causing mild renal insufficiency, and are usually receiving diuretics. Also, most of these patients have underlying degenerative joint disease, and inflamed tophaceous deposits may be seen on Heberden's and Bouchard's nodes.

Laboratory Diagnosis Even if the clinical appearance strongly suggests gout, the diagnosis should be confirmed by needle aspiration of acutely or chronically inflamed joints or tophaceous deposits. Acute septic arthritis, several of the other crystalline-associated arthropathies, palindromic rheumatism, and psoriatic arthritis may present with similar clinical features. During acute gouty attacks, strongly birefringent needle-shapedMSUcrystals with negative elongation are largely intracellular (Fig. 322-1). Synovial fluid cell counts are elevated from 2000 to 60,000/uL. Effusions appear cloudy due to leukocytes, and large amounts crystals occasionally produce a thick pasty or chalky joint fluid. Bacterial infection can coexist with urate crystals in synovial fluid; if there is any suspicion of septic arthritis, joint fluid must also be cultured. MSU crystals can often be demonstrated in the first metatarsophalangeal (MTP) joint and in knees not acutely involved with gout. Arthrocentesis of these joints is a useful technique to establish the diagnosis of gout between attacks. Serum uric acid levels can be normal or low at the time of the acute attack, since lowering of uric acid with hypouricemic therapy or other medications limits the value of serum uric acid determinations for the diagnosis of gout. Despite these limitations, serum uric acid is almost always elevated at some time and can be used to follow the course of hypouricemic therapy. A 24-h urine collection for uric acid is valuable in assessing the risk of stones, in elucidating overproduction or underexcretion of uric acid, and in deciding which hypouricemic regimen to use (Chap. 347). Excretion of more than 800 mg of uric acid per 24 h on a regular diet suggests that causes of overproduction of purine should be considered. Urinalysis, blood urea nitrogen, serum creatinine, white blood cell (WBC) count, and serum lipids should be monitored because of possible pathologic sequelae of gout and other associated diseases requiring treatment.

Radiographic Features Cystic changes, well-defined erosions described as punched-out lytic lesions with overhanging bony edges (Martel's sign), associated with soft tissue calcified masses are characteristic radiographic features of chronic tophaceous gout. However, similar radiographic signs can also be observed in erosive osteoarthritis, destructive apatite arthropathies, and rheumatoid arthritis.

TREATMENT

Acute Gouty Arthritis The mainstay of treatment during an acute attack is the administration of an anti-inflammatory drug such as colchicine, nonsteroidal anti-inflammatory drugs (NSAIDs), or glucocorticoids depending on the age of the patient and comorbid conditions. Both colchicine and NSAIDs may be quite toxic in the

elderly, particularly in the presence of renal insufficiency and gastrointestinal disorders. In elderly patients, one may favor the use of intraarticular glucocorticoid injections for attacks involving one or two larger joints or cool applications along with lower oral doses of colchicine for gouty synovitis affecting small joints. Colchicine given orally is a traditional and effective treatment, if used early in the attack, in at least 85% of patients. One tablet (0.6 mg) is given every hour until relief of symptoms or gastrointestinal toxicity occurs, or a total of four to eight tablets have been taken in accordance with the age of the patient. The drug must be stopped promptly at the first sign of loose stools, and symptomatic treatment must be given for the diarrhea. Intravenous colchicine is sometimes used and can reduce, though not eliminate, the gastrointestinal side effects. Intravenous colchicine is most reliable for pre- or postoperative prophylaxis in 1- to 2-mg doses when patients cannot take medications orally. Life-threatening colchicine toxicity and sudden death have been described with the administration of more than 4 mg/d intravenously. The intravenous dose for acute gouty arthritis is 1 to 2 mg given slowly through an established venous line over 10 min in a soluset, and two additional doses of 1 mg each may be given at 6-h intervals, but the total dose should never exceed 4 mg. NSAIDs are affective in about 90% of patients, and the resolution of signs and symptoms usually occurs in 5 to 7 days. The most effective drugs are those with a short half-life and include indomethacin, 25 to 50 mg tid, ibuprofen, 800 mg tid, or diclofenac, 50 mg tid. Cyclooxigenase-2-specific inhibitors are probably equally effective but with less short-term gastrointestinal toxicity. Oral glucocorticoids such as prednisone, 30 to 50 mg/d as the initial dose and tapered over 5 to 7 days, a single intravenous dose of methylprednisolone, 7 mg of betametasone, or 60 mg of triamcinolone acetonide have been equally effective.ACTH as an intramuscular injection of 40 to 80 IU in a single dose or every 12 h for 1 to 2 days is effective in patients with acute polyarticular refractory gout or with a contraindication for using colchicine or NSAIDs.

Hypouricemic Therapy Attempts to normalize serum uric acid to <300 umol/L (5.0 mg/dL) to prevent recurrent gouty attacks and eliminate tophaceous deposits entail a commitment to long-term hypouricemic regimens and medications that generally are required for life. Hypouricemic therapy should be considered when the hyperuricemia cannot be corrected by simple means (control of body weight, low-purine diet, increase in liquid ingestion, limitation of ethanol intake, and avoidance of diuretic use). The decision to initiate hypouricemic therapy is usually made taking into consideration the number of acute attacks, family history of gout, presence ofMSUtophaceous deposits, uric acid excretion >800 mg per 24 hours, presence of uric acid stones, and risk for acute uric acid nephropathy during chemotherapy for myeloproliferative disorders. Uricosuric agents, such as probenecid, can be used in patients with good renal function who underexcrete uric acid, with <600 mg in a 24-hour urine sample. Urine volume must be maintained by ingestion of 1500 mL of water every day. Probenecid can be started at a dosage of 200 mg twice daily and increased gradually as needed up to 2 g in order to maintain a serum uric acid level <300 umol/L (5 mg/dL). Probenecid is the drug of choice to treat elderly patients with hypertension and thiazide dependence; however, probenecid is not effective with a renal creatinine clearance<1 mL/s. These patients may require allopurinol or benzbromarone (not available in the United States), which is another uricosuric drug that is effective in patients with renal failure and who are receiving diuretics. Allopurinol is the best drug to lower serum urate in overproducers, stone formers, and patients with advanced renal failure. It can be given in a single morning dose, 300 mg initially and increasing up to 800 mg if needed. In most patients,

it is not necessary to start at a lower dose; however, in patients with renal failure, the dosage should be adjusted depending on the serum creatinine concentration in order to minimize side effects. Patients with frequent acute attacks may require lower initial doses to prevent exacerbations. Toxicity of allopurinol has been recognized increasingly in patients with renal failure who use thiazide diuretics and in those patients allergic to penicillin and ampicillin. The most serious side effects include skin rash with progression to life-threatening toxic epidermal necrolysis, systemic vasculitis, bone marrow suppression, granulomatous hepatitis, and renal failure. Urate-lowering drugs should not be initiated during acute attacks. This is especially important in patients who have refractory acute arthritis or who had a flare-up previously with hypouricemic drugs. Colchicine prophylaxis in doses of 0.6 mg one to two times daily is usually continued, along with hypouricemic therapy, until the patient is normouricemic and without gouty attacks for 3 months. However, prophylactic colchicine treatment may be necessary as long as tophi are present.

CPPD DEPOSITION DISEASE

Pathogenesis The deposition of CPPDcrystals in articular tissues is most common in the elderly, affecting 10 to 15% of persons 65 to 75 years old and 30 to 60% of those more than 85 years old. In most cases this process is asymptomatic, and the cause of CPPD deposition is uncertain. Because over 80% of patients are more than 60 years old and 70% have preexisting joint damage from other conditions, it is likely that biochemical changes in aging cartilage favor crystal nucleation. Examples of such chemical alterations include the following. There is an increased production of inorganic pyrophosphate and decreased levels of pyrophosphatases in cartilage extracts from patients with CPPD arthritis. The increase in pyrophosphate production appears to be related to enhanced activity of ATP pyrophosphohydrolase and 5¢-nucleotidase, which catalyze the reaction of ATP to adenosine and pyrophosphate. This pyrophosphate could combine with calcium to form CPPD crystals in matrix vesicles or on collagen fibers. There is a diminution in the levels of cartilage glycosaminoglycans that normally inhibit and regulate crystal nucleation. These deficiencies may lead to increased crystal deposition. In vitro studies have demonstrated that transforming growth factor b1 and epidermal growth factor both stimulate the production of pyrophosphate by articular cartilage and thus may contribute to the deposition of CPPD crystals. The release of CPPD crystals into the joint space is followed by the phagocytosis of these crystals by neutrophils, which respond by releasing inflammatory substances. In addition, neutrophils release a glycopeptide that is chemotactic for other neutrophils, thus augmenting the inflammatory events. The same substance is present inMSUgout.

A minority of patients withCPPDarthropathy have metabolic abnormalities or hereditary CPPD disease (Table 322-2). These associations suggest that a variety of different metabolic products may enhance CPPD deposition. Included among these conditions are the "four H's" of hyperparathyroidism, hemochromatosis, hypophosphatasia, and hypomagnesemia. Hemochromatosis and hyperparathyroidism are good examples. Ferrous ions and hypercalcemia may either directly alter cartilage or inhibit inorganic pyrophosphatases, leading to enhanced susceptibility to CPPD deposition. The presence of CPPD arthritis in individuals less than 50 years old should lead to consideration of these metabolic disorders and inherited forms of disease, including those identified in a variety of ethnic groups (Table 322-2). Genomic DNA studies

performed on four different kindreds have shown a possible location of the genetic defects on chromosome 8q in one, and on chromosome 5p in the other three. Identification of these genes will help elucidate the pathogenesis of both the familial and the more common sporadic form of the disease. Investigation should include inquiry for evidence of familial aggregation and evaluation of serum calcium, phosphorus, alkaline phosphatase, magnesium, serum ferritin, and transferritin saturation.

Clinical Manifestations CPPDarthropathy may be asymptomatic, acute, subacute, or chronic or cause acute synovitis superimposed on chronically involved joints. Acute CPPD arthritis was originally termed *pseudogout* by McCarty and coworkers because of its striking similarity toMSUgout. Other clinical manifestations of CPPD deposition include (1) induction or enhancement of peculiar forms of osteoarthritis; (2) induction of severe destructive disease that may radiographically mimic neuropathic arthritis; (3) production of symmetric proliferative synovitis, clinically similar to rheumatoid arthritis and frequently seen in familial forms with early onset; (4) intervertebral disk and ligament calcification with restriction of spine mobility, mimicking ankylosing spondylitis (also seen in hereditary forms); and (5) rarely spinal stenosis (most commonly seen in the elderly (Table 322-1).

The knee is the joint most frequently affected inCPPDarthropathy. Other sites include the wrist, shoulder, ankle, elbow, and hands. Rarely, the temporomandibular joint and ligamentum flavum of the spinal canal are involved. Clinical and radiographic evidence indicates that CPPD deposition is polyarticular in at least two-thirds of patients. When the clinical picture resembles that of slowly progressive osteoarthritis, diagnosis may be more difficult. Joint distribution may provide important clues suggesting CPPD disease. For example, primary osteoarthritis rarely involves a metacarpophalangeal, wrist, elbow, shoulder, or ankle joint. If radiographs reveal punctate and/or linear radiodense deposits in fibrocartilaginous joint menisci or articular hyaline cartilage (chondrocalcinosis), the diagnostic certainty of CPPD is further enhanced. *Definitive diagnosis* requires demonstration of typical crystals in synovial fluid or articular tissue (Fig. 322-2). In the absence of joint effusion or indications to obtain a synovial biopsy, chondrocalcinosis is presumptive of CPPD deposition. One exception is chondrocalcinosis due toCaOx in some patients with chronic renal failure.

Acute attacks ofCPPDarthritis may be precipitated by trauma, arthroscopy, or hyaluronate injections. Rapid diminution of serum calcium concentration, as may occur in severe medical illness or after surgery (especially parathyroidectomy), can also lead to pseudogout attacks.

In as many as 50% of cases,CPPDgout is associated with low-grade fever and, on occasion, temperatures as high as 40°C. Whether or not radiographic proof of chondrocalcinosis is evident in the involved joint(s), synovial analysis with microbial cultures is essential to rule out the possibility of infection. In fact, infection in a joint with any microcrystalline deposition process can lead to crystal shedding and subsequent synovitis from both crystals and microorganisms. Synovial fluid in acute CPPD gout has inflammatory qualities. The WBCcount can range from several thousand cells to 100,000 cells/uL, the mean being about 24,000 cells/uL and the predominant cell being the neutrophil. Polarization microscopy usually reveals rhomboid crystals with weak positive birefringence inside fibrim and in neutrophils (Fig. 322-2).

TREATMENT

Untreated acute attacks may last a few days to as long as a month. Treatment by joint aspiration andNSAIDs, or colchicine, or intraarticular glucocorticoid injection may result in return to prior status in 10 days or less. For patients with frequent recurrent attacks of CPPDgout, daily prophylactic treatment with low doses of colchicine may be helpful in decreasing the frequency of the attacks. Severe polyarticular attacks usually require short courses of glucocorticoids. Unfortunately, there is no effective way to remove CPPD deposits from cartilage and synovium. Uncontrolled studies suggest that radioactive synovectomy (with yttrium 90) or the administration of antimalarial agents may be helpful in controlling persistent synovitis. Patients with progressive destructive large-joint arthropathy usually require joint replacement.

CALCIUM HYDROXYAPATITE DEPOSITION DISEASE

Pathogenesis HA is the primary mineral of bone and teeth. Abnormal accumulation can occur in areas of tissue damage (dystrophic calcification), in hypercalcemic or hyperparathyroid states (metastatic calcification), and in certain conditions of unknown cause (Table 322-3). In chronic renal failure, hyperphosphatemia enhances HA deposition both in and around joints.

HAmay be released from exposed bone and cause the acute synovitis occasionally seen in chronic stable osteoarthritis (e.g., "hot" Heberden's nodes). HA deposition is also an important factor in an extremely destructive chronic arthropathy of the elderly that occurs most often in knees and shoulders (Milwaukee shoulder). Joint destruction is associated with attenuation or rupture of supporting structures, leading to instability and deformity. Progression tends to be indolent, and synovial fluidWBCcounts are usually less than 1000/uL. Symptoms range from minimal to severe pain and disability that may lead to joint replacement surgery. Whether severely affected patients merely represent an extreme synovial tissue response to the HA crystals that are so common in osteoarthritis is uncertain. Synovial membrane tissue cultures exposed to HA (orCPPD) crystals markedly increased the release of collagenases and neutral proteases, underscoring the destructive potential of abnormally stimulated synovial lining cells.

Clinical Manifestations Periarticular and articular deposits may coexist and be associated with acute and/or chronic damage to the joint capsule, tendons, bursa, or articular surfaces. The most common sites ofHAdeposition include bursae and tendons in and/or around the knees, shoulders, hips, and fingers. Clinical manifestations include asymptomatic radiographic abnormalities, acute synovitis, bursitis, tendinitis, and chronic destructive arthropathy. Most patients with HA arthropathy are elderly. Although the true incidence of HA arthritis is not known, 30 to 50% of patients with osteoarthritis have HA microcrystals in their synovial fluid. Such crystals can frequently be identified in clinically stable osteoarthritic joints, but they are more likely to come to attention in persons experiencing acute or subacute worsening of joint pain and swelling. The synovial fluidWBCcount in HA arthritis is usually low (<2000/uL) but may at times have as many as 50,000/uL. Most synovial fluid analyses reveal a predominance of mononuclear cells. Occasionally, neutrophils may dominate.

Diagnosis Radiographic findings inHAarthropathy are not diagnostic. Intra- and/or periarticular calcifications with or without erosive, destructive, or hypertrophic changes may be present.

Definitive diagnosis ofHAarthropathy depends on identification of crystals from synovial fluid or tissue (Fig. 322-3). Individual crystals are very small, nonbirefringent, and can only be seen by electron microscopy. Clumps of crystals may appear as 1- to 20-um shiny intra- or extracellular globules that stain purplish with Wright's stain and bright red with alizarin red S. Absolute identification depends on electron microscopy with energy-dispersive elemental analysis, x-ray diffraction, or infrared spectroscopy.

TREATMENT

Treatment of HAarthritis is nonspecific. Acute attacks of bursitis or synovitis may be self-limiting, resolving in from days to several weeks. Aspiration of effusions and the use of eitherNSAIDsor oral colchicine for 2 weeks or intra- or periarticular injection of glucocorticoid salts appear to shorten the duration and intensity of symptoms. In patients with underlying severe destructive articular changes, response to medical therapy is usually less rewarding.

CAOXDEPOSITION DISEASE

Pathogenesis *Primary oxalosis* is a rare hereditary metabolic disorder (Chap. 352). Enhanced production of oxalic acid may result from at least two different enzyme defects, leading to hyperoxalemia and deposition of calcium oxalate crystals in tissues. Nephrocalcinosis, renal failure, and death usually occur before age 20. Acute and/or chronicCaOxarthritis and periarthritis may complicate primary oxalosis during later years of illness.

Secondary oxalosis is more common than the primary disorder. It is one of the many metabolic abnormalities that complicate end-stage renal disease (ESRD). In ESRD, calcium oxalate deposits have long been recognized in visceral organs, blood vessels, bones, and even cartilage. However, it was not until 1982 that such deposits were demonstrated to be one of the causes of arthritis in chronic renal failure. Thus far, reported patients have been dependent on long-term hemodialysis or peritoneal dialysis (Chap. 272), and many had received ascorbic acid supplements. Ascorbic acid is metabolized to oxalate, which is inadequately cleared in uremia and by dialysis. Such supplements are now usually avoided in dialysis programs because of the risk of enhancing hyperoxalosis and its sequelae.

Clinical Manifestations and Diagnosis As was noted for the other calcium salts,CaOxaggregates can be found in bone, articular cartilage, synovium, and periarticular tissues. From these sites, crystals may be shed, causing acute synovitis. Persistent aggregates of CaOx may, likeHA andCPPD, stimulate synovial proliferation and enzyme release, resulting in progressive articular destruction. Deposits have been documented in fingers, wrists, elbows, knees, ankles, and feet.

Each of the known microcrystalline arthropathies may be a complication ofESRD, and rare patients have more than one type of crystal present in a joint effusion. The advent

of crystallographic techniques has made it clear that most arthritic problems in ESRD are not, as was once believed, due toMSUgout. Clinical features of acuteCaOxarthritis may not be distinguishable from those due to sodium urate,CPPD, orHA. Radiographs may reveal chondrocalcinosis, a feature of either CPPD or CaOx deposition. CaOx-induced synovial effusions are usually noninflammatory, with fewer than 2000 leukocytes/uL. Neutrophils or mononuclear cells have predominated. CaOx crystals have a variable shape and variable birefringence to polarized light. The most easily recognized forms are bipyramidal and have strong positive birefringence (Fig. 322-4).

TREATMENT

Treatment of CaOxarthropathy withNSAIDs, colchicine, intraarticular glucocorticoids, and/or an increased frequency of dialysis has produced only slight improvement. In primary oxalosis, liver transplantation has induced a significant reduction in crystal deposits (Chap. 352).

323. INFECTIOUS ARTHRITIS - *Scott J. Thaler*, *James H. Maguire*

INTRODUCTION AND APPROACH TO THE PATIENT

While *Staphylococcus aureus*, *Neisseria gonorrhoeae*, and other bacteria are the most common causes of infectious arthritis, various mycobacteria, spirochetes, fungi, and viruses also infect joints. Since acute bacterial infection can rapidly destroy articular cartilage, all inflamed joints must be evaluated without delay to exclude noninfectious processes and to determine appropriate antimicrobial therapy and drainage procedures. For more detailed information on infectious arthritis due to specific organisms, the reader is referred to the chapters on those organisms.

Acute bacterial infection typically involves a single joint or a few joints. Subacute or chronic monarthritis or oligoarthritis suggests mycobacterial or fungal infection; episodic inflammation is seen in syphilis, Lyme disease, and the reactive arthritis that follows enteric infections and chlamydial urethritis (Table 323-1). Acute polyarticular inflammation occurs as an immunologic reaction during the course of endocarditis, rheumatic fever, disseminated neisserial infection, and acute hepatitis B. Bacteria and viruses occasionally infect multiple joints, the former most commonly in persons with rheumatoid arthritis.

Aspiration of synovial fluid, an essential element in the evaluation of potentially infected joints, can be performed without difficulty in most cases by the insertion of a large-bore needle into the site of maximal fluctuation or tenderness or by the route of easiest access. Ultrasonography or fluoroscopy may be used to guide aspiration of difficult-to-localize effusions of the hip and, occasionally, the shoulder and other joints. Normal synovial fluid contains<180 cells (predominantly mononuclear cells) per microliter. Synovial cell counts averaging 100,000/uL (range, 25,000 to 250,000/uL), with >90% neutrophils, are characteristic of acute bacterial infections. Crystal-induced, rheumatoid, and other noninfectious inflammatory arthritides are usually associated with<30,000 to 50,000 cells/uL; cell counts of 10,000 to 30,000/uL, with 50 to 70% neutrophils and the remainder lymphocytes, are common in mycobacterial and fungal infections. Definitive diagnosis of an infectious process relies on identification of the pathogen in stained smears of synovial fluid, isolation of the pathogen from cultures of synovial fluid and blood, or detection of microbial nucleic acids and proteins by polymerase chain reaction (PCR)-based assays and immunologic techniques.

ACUTE BACTERIAL ARTHRITIS

Pathogenesis Bacteria enter the joint from the bloodstream, from a contiguous site of infection in bone or soft tissue, or by direct inoculation during surgery, injection, or trauma. In hematogenous infection, bacteria escape from synovial capillaries, which have no limiting basement membrane, and within hours provoke neutrophilic infiltration of the synovium. Neutrophils and bacteria enter the joint space; later, bacteria adhere to articular cartilage. Degradation of cartilage begins within 48 h as a result of increased intraarticular pressure, release of proteases and cytokines from chondrocytes and synovial macrophages, and invasion of the cartilage by bacteria and inflammatory cells. Histologic studies reveal bacteria lining the synovium and cartilage as well as abscesses extending into the synovium, cartilage, and -- in severe cases -- subchondral

bone. Synovial proliferation results in the formation of a pannus over the cartilage, and thrombosis of inflamed synovial vessels develops. Bacterial factors that appear important in the pathogenesis of infective arthritis include various surface-associated adhesins in *S. aureus* that permit adherence to cartilage and endotoxins that promote chondrocyte-mediated breakdown of cartilage.

Microbiology The hematogenous route of infection is the most common route in all age groups. In infants, group B streptococci, gram-negative enteric bacilli, and *S. aureus* are the usual pathogens. Since the advent of the *Haemophilus influenzae* vaccine, *S. aureus*, *Streptococcus pyogenes* (group A *Streptococcus*), and (in some centers) *Kingella kingae* have predominated among children <5 years of age. Among young adults and adolescents, *N. gonorrhoeae* is the most commonly implicated organism. *S. aureus* accounts for most nongonococcal isolates in adults of all ages; gram-negative bacilli, pneumococci, andb-hemolytic streptococci -- particularly groups A and B, but also groups C, G, and F -- are involved in up to one-third of cases in older adults, especially those with underlying comorbid illnesses.

Infections following surgical procedures or penetrating injuries are due most often to *S. aureus* and occasionally to other gram-positive bacteria or gram-negative bacilli. Infections with coagulase-negative staphylococci are unusual except after the implantation of prosthetic joints or arthroscopy. Anaerobic organisms, often in association with aerobic or facultative bacteria, are found after human bites and when decubitus ulcers or intraabdominal abscesses spread into adjacent joints. Polymicrobial infections complicate traumatic injuries with extensive contamination. Cat bites or scratches may introduce *Pasteurella multocida* into joints.

Nongonococcal Bacterial Arthritis

Epidemiology Although hematogenous infections with virulent organisms such as *S. aureus*, *H. influenzae*, and pyogenic streptococci occur in healthy persons, there is an underlying host predisposition in many cases of septic arthritis. Patients with rheumatoid arthritis have the highest incidence of infective arthritis, most often secondary to *S. aureus*, because of chronically inflamed joints, glucocorticoid therapy, and frequent breakdown of rheumatoid nodules, vasculitic ulcers, and skin overlying deformed joints. Diabetes mellitus, glucocorticoid therapy, hemodialysis, and malignancy all carry an increased risk of infection with *S. aureus* and gram-negative bacilli. Pneumococcal infections complicate alcoholism, deficiencies of humoral immunity, and hemoglobinopathies. Pneumococci, *Salmonella*, and *H. influenzae* cause septic arthritis in persons infected with HIV. Persons with primary immunoglobulin deficiency are at risk for mycoplasmal arthritis, which results in permanent joint damage if treatment with tetracycline and intravenous immunoglobulin replacement is not administered promptly. Intravenous drug users acquire staphylococcal and streptococcal infections from their own flora and acquire pseudomonal and other gram-negative infections from drugs and injection paraphernalia.

Clinical Manifestations Some 90% of patients present with involvement of a single joint: most commonly the knee, less frequently the hip, and still less often the shoulder, wrist, or elbow. Small joints of the hands and feet are more likely to be affected after direct inoculation or a bite. Among intravenous drug users, infections of the spine, sacroiliac

joints, or sternoclavicular joints are more common than infections of the appendicular skeleton. Polyarticular infection is most common among patients with rheumatoid arthritis and may resemble a flare of the underlying disease.

The usual presentation consists of moderate to severe pain that is uniform around the joint, effusion, muscle spasm, and decreased range of motion. Fever in the range of 38.3 to 38.9°C (101 to 102°F) and sometimes higher is common but may be lacking, especially in persons with rheumatoid arthritis, renal or hepatic insufficiency, or conditions requiring immunosuppressive therapy. The inflamed, swollen joint is usually evident on examination except in the case of a deeply situated joint, such as the hip, shoulder, or sacroiliac joint. Cellulitis, bursitis, and acute osteomyelitis, which may produce a similar clinical picture, should be distinguished from septic arthritis by their greater range of motion and less-than-circumferential swelling. A focus of extraarticular infection, such as a boil or pneumonia, should be sought. Peripheral-blood leukocytosis with a left shift and elevation of the erythrocyte sedimentation rate or C-reactive protein are common findings.

Plain radiographs show evidence of soft tissue swelling, joint-space widening, and displacement of tissue planes by the distended capsule. Narrowing of the joint space and bony erosions indicate advanced infection and a poor prognosis. Ultrasound is useful for detecting effusions in the hip, and computed tomography or magnetic resonance imaging can demonstrate infections of the sacroiliac joint, sternoclavicular joint, and the spine very well.

Laboratory Findings Specimens of peripheral blood and synovial fluid should be obtained before antibiotics are administered. Blood cultures are positive in up to 50% of *S. aureus* infections but are less frequently positive in infections due to other organisms. The synovial fluid is turbid, serosanguineous, or frankly purulent. Gram-stained smears confirm the presence of large numbers of neutrophils. Levels of total protein and lactate dehydrogenase in synovial fluid are elevated, and the glucose level is depressed; however, these findings are not specific for infection, and measurement of these levels is not necessary to make the diagnosis. The synovial fluid should be examined for crystals, because gout and pseudogout can resemble septic arthritis clinically, and infection and crystal-induced disease occasionally occur together. Organisms are seen on synovial fluid smears in nearly three-quarters of infections with *S. aureus* and streptococci and in 30 to 50% of infections due to gram-negative and other bacteria. Cultures of synovial fluid are positive in>90% of cases. Inoculation of synovial fluid into bottles containing liquid media for blood cultures increases the yield of culture, especially if the pathogen is a fastidious organism or the patient is taking an antibiotic. Although not yet widely available,PCR-based assays for bacterial DNA will also be useful for the diagnosis of partially treated or culture-negative bacterial arthritis.

TREATMENT

Prompt administration of systemic antibiotics and drainage of the involved joint can prevent destruction of cartilage, postinfectious degenerative arthritis, joint instability, or deformity. Once samples of blood and synovial fluid have been obtained for culture, empirical antibiotics should be given that are directed against bacteria visualized on smears or against the pathogens that are likely, given the patient's age and risk factors.

Initial therapy should consist of the intravenous administration of bactericidal agents; direct instillation of antibiotics into the joint is not necessary to achieve adequate levels in synovial fluid and tissue. An intravenous third-generation cephalosporin such as cefotaxime (1 g every 8 h) or ceftriaxone (1 to 2 g every 24 h) will provide adequate empirical coverage for most community-acquired infections in adults when smears show no organisms. Either oxacillin or nafcillin (2 g every 4 h) is used if there are gram-positive cocci on the smear. If methicillin-resistant *S. aureus* is a possible pathogen, as in hospitalized patients, intravenous vancomycin (1 g every 12 h) should be given. In addition, an aminoglycoside should be given to intravenous drug users or other patients in whom *Pseudomonas aeruginosa* may be the responsible agent.

Definitive therapy is based on the identity and antibiotic susceptibility of the bacteria isolated in culture. Infections due to staphylococci are treated with oxacillin, nafcillin, or vancomycin for 4 weeks. Pneumococcal and streptococcal infections due to penicillin-susceptible organisms respond to 2 weeks of therapy with penicillin G (2 million units intravenously every 4 h); infections caused by *H. influenzae* and by strains of *S. pneumoniae* that are resistant to penicillin are treated with cefotaxime or ceftriaxone for 2 weeks. Most enteric gram-negative infections can be cured in 3 to 4 weeks by a second- or third-generation cephalosporin given intravenously or by a fluoroquinolone, such as levofloxacin (500 mg intravenously or orally every 24 h). *P. aeruginosa* infection should be treated for at least 2 weeks with a combination regimen of an aminoglycoside plus either an extended-spectrum penicillin, such as mezlocillin (3 g intravenously every 4 h), or an antipseudomonal cephalosporin, such as ceftazidime (1 g intravenously every 8 h). If tolerated, this regimen is continued for an additional 2 weeks; alternatively, a fluoroquinolone, such as ciprofloxacin (750 mg orally bid), is given by itself or with the penicillin or cephalosporin in place of the aminoglycoside.

Timely drainage of pus and necrotic debris from the infected joint is required for a favorable outcome. Needle aspiration of readily accessible joints such as the knee may be adequate if loculations or particulate matter in the joint does not prevent its thorough decompression. Arthroscopic drainage and lavage may be employed initially or within several days if repeated needle aspiration fails to relieve symptoms, decrease the volume of the effusion and the synovial white cell count, and clear bacteria from smears and cultures. In some cases, arthrotomy is necessary to remove loculations and debride infected synovium, cartilage, or bone. Septic arthritis of the hip is best managed with arthrotomy, particularly in young children, in whom infection threatens the viability of the femoral head. Septic joints do not require immobilization except for pain control before symptoms are alleviated by treatment. Weight bearing should be avoided until signs of inflammation have subsided, but frequent passive motion of the joint is indicated to maintain full mobility. While addition of glucocorticoids to antibiotic treatment improves the outcome of *S. aureus* arthritis in experimental animals, no clinical trials have yet evaluated this approach in humans.

Gonococcal Arthritis

Epidemiology Gonococcal arthritis, accounting for 70% of episodes of infectious arthritis in persons<40 years of age, results from bacteremia arising from gonococcal infection or, more frequently, from asymptomatic gonococcal mucosal colonization of the urethra, cervix, or pharynx. Women are at greatest risk during menses or during pregnancy and

overall are two to three times more likely than men to develop disseminated gonococcal infection and arthritis. Persons with complement deficiencies, especially of the terminal components, are prone to recurrent episodes of gonococcemia. Strains of gonococci that are most likely to cause disseminated infection include those that produce transparent colonies in culture, have the type IA outer-membrane protein, or are of the AUH-auxotroph type.

Clinical Manifestations and Laboratory Findings The most common manifestation of disseminated gonococcal infection is a syndrome of fever, chills, rash, and articular symptoms. Small numbers of papules that progress to hemorrhagic pustules develop on the trunk and the extensor surfaces of the distal extremities. Migratory arthritis and tenosynovitis of the knees, hands, wrists, feet, and ankles are prominent. The cutaneous lesions and articular findings are believed to be the consequence of an immune reaction to circulating gonococci and immune-complex deposition in tissues. Thus, cultures of synovial fluid are consistently negative, and blood cultures are positive in <45% of patients. Synovial fluid may be difficult to obtain from inflamed joints and usually contains only 10,000 to 20,000 leukocytes/uL.

True gonococcal septic arthritis is less common than the disseminated gonococcal infection syndrome and always follows disseminated infection, which is unrecognized in one-third of patients. A single joint, such as the hip, knee, ankle, or wrist, is usually involved. Synovial fluid, which contains >50,000 leukocytes/uL, can be obtained with ease; the gonococcus is only occasionally evident in gram-stained smears, and cultures of synovial fluid are positive in<40% of cases. Blood cultures are almost always negative.

Because it is difficult to isolate gonococci from synovial fluid and blood, specimens for culture should be obtained from potentially infected mucosal sites. Cultures and gram-stained smears of skin lesions occasionally are positive. All specimens for culture should be plated onto Thayer-Martin agar directly or in special transport media at the bedside and transferred promptly to the microbiology laboratory in an atmosphere of 5% CO_2, as generated in a candle jar.PCR-based assays are extremely sensitive in detecting gonococcal DNA in synovial fluid. A dramatic alleviation of symptoms within 12 to 24 h after the initiation of appropriate antibiotic therapy supports a clinical diagnosis of the disseminated gonococcal infection syndrome if cultures are negative.

TREATMENT

Initial treatment consists of ceftriaxone (1 g intravenously or intramuscularly every 24 h) to cover possible penicillin-resistant organisms. Once local and systemic signs are clearly resolving, the 7-day course of therapy can be completed with an oral agent such as cefixime (400 mg bid) or ciprofloxacin (500 mg bid) or, if penicillin-susceptible organisms are isolated, amoxicillin (500 mg tid). Suppurative arthritis usually responds to needle aspiration of involved joints and 7 to 14 days of antibiotic treatment. Arthroscopic lavage or arthrotomy is rarely required.

It is noteworthy that arthritis symptoms similar to those seen in disseminated gonococcal infections occur in meningococcemia. A dermatitis-arthritis syndrome, purulent monarthritis, and reactive polyarthritis have been described. All respond to

treatment with intravenous penicillin.

SPIROCHETAL ARTHRITIS

Lyme Disease Lyme disease due to infection with the spirochete *Borrelia burgdorferi* causes arthritis in up to 70% of persons who are not treated. Intermittent arthralgias and myalgias, but not arthritis, occur within days or weeks of inoculation of the spirochete by the *Ixodes* tick. Later, there are three patterns of joint disease: (1) Fifty percent of untreated persons experience intermittent episodes of monarthritis or oligoarthritis involving the knee and/or other large joints. The symptoms wax and wane without treatment over months, and each year 10 to 20% of patients report loss of joint symptoms. (2) Twenty percent of untreated persons develop a pattern of waxing and waning arthralgias. (3) Ten percent of patients develop chronic inflammatory synovitis resulting in erosive lesions and destruction of the joint. Serologic tests for IgG antibodies to *B. burgdorferi* are positive in >90% of persons with Lyme arthritis, and aPCR-based assay detects *Borrelia* DNA in 85%.

TREATMENT

Lyme arthritis generally responds well to therapy. A regimen of oral doxycycline (100 mg bid for 30 days), oral amoxicillin (500 mg qid for 30 days), or parenteral ceftriaxone (2 g/d for 2 to 4 weeks) is recommended. Patients who do not respond to a total of 2 months of oral therapy or 1 month of parenteral therapy are unlikely to benefit from additional antibiotic therapy and are treated with anti-inflammatory agents or synovectomy. Failure of therapy is associated with host features such as the HLA-DR4 genotype, persistent reactivity to OspA (outer-surface protein A), and the presence of hLFA-1 (human leukocyte function-associated antigen-1), which cross-reacts with OspA.

Syphilitic Arthritis Articular manifestations occur in different stages of syphilis. In early congenital syphilis, periarticular swelling and immobilization of the involved limbs (Parrot's pseudoparalysis) complicate osteochondritis of long bones. Clutton's joint, a late manifestation of congenital syphilis that typically develops between the ages of 8 and 15 years, is caused by chronic painless synovitis with effusions of large joints, particularly the knees and elbows. Secondary syphilis may be associated with arthralgias; symmetric arthritis of the knees and ankles and occasionally of the shoulders and wrists; and sacroiliitis. The arthritis follows a subacute to chronic course with a mixed mononuclear and neutrophilic synovial-fluid pleocytosis (typical cell counts, 5000 to 15,000/uL). Immunologic mechanisms may contribute to the arthritis, and symptoms usually improve rapidly with penicillin therapy. In tertiary syphilis, Charcot's joint is a result of sensory loss due to tabes dorsalis. Penicillin is not helpful in this setting.

MYCOBACTERIAL ARTHRITIS

Tuberculous arthritis accounts for ~1% of all cases of tuberculosis and for 10% of extrapulmonary cases. The most common presentation is chronic granulomatous monarthritis. An unusual syndrome, Poncet's disease, is a reactive symmetric form of polyarthritis that affects persons with visceral or disseminated tuberculosis. No

mycobacteria are found in the joints, and symptoms resolve with antituberculous therapy.

Unlike tuberculous osteomyelitis, which typically involves the thoracic and lumbar spine (50% of cases), tuberculous arthritis primarily involves the large weight-bearing joints, in particular the hips, knees, and ankles, and only occasionally involves smaller non-weight-bearing joints. Progressive monarticular swelling and pain develop over months to years, and systemic symptoms are seen in only half of all cases. Tuberculous arthritis occurs as part of a disseminated primary infection or through late reactivation, often in persons with HIV infection or other immunocompromised hosts. Coexistent active pulmonary tuberculosis is unusual.

Aspiration of the involved joint yields fluid with an average cell count of 20,000/uL, with ~50% neutrophils. Acid-fast staining of the fluid yields positive results in fewer than one-third of cases, and cultures are positive in 80%. Culture of synovial tissue taken at biopsy is positive in ~ 90% of cases and shows granulomatous inflammation in most. DNA amplification methods such asPCR can shorten the time to diagnosis to 1 or 2 days. Radiographs reveal peripheral erosions at the points of synovial attachment, periarticular osteopenia, and eventually joint-space narrowing. Therapy for tuberculous arthritis is the same as that for tuberculous pulmonary disease, requiring the administration of multiple agents for 6 to 9 months. Therapy is more prolonged in immunosuppressed individuals, such as those infected with HIV.

Various atypical mycobacteria found in water and soil may cause chronic indolent arthritis. Such disease results from trauma and direct inoculation associated with farming, gardening, or aquatic activities. Smaller joints, such as the digits, wrists, and knees, are usually involved. Involvement of tendon sheaths and bursae is typical. The mycobacterial species involved include *Mycobacterium marinum*, *M. avium-intracellulare*, *M. terrae*, *M. kansasii*, *M. fortuitum*, and *M. chelonae*. In persons who have HIV infection or are receiving immunosuppressive therapy, hematogenous spread to the joints has been reported for *M. kansasii*, *M. avium-intracellulare*, and *M. haemophilum*. Diagnosis usually requires biopsy and culture, and therapy is based on antimicrobial susceptibility patterns.

FUNGAL ARTHRITIS

Fungi are an unusual cause of chronic monarticular arthritis. Granulomatous articular infection with the endemic dimorphic fungi *Coccidioides immitis*, *Blastomyces dermatitidis*, and (less commonly) *Histoplasma capsulatum* results from hematogenous seeding or direct extension from bony lesions in persons with disseminated disease. Joint involvement is an unusual complication of sporotrichosis (infection with *Sporothrix schenckii*) among gardeners and other persons who work with soil or sphagnum moss. Articular sporotrichosis is six times more common among men than among women, and alcoholics and other debilitated hosts are at risk for polyarticular infection.

Candida infection involving a single joint, usually the knee, hip, or shoulder, results from surgical procedures, intraarticular injections, or (among critically ill patients with debilitating illnesses such as diabetes mellitus or hepatic or renal insufficiency and patients receiving immunosuppressive therapy) hematogenous spread. *Candida*

infections in intravenous drug users typically involve the spine, sacroiliac joints, or other fibrocartilaginous joints. Unusual cases of arthritis due to *Aspergillus* species, *Cryptococcus neoformans*, *Pseudallescheria boydii*, and the dematiaceous fungi have also resulted from direct inoculation or disseminated hematogenous infection in immunocompromised persons.

The synovial fluid in fungal arthritis usually contains 10,000 to 40,000 cells/uL, with ~70% neutrophils. Stained specimens and cultures of synovial tissue often confirm the diagnosis of fungal arthritis when studies of synovial fluid give negative results. Treatment consists of drainage and lavage of the joint and systemic administration of amphotericin B, fluconazole, or itraconazole (the exact drug depending on the species involved). The doses and duration of therapy are the same as for disseminated disease (see Part Seven, Section 15). Intraarticular instillation of amphotericin B has been used in addition to intravenous therapy.

VIRAL ARTHRITIS

Viruses produce arthritis by infecting synovial tissue during systemic infection or by provoking an immunologic reaction that involves joints. As many as 50% of women report persistent arthralgias and 10% frank arthritis within 3 days of the rash that follows natural infection with *rubella virus* and within 2 to 6 weeks after receipt of live virus vaccine. Episodes of symmetric inflammation of fingers, wrists, and knees uncommonly recur for longer than a year, but a syndrome of chronic fatigue, low-grade fever, headaches, and myalgias can persist for months or years. Intravenous immunoglobulin has been helpful in selected cases. Self-limited monarticular or migratory polyarthritis may develop within 2 weeks of the parotitis of *mumps*; this sequela is more common in men than in women. Approximately 10% of children and 60% of women develop arthritis after infection with *parvovirus B19*. In adults, arthropathy sometimes occurs without fever or rash. Pain and stiffness, with less prominent swelling (primarily of the hands but also of the knees, wrists, and ankles), usually resolve within weeks, although a small proportion of patients develop chronic arthropathy.

About 2 weeks before the onset of jaundice, up to 10% of persons with acute *hepatitis B* develop an immune complex-mediated, serum sickness-like reaction with maculopapular rash, urticaria, fever, and arthralgias. Less common developments include symmetric arthritis involving the hands, wrists, elbows, or ankles and morning stiffness that resembles a flare of rheumatoid arthritis. Symptoms resolve at the time jaundice develops. Approximately one-third of persons with chronic hepatitis C infection report persistent arthralgia or arthritis, both in the presence and in the absence of cryoglobulinemia. Painful arthritis involving larger joints often accompanies the fever and rash of several arthropod-borne viral infections, including those caused by *chikungunya*, *O'nyong-nyong*, *Ross River*, *Mayaro*, and *Barmah Forest* viruses. Symmetric arthritis involving the hands and wrists may occur during the convalescent phase of infection with *lymphocytic choriomeningitis virus*. Patients infected with an *enterovirus* frequently report arthralgias, and *echovirus* has been isolated from patients with acute polyarthritis.

Several arthritis syndromes are associated with *HIV* infection. Reiter's syndrome with painful lower-extremity oligoarthritis often follows an episode of urethritis in HIV-infected

persons. HIV-associated Reiter's syndrome appears to be extremely common among persons with the HLA-B27 haplotype, but sacroiliac joint disease is unusual and is seen mostly in the absence of HLA-B27. Up to one-third of HIV-infected persons with psoriasis develop psoriatic arthritis. Painless monarthropathy and persistent symmetric polyarthropathy occasionally complicate HIV infection. Chronic persistent oligoarthritis of the shoulders, wrists, hands, and knees occurs in women infected with human T lymphotropic virus type I. Synovial thickening, destruction of articular cartilage, and leukemic-appearing atypical lymphocytes in synovial fluid are characteristic, but progression to T cell leukemia is unusual.

PARASITIC ARTHRITIS

Arthritis due to parasitic infection is rare. The guinea worm *Dracunculus medinensis* may cause destructive joint lesions in the lower extremities as migrating gravid female worms invade joints or cause ulcers in adjacent soft tissues that become secondarily infected. Hydatid cysts infect bones in 1 to 2% of cases of infection with *Echinococcus granulosus*. The expanding destructive cystic lesions may spread to and destroy adjacent joints, particularly the hip and pelvis. In rare cases, chronic synovitis has been associated with the presence of schistosomal eggs in synovial biopsies. Monarticular arthritis in children with lymphatic *filariasis* appears to respond to therapy with diethylcarbamazine even in the absence of microfilariae in synovial fluid. Reactive arthritis has been attributed to *hookworm*, *Strongyloides*, *Cryptosporidium*, and *Giardia* infection in case reports, but confirmation is required.

POSTINFECTIOUS OR REACTIVE ARTHRITIS

Reiter's syndrome, a reactive polyarthritis, develops several weeks after ~1% of cases of nongonococcal urethritis and 2% of enteric infections, particularly those due to *Yersinia enterocolitica*, *Shigella flexneri*, *Campylobacter jejuni*, and *Salmonella* species. Only a minority of these patients have the other findings of classic Reiter's syndrome, including urethritis, conjunctivitis, uveitis, oral ulcers, and rash. Studies have identified microbial DNA or antigen in synovial fluid or blood, but the pathogenesis of this condition is poorly understood.

Reiter's syndrome is most common among young men (except after *Yersinia* infection) and has been linked to the HLA-B27 locus as a potential genetic predisposing factor. Patients report painful, asymmetric oligoarthritis affecting mainly the knees, ankles, and feet. Low-back pain is common, and radiographic evidence of sacroiliitis is found in patients with long-standing disease. Most patients recover within 6 months, but prolonged recurrent disease is more common in cases following chlamydial urethritis. Anti-inflammatory agents help to relieve symptoms, but the role of prolonged antibiotic therapy in eliminating microbial antigen from the synovium is controversial.

Migratory polyarthritis and fever constitute the usual presentation of acute rheumatic fever in adults. This presentation is distinct from that of poststreptococcal reactive arthritis, which also follows infections with group A b-hemolytic *Streptococcus* but is not migratory, lasts beyond the typical 3-week maximum of acute rheumatic fever, and responds poorly to aspirin.

INFECTIONS IN PROSTHETIC JOINTS

Infection complicates 1 to 4% of total joint replacements. The majority of infections are acquired intraoperatively or immediately postoperatively as a result of wound breakdown or infection; less commonly, these joint infections develop later after joint replacement and are the result of hematogenous spread or direct inoculation. The presentation may be acute, with fever, pain, and local signs of inflammation, especially in infections due to *S. aureus*, pyogenic streptococci, and enteric bacilli. Alternatively, infection may persist for months or years without causing constitutional symptoms when less virulent organisms, such as coagulase-negative staphylococci or diphtheroids, are involved. Such indolent infections are usually acquired during joint implantation and are discovered during evaluation of chronic unexplained pain or after a radiograph shows loosening of the prosthesis; the erythrocyte sedimentation rate and C-reactive protein are usually elevated in such cases.

The diagnosis is best made by needle aspiration of the joint; accidental introduction of organisms during aspiration must be meticulously avoided. Synovial fluid pleocytosis with a predominance of polymorphonuclear leukocytes is highly suggestive of infection, since other inflammatory processes uncommonly affect prosthetic joints. Culture and Gram's stain usually yield the responsible pathogen. Use of special media for unusual pathogens such as fungi, atypical mycobacteria, and *Mycoplasma* may be necessary if routine and anaerobic cultures are negative.

TREATMENT

Treatment includes surgery and high doses of parenteral antibiotics, which are given for 4 to 6 weeks because bone is usually involved. In most cases, the prosthesis must be replaced to cure the infection. Implantation of a new prosthesis is best delayed for several weeks or months because relapses of infection occur most commonly within this time frame. In some cases, reimplantation is not possible, and the patient must manage without a joint, with a fused joint, or even with amputation. Cure of infection without removal of the prosthesis is occasionally possible in cases that are due to streptococci or pneumococci and that lack radiologic evidence of loosening of the prosthesis. In these cases, antibiotic therapy must be initiated within several days of the onset of infection, and the joint should be drained vigorously either by open arthrotomy or arthroscopically. A high cure rate with retention of the prosthesis has been reported when the combination of oral rifampin and ciprofloxacin is given for 3 to 6 months to persons with staphylococcal prosthetic joint infection of short duration. This approach, which is based on the ability of rifampin to kill organisms adherent to foreign material and in the stationary growth phase, requires confirmation in prospective trials.

Prevention To avoid the disastrous consequences of infection, candidates for joint replacement should be selected with care. Rates of infection are particularly high among patients with rheumatoid arthritis, persons who have undergone previous surgery on the joint, and persons with medical conditions requiring immunosuppressive therapy. Perioperative antibiotic prophylaxis, usually with cefazolin, and measures to decrease intraoperative contamination, such as laminar flow, have lowered the rates of perioperative infection to <1% in many centers. After implantation, measures should be taken to prevent or rapidly treat extraarticular infections that might give rise to

hematogenous spread to the prosthesis. The effectiveness of prophylactic antibiotics for the prevention of hematogenous infection following dental procedures has not been demonstrated; in fact, viridans streptococci and other components of the oral flora are extremely unusual causes of prosthetic joint infection. Accordingly, the American Dental Association and the American Academy of Orthopaedic Surgeons do not recommend antibiotic prophylaxis for most dental patients with total joint replacements. They do, however, recommend prophylaxis for patients who may be at high risk of hematogenous infection, including those with inflammatory arthropathies, immunosuppression, type 1 diabetes mellitus, joint replacement within 2 years, previous prosthetic joint infection, malnourishment, or hemophilia. The recommended regimen is amoxicillin (2 g orally) 1 h before dental procedures associated with a high incidence of bacteremia. Clindamycin (600 mg orally) is suggested for patients allergic to penicillin.

324. PSORIATIC ARTHRITIS AND ARTHRITIS ASSOCIATED WITH GASTROINTESTINAL DISEASE - *Peter H. Schur*

PSORIATIC ARTHRITIS

Psoriatic arthritis (PsA) is a chronic inflammatory arthritis that affects 5 to 42% of people with psoriasis.

ETIOLOGY AND PATHOGENESIS

To date, the cause and pathogenesis ofPsA are unknown. Indirect evidence has suggested that interactions of infections, trauma, increased humoral and cellular immunity (e.g., to streptococci), cytokines (including TH1 and TH2), adhesion molecules, and abnormal fibroblast, dendritic cell, keratinocyte, and polymorphonuclear leukocyte (PMN) function are involved. Polyarthritis has developed in patients with psoriasis and hepatitis treated with interferon a. Most studies have observed an increased frequency of HLA-B17, CW6, and/or B27 in patients with psoriatic spondylitis, while B27, B38, B39, and DR7 have been noted in association with peripheral arthritis in different studies. Fulminant disease should make one suspect HIV disease (Chap. 309).

CLINICAL MANIFESTATIONS

Three major types ofPsA are generally recognized: asymmetric inflammatory arthritis, symmetric arthritis, and psoriatic spondylitis. A mean of 47% of patients (range, 16 to 70%) have an asymmetric inflammatory arthritis. Disease appears equally in men and women. Psoriasis tends to precede the arthritis by years. Many patients complain of morning stiffness. The proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints are commonly involved [with characteristic sausage-shaped digits (dactylitis)], while knees, hips, ankles, temporomandibular joints, and wrists are less frequently involved. Most patients have onychodystrophy (onycholysis, ridging and pitting of nails), the course of which does not parallel that of the synovitis. The prognosis is good, with only one-fourth of the patients developing progressive destructive disease; one-third develop inflammatory ocular complications (conjunctivitis, iritis, episcleritis).

A mean of 25% of patients (range, 15 to 39%) develop symmetric arthritis resembling rheumatoid arthritis (Chap. 312). This disease occurs twice as frequently in women. Psoriasis and inflammatory arthritis usually develop simultaneously; most patients experience morning stiffness. TheDIP,PIP, metacarpophalangeal (MCP), metatarsophalangeal (MTP), sternoclavicular, and, in particular, large peripheral joints are involved. Practically all patients have onychodystrophy, which helps distinguish them from patients with rheumatoid arthritis. Over half of the patients in this group go on to develop destructive arthritis, including arthritis mutilans. Eye complications are uncommon. Subcutaneous nodules are not present, but one-fourth of patients have rheumatoid factors. Unilateral upper limb edema has been described.

A mean of 23% of the patients (range 5 to 40%) have psoriatic "spondylitis," with or without peripheral joint involvement. Psoriasis tends to precede the arthritis by a few years, and low back pain with morning stiffness is common. Psoriatic spondylitis is more common in men. About half the patients in this group have spondylitis and the other half

have sacroiliitis. The back disease is usually slowly progressive, with little clinical deterioration as compared with ankylosing spondylitis; the peripheral disease also tends not to be destructive except for the occasional patient with arthritis mutilans. Enthesopathy, i.e., inflammation of tendons and ligamentous attachments to bone, is characteristic, for example, of the Achilles tendon or of the plantar fascia causing heel pain. Many patients have onychodystrophy, but few have inflammatory ocular complications. Gut inflammation occurs in 30% (no gut inflammation was noted in patients with only peripheral arthritis).

Some authors have described additional subsets of psoriatic arthritis: predominantDIPjoint involvement, arthritis mutilans, peripheral enthesitis, juvenilePsA, and SAPHO (synovitis, acne, pustulosis, hyperostosis, osteomyelitis).

The pathology ofPsA is similar to that seen in rheumatoid arthritis: synoviocytic hyperplasia, earlyPMNinfiltration and later mononuclear cell infiltration, cartilage erosion, and pannus formation. However, in PsA, the synovium is more vascular and there are fewer macrophages and less expression of endothelial cell leukocyte adhesion molecule-1 (ELAM-1). Fibrosis of the joint capsule and marrow is prominent in many patients.

LABORATORY FINDINGS

There are few laboratory abnormalities. Elevated erythrocyte sedimentation rates, C-reactive proteins, and complement levels reflect inflammation. Rheumatoid factors are uncommon and are more likely to be observed in those with symmetric arthritis. Immunoglobulin levels, especially IgA levels, may be elevated (IgA antibodies to cytokeratins and antienterobacteria antibodies are elevated). Uric acid levels may be elevated; sodium urate crystals in joint fluids suggest gout.

Radiologic investigation reveals findings similar to those of rheumatoid arthritis: soft tissue swelling, loss of the cartilage space, erosions, bony ankylosis of fingers, subluxations, and subchondral cysts; of note, there is less demineralization. However, more unique and suggestive of psoriatic arthritis are erosions atDIPjoints, expansion of the base of the terminal phalanx, tapering of the proximal phalanx and cuplike erosions and bony proliferation of the distal terminal phalanx ("pencil-in-cup" appearance), proliferation of bone near osseous erosions, terminal phalangeal osteolysis, bone proliferation and periostitis (especially of phalanges), and telescoping of one bone into its neighbor, leading to the "opera-glass" deformity (Fig. 324-1). The axial skeleton shows asymmetric or unilateral sacroiliitis, often asymptomatic paravertebral ossification, including cervical involvement, and large asymmetric nonmarginal syndesmophytes. Echocardiographic abnormalities resemble those of ankylosing spondilitis.

DIAGNOSIS

The diagnosis ofPsAshould be considered in individuals with arthritis and psoriasis. Psoriasis should be distinguished from seborrheic dermatitis and eczema. Psoriatic lesions may be quite small peripherally and are often hidden in the scalp, umbilicus, and gluteal folds. Fungal infection of nails can be distinguished from psoriasis, for the latter

will demonstrate pitting and onycholysis. Furthermore, onychodystrophy is uncommon (20% of cases) in uncomplicated psoriasis. It is often difficult to distinguish Reiter's syndrome (Chap. 315) from PsA, since both manifest dactylitis. Reiter's syndrome usually presents in younger individuals, especially males; is less frequently progressive or destructive; and is more likely to be associated with characteristic skin lesions (keratoderma blenorrhagica -- which may, however, resemble pustular psoriasis), urethritis, and conjunctivitis. Gout can be distinguished by the presence of intraarticular sodium urate crystals (Chap. 322). Psoriasis in association with Heberden's nodes or Bouchard's nodes of theDIP andPIPjoints, respectively, rather suggests osteoarthritis (Chap. 321). PsA differs from rheumatoid arthritis by the relative lack of rheumatoid factors; the tendency to asymmetry, dactylitis, iritis, enthesopathy, and onychodystrophy; the high frequency of HLA-B27, especially in patients with axial skeletal involvement; and characteristic radiologic features.

TREATMENT

The treatment ofPsAbegins with patient education and physical and occupational therapy to maintain muscle strength and joint and muscle function. Orthotics and occasional intraarticular glucocorticoids for isolated acutely and severely inflamed joints may be added as needed (Fig. 324-2). The mainstay, however, is the use of nonsteroidal anti-inflammatory drugs (NSAIDs), which reduce inflammation and alleviate pain for most patients. For patients with more severe involvement, a disease-modifying antirheumatic drug should be used. While hydroxychloroquine is often successful in producing either amelioration or remission, it carries a significant risk of exacerbation of psoriasis and exfoliation. Sulfasalizine (2 to 4 g/d) has well-demonstrated efficacy for PsA. For more severe cases, especially with extensive skin involvement, 5 to 25 mg methotrexate per week is recommended. Most patients respond well with respect to both skin lesions and arthritis. Patients who are resistant to oral therapy may respond to parenteral therapy. Folic acid (1 mg/d) is recommended to prevent hematologic complications. Renal and liver function tests and a complete blood count should be performed every 6 to 8 weeks, and any abnormalities should suggest modification of the dosage. Liver biopsies are recommended after a total of 1.5 g methotrexate have been given and then every 2 years to identify the rare patient with fibrosis and cirrhosis, which necessitate withdrawal of the drug. Patients are advised to avoid nephrotoxic and hepatotoxic (e.g., ethanol) drugs. Patients with HIV infection may have worsening of their disease when treated with methotrexate. Intramuscular gold, cyclosporine (2 to 5 mg/kg per day), etretinate (0.5 mg/kg per day), and azathioprine have also proved successful. The arthritis may also respond to heliotherapy.

ARTHRITIS ASSOCIATED WITH GASTROINTESTINAL DISEASE

INFLAMMATORY BOWEL DISEASE

Peripheral arthritis occurs in 9 to 30% of patients with inflammatory bowel disease (IBD) (e.g., ulcerative colitis or Crohn's disease; Chap. 287), and arthralgia is more common. Arthritis is somewhat more likely to occur in patients with large-bowel disease and in those patients with complications such as abscesses, pseudomembranous polyposis, perianal disease, massive hemorrhage, erythema nodosum, stomatitis, uveitis, and pyoderma gangrenosum. Males and females are affected equally. The arthritis tends to

be acute, is associated with a flare-up of the bowel disease, occurs early in the course of the bowel disease, is self-limiting (90% of cases resolve within 6 months), and does not result in destruction. Most patients have a symmetric, migratory polyarthritis affecting primarily large joints of the lower extremity. Rheumatoid factors are not present. There is some association with HLA-BW62. Synovial fluids have 5000 to 12,000 white blood cells per microliter, mostlyPMNs. Radiographs demonstrate soft tissue swelling and effusions without erosions or destruction. Pathologic examination of synovial biopsy specimens reveals only nonspecific inflammation. The peripheral arthritis responds to successful treatment of the bowel disease, such as colectomy (for ulcerative colitis), or administration of glucocorticoids, anti-tumor necrosis factora therapy, or sulfasalazine.NSAIDsrelieve pain and inflammation but should be used with caution because of possible gastrointestinal side effects.

Spondylitis occurs in 1.1 to 43% of patients withIBD(while gut inflammation develops in 68% of patients with spondyloarthropathies). Spondylitis often precedes IBD; their clinical courses are often strongly related. Males are affected more frequently. Patients typically complain of stiffness in the back and/or buttocks in the morning or after rest. The stiffness and associated pain are often relieved by exercise. Gastrointestinal infection/inflammation is thought to play a role in exacerbation of spondylitis. Physical examination reveals limitation of spinal flexion and reduced chest expansion. Some patients may have peripheral arthritis, especially of the hips and/or shoulders. Uveitis is a frequent complication. Radiographs of the back show the typical findings of ankylosing spondylitis and bilateral sacroiliitis. HLA-B27 is found in 53 to 75% of these patients. Treatment includes physical therapy,NSAIDs, glucocorticoids, and sulfasalazine. NSAIDs should be used with caution lest they exacerbate the IBD. The axial disease progresses slowly in a manner akin to that of ankylosing spondylitis.

Asymptomatic sacroiliitis detected by radiography occurs in 4 to 32% of patients withIBD. By contrast, 52% of patients with IBD have abnormalities on technetium pyrophosphate bone scans of the sacroiliac joint. There is no increased frequency of HLA-B27 in these patients. This "disease" does not necessarily progress to spondylitis.

Other complications of chronicIBDinclude (1) finger clubbing (observed in 4 to 13% of patients with Crohn's disease, especially those with small-bowel involvement), which may regress after surgery; (2) development of amyloid, especially in association with Crohn's disease; and (3) osteoporosis resulting from inactivity, malabsorption, and/or treatment with glucocorticoids. Osteomalacia can result from malabsorption. In this setting, with acutely increased back pain, one should suspect compression fracture.

INTESTINAL BYPASS ARTHRITIS

Intestinal bypass surgery was developed for the treatment of obesity in 1952; 11 years later arthritis was recognized as a postoperative complication. Polyarthralgia, tenosynovitis, and sometimes arthritis occur weeks, even years, after surgery in 8 to 36% of patients. There is often an associated urticarial, vesicular, pustular, macular, or nodular eruption. X-rays generally show no joint damage. Tests for rheumatoid factors, antinuclear antibodies, and HLA-B27 are usually negative, while immune complexes (and cryoglobulins) are often present. They contain bacterial antigens, the corresponding antibodies, IgA secretory component, and complement components.

These observations suggest that the syndrome has the following pathogenesis: Bacteria proliferate in intestinal blind loops; bacterial antigens are absorbed; and antibodies to these antigens develop and combine with them to form immune complexes, which deposit in synovial tissue to cause arthritis.NSAIDsand glucocorticoids can relieve the joint symptoms, but more lasting results can be achieved by tetracycline therapy to decrease the bacterial load; even better is reanastomosis of the bowel or resection of the blind loop.

WHIPPLE'S DISEASE (INTESTINAL LIPODYSTROPHY)

Whipple's disease is rare and occurs mostly in middle-aged Caucasian males, who develop arthritis, prolonged diarrhea, malabsorption, and weight loss as a result of infection with the actinomyocete, *Tropheryma whippelii*. The organism has been found in waste water. Up to 90% of patients with the disease develop arthritis, usually prior to other symptoms. Knees and ankles and, to a lesser extent, fingers, hips, shoulders, elbows, and wrists are involved. The arthritis is acute in onset, migratory, usually lasts just a few days, and is rarely chronic or a cause of permanent joint damage. Associated symptoms may include fever (54%), edema, serositis (pleurisy, pericarditis, endocarditis), pneumonia, hypotension, lymphadenopathy (54%), hyperpigmentation (54%), subcutaneous nodules, clubbing, and uveitis. Central nervous system involvement may develop (80%), with cognitive changes, headache, diplopia, and papilledema, and may be appreciated by abnormalities in magnetic resonance images of the brain. Oculomasticatory myorhythmia and oculo-facial-skeletal myorhythmia are felt to be pathognomonic and are found in 20% of patients; they are always accompanied by supranuclear vertical gaze palsy. Laboratory abnormalities include anemia (75%), low serum levels of carotene (95%), and albumin (93%). The presence of HLA-B27 (8 to 30%) occurs in those patients with axial arthritis. Synovial fluids have been reported to contain 450 to 36,000 white blood cells per microliter (30 to 95% neutrophils) or a mild monocytosis. Joint x-rays rarely show erosions but may show a sacroiliitis in the occasional patients who have axial skeletal symptoms; abdominal computed tomographic scans may reveal lymphadenopathy. The lamina propria and/or foamy macrophages in small intestine contain PAS-staining bacterial remnants, presumably of *T. whippelii*. These inclusion-containing foamy macrophages have also been detected in the synovium, lymph nodes, and other tissues. Diagnosis is often established by polymerase chain reaction of the 165 ribosomal gene sequences of these bacteria in biopsied tissue, usually the duodenum. The syndrome responds best to therapy with penicillin (or ceftriaxone) and streptomycin for 2 weeks followed by trimethoprim-sulfamethoxazole for 1 to 2 years. However, central nervous system relapse may develop, which has been treated with cefixime.

REACTIVE ARTHRITIS

A Reiter's-like syndrome of arthritis can develop 2 to 3 weeks following diarrhea caused by *Shigella*, *Salmonella*, *Yersinia*, *Chlamydia trachomatis*, or *Campylobacter* organisms.**This condition is described in Chap. 315.*

325. RELAPSING POLYCHONDRITIS AND OTHER ARTHRITIDES- *Bruce C. Gilliland*

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is an uncommon inflammatory disorder of unknown cause characterized by an episodic and generally progressive course affecting predominantly the cartilage of the ears, nose, and laryngotracheobronchial tree. Other manifestations include scleritis, neurosensory hearing loss, polyarthritis, vasculitis, cardiac abnormalities, skin lesions, and glomerulonephritis. The peak age of onset is between the ages of 40 to 50 years but relapsing polychondritis may affect children and the elderly. It is found in all races, and both sexes are equally affected. No familial tendency is apparent. A significantly higher frequency of HLA-DR4 has been found in patients with relapsing polychondritis than in normal individuals. A predominant subtype allele(s) of HLA-DR4 was not found. Approximately 30% of patients with relapsing polychondritis will have another rheumatologic disorder, the most frequent being systemic vasculitis, followed by rheumatoid arthritis, systemic lupus erythematosus (SLE), or Sjogren's syndrome. Nonrheumatic disorders associated with relapsing polychondritis include inflammatory bowel disease, primary biliary cirrhosis, and myelodysplastic syndrome.

Diagnostic criteria were suggested several years ago by McAdam et al. and modified by Damiani and Levine a few years later. These criteria continue to be generally used in clinical practice. McAdam et al. proposed the following: (1) recurrent chondritis of both auricles; (2) nonerosive inflammatory arthritis; (3) chondritis of nasal cartilage; (4) inflammation of ocular structures including conjunctivitis, keratitis, scleritis/episcleritis, and/or uveitis; (5) chondritis of the laryngeal and/or tracheal cartilages; and (6) cochlear and/or vestibular damage manifested by neurosensory hearing loss, tinnitus, and/or vertigo. The diagnosis is certain when three or more of these features were present with biopsy confirmation. Damiana and Levine later suggested that the diagnosis could be made when one or more of the above features and a positive biopsy were present, when two or more separate sites of cartilage inflammation were present that responded to glucocorticoids or dapsone, or when three or more of the above features were present. A biopsy is not necessary in most patients with clinically evident disease.

PATHOLOGY AND PATHOPHYSIOLOGY

The earliest abnormality of cartilage noted histologically is a focal or diffuse loss of basophilic staining indicating depletion of proteoglycan from the cartilage matrix. Inflammatory infiltrates are found adjacent to involved cartilage and consist predominantly of mononuclear cells and occasional plasma cells. In acute disease, polymorphonuclear white cells may also be present. Destruction of cartilage begins at the outer edges and advances centrally. There is lacunar breakdown and loss of chondrocytes. Degenerating cartilage is replaced by granulation tissue and later by fibrosis and focal areas of calcification. Small loci of cartilage regeneration may be present. Immunofluorescence studies have shown immunoglobulins and complement at sites of involvement. Fine granular material observed in the degenerating cartilage matrix by electron microscopy has been interpreted to be enzymes or immunoglobulins.

Immunologic mechanisms play a role in the pathogenesis of relapsing polychondritis.

Immunoglobulin and complement deposits are found at sites of inflammation. In addition, antibodies to type II collagen and to matrilin-1 and immune complexes are detected in the sera of some patients. The possibility that an immune response to type II collagen may be important in the pathogenesis is supported experimentally by the occurrence of auricular chondritis in rats immunized with type II collagen. Antibodies to type II collagen are found in the sera of these animals, and immune deposits are detected at sites of ear inflammation. Cell-mediated immunity may also be operative in causing tissue injury, since lymphocyte transformation can be demonstrated when lymphocytes of patients are exposed to cartilage extracts. Humoral and cellular immune responses to type IX and type XI collagen have been demonstrated in some patients. In a recent study, rats immunized with cartilage matrix protein (matrilin-1) were found to develop severe inspiratory stridor and swelling of the nasal septum. Cartilage matrix protein is a noncollagenous protein present in the extracellular matrix in cartilage. It is present in high concentrations in the trachea and is also present in the nasal septum but not in articular cartilage. The immunized rats had severe inflammation in the larynx close to the epiglottis, which was characterized by increased numbers of CD 4+ and CD 8+ T cells. All had IgG antibodies to cartilage matrix protein. The inflammation was believed to have been largely mediated by T cells. The results of the study suggest that immune responses to various cartilage proteins play a role in the pathogenesis of relapsing polychondritis.

Dissolution of cartilage matrix can be induced by the intravenous injection of crude papain, a proteolytic enzyme, into young rabbits, which results in collapse of their normally rigid ears within 4 h. Reconstitution of the matrix occurs in about 7 days. In relapsing polychondritis, loss of cartilage matrix also most likely results from action of proteolytic enzymes released from chondrocytes, polymorphonuclear white cells, and monocytes that have been activated by inflammatory mediators.

CLINICAL MANIFESTATIONS

The onset of relapsing polychondritis is frequently abrupt with the appearance of one or two sites of cartilagenous inflammation. Fever, fatigue, and weight loss occur and may precede the clinical signs of relapsing polychondritis by several weeks. Relapsing polychondritis may go unrecognized for several months or even years in patients who only initially manifest intermittent joint pain and/or swelling, or who have unexplained eye inflammation, hearing loss, valvular heart disease, or pulmonary symptoms. The pattern of cartilagenous involvement and the frequency of episodes vary widely among patients.

Auricular chondritis is the most frequent presenting manifestation of relapsing polychondritis in 40% of patients and eventually affects about 85% of patients (Table 325-1). One or both ears are involved, either sequentially or simultaneously. Patients experience the sudden onset of pain, tenderness, and swelling of the cartilaginous portion of the ear. Earlobes are spared because they do not contain cartilage. The overlying skin has a beefy red or violaceous color. Prolonged or recurrent episodes result in a flabby or droopy ear as a sequela of cartilage destruction. Swelling may close off the eustachian tube (causing otitis media) or the external auditory meatus, either of which can impair hearing. Inflammation of the internal auditory artery or its cochlear branch produces hearing loss, vertigo, ataxia, nausea, and vomiting. The cartilage of

the nose becomes inflamed during the first or subsequent attacks. Approximately 50% of patients will eventually have nose involvement. Patients may experience nasal stuffiness, rhinorrhea, and epistaxis. The bridge of the nose becomes red, swollen, and tender and may collapse, producing a saddle deformity. In some patients, the saddle deformity develops insidiously without overt inflammation. Saddle nose is observed more frequently in younger patients, especially in women.

Arthritis is the presenting manifestation in relapsing polychondritis in approximately one-third of patients and may be present for several months before other features appear. Eventually, more than half the patients will have arthritis. The arthritis is usually asymmetric and oligo- or polyarticular, and involves both large and small peripheral joints. An episode of arthritis lasts from a few days to several weeks and resolves spontaneously without residual joint deformity. Attacks of arthritis may not be temporally related to other manifestations of relapsing polychondritis. The joints are warm, tender, and swollen. Joint fluid has been reported to be noninflammatory. In addition to peripheral joints, inflammation may involve the costochondral, sternomanubrial, and sternoclavicular cartilages. Destruction of these cartilages may result in a pectus excavatum deformity or even a flail anterior chest wall. Relapsing polychondritis may occur in patients with preexisting rheumatoid arthritis, Reiter's syndrome, psoriatic arthritis, or ankylosing spondylitis.

Eye manifestations occur in more than half of patients and include conjunctivitis, episcleritis, scleritis, iritis, and keratitis. Ulceration and perforation of the cornea may occur and cause blindness. Other manifestations include eyelid and periorbital edema, proptosis, cataracts, optic neuritis, extraocular muscle palsies, retinal vasculitis, and renal vein occlusion.

Laryngotracheobronchial involvement occurs in ~50% of patients. Symptoms include hoarseness, a nonproductive cough, and tenderness over the larynx and proximal trachea. Mucosal edema, strictures, and/or collapse of laryngeal or tracheal cartilage may cause stridor and life-threatening airway obstruction necessitating tracheostomy. Collapse of cartilage in bronchi leads to pneumonia and, when extensive, to respiratory insufficiency.

Aortic regurgitation occurs in about 5% of patients and is due to progressive dilation of the aortic ring or to destruction of the valve cusps. Mitral and other heart valves are less often affected. Other cardiac manifestations include pericarditis, myocarditis, and conduction abnormalities. Aneurysms of the proximal, thoracic, or abdominal aorta may occur and occasionally rupture.

Systemic vasculitis may occur in association with relapsing polychondritis. Vasculitides include leukocytoclastic vasculitis, polyarteritis, temporal arteritis, and Takayasu's arteritis (Chap. 317). Neurologic abnormalities usually occur as a result of underlying vasculitis, manifesting as seizures, strokes, ataxia, and peripheral and cranial nerve neuropathies. Cranial nerves VI and VII are most often involved. Approximately 25% of patients have skin lesions, none of which is characteristic for relapsing polychondritis. These include purpura, erythema nodosum, erythema multiforme, angioedema/urticaria, livedo reticularis, and panniculitis. Segmental necrotizing glomerulonephritis with crescent formation has been noted in some patients in the absence of systemic

vasculitis.

The course of disease is highly variable, with episodes lasting from a few days to several weeks and then subsiding spontaneously. Attacks may recur at intervals varying from weeks to months. In other patients, the disease has a chronic, smoldering course. In a few patients, the disease may be limited to one or two episodes of cartilage inflammation. In one study, the 5-year estimated survival rate was 74% and the 10-year survival rate 55%. In contrast to earlier series, only about half the deaths could be attributed to relapsing polychondritis or complications of treatment. Pulmonary complications accounted for only 10% of all fatalities. In general, patients with more widespread disease have a worse prognosis.

LABORATORY FINDINGS

Mild leukocytosis and normocytic, normochromic anemia are often present. The erythrocyte sedimentation rate is usually elevated. Rheumatoid factor and antinuclear antibody tests are occasionally positive in low titers. Antibodies to type II collagen are present in most patients, but they are not specific. Circulating immune complexes may be detected, especially in patients with early active disease. Elevated levels ofg globulin may be present. Antineutrophil cytoplasmic antibodies (ANCA), either cytoplasmic (C-ANCA) or perinuclear (P-ANCA), are found in some patients with active disease. The upper and lower airways can be evaluated by imaging techniques such as linear tomography, laryngotracheography, and computed tomography, and by bronchoscopy. Bronchography is performed to demonstrate bronchial narrowing. Intrathoracic airway obstruction can also be evaluated by inspiratory-expiratory flow studies. The chest film may show narrowing of the trachea and/or the main bronchi, widening of the ascending or descending aorta due to an aneurysm, and cardiomegaly when aortic insufficiency is present. Radiographs may show calcification at previous sites of cartilage damage involving ear, nose, larynx, or trachea.

DIAGNOSIS

Diagnosis is based on recognition of the typical clinical features. Biopsies of the involved cartilage from the ear, nose, or respiratory tract will confirm the diagnosis but are only necessary when clinical features are not typical. Patients with Wegener's granulomatosis may have a saddle nose and pulmonary involvement but can be distinguished by the absence of auricular involvement and the presence of granulomatous lesions in the tracheobronchial tree. Patients with Cogan's syndrome have interstitial keratitis and vestibular and auditory abnormalities, but this syndrome does not involve the respiratory tract or ears. Reiter's syndrome may initially resemble relapsing polychondritis because of oligoarticular arthritis and eye involvement, but it is distinguished in time by the appearance of urethritis and typical mucocutaneous lesions and the absence of nose or ear cartilage involvement. Rheumatoid arthritis may initially suggest relapsing polychondritis because of arthritis and eye inflammation. The arthritis in rheumatoid arthritis, however, is erosive and symmetric. In addition, rheumatoid factor titers are usually high compared with those in relapsing polychondritis. Bacterial infection of the pinna may be mistaken for relapsing polychondritis but differs by usually involving only one ear, including the earlobe. Auricular cartilage may also be damaged by trauma or frostbite.

Relapsing polychondritis may develop in patients with a variety of autoimmune disorders, includingSLE, rheumatoid arthritis, Sjogren's syndrome, and vasculitis. In most cases, these disorders antedate the appearance of polychondritis, usually by months or years. It is likely that these patients have an immunologic abnormality that predisposes them to development of this group of autoimmune disorders.

TREATMENT

In patients with active chondritis or associated vasculitis, prednisone, 40 to 60 mg/d, is often effective in suppressing disease activity; it is tapered gradually once disease is controlled. In some patients, prednisone can be stopped, while in others low doses in the range of 10 to 15 mg/d are required for continued suppression of disease. Immunosuppressive drugs such as methotrexate, cyclophosphamide, or azathioprine should be reserved for patients who fail to respond to prednisone or who require high doses for control of disease activity. Methotrexate has been found by some investigators to be very effective in treating relapsing polychondritis. Dapsone and cyclosporine have been reported to be beneficial in a few patients. Patients with significant ocular inflammation often require intraocular steroids as well as high doses of prednisone. Heart valve replacement or repair of an aortic aneurysm may be necessary. In patients with early subglottic disease, intralesional injection of glutocorticoids may be beneficial. When obstruction is severe, tracheostomy is required. Stents may be necessary in patients with tracheobronchial collapse.

OTHER ARTHRITIDES

NEUROPATHIC JOINT DISEASE

Neuropathic joint disease (Charcot's joint) is a progressive destructive arthritis associated with loss of pain sensation, proprioception, or both. In addition, normal muscular reflexes that modulate joint movement are decreased. Without these protective mechanisms, joints are subjected to repeated trauma, resulting in progressive cartilage and bone damage. Neuropathic arthropathy was first described by Jean-Martin Charcot in 1868 in patients with tabes dorsalis. The term *Charcot joint* is commonly used interchangeably with *neuropathic joint*. Today, diabetes mellitus is the most frequent cause of neuropathic joint disease. A variety of other disorders are associated with neuropathic arthritis including leprosy, yaws, syringomyelia, meningomyelocoele, congenital indifference to pain, peroneal muscular atrophy (Charcot-Marie-Tooth disease), and amyloidosis. An arthritis resembling neuropathic joint disease is seen in patients who have received frequent intraarticular glucocorticoid injections into a weight-bearing joint and in patients with calcium pyrophosphate dihydrate crystal deposition disease. The distribution of joint involvement depends on the underlying neurologic disorder (Table 325-2). In tabes dorsalis, knees, hips, and ankles are most commonly affected; in syringomyelia, the glenohumeral joint, elbow, and wrist; and in diabetes mellitus, the tarsal and tarsometatarsal joints.

Pathology and Pathophysiology The pathologic changes in the neuropathic joint are similar to those found in the severe osteoarthritic joint. There is fragmentation and eventual loss of articular cartilage with eburnation of the underlying bone. Osteophytes

are found at the joint margins. With more advanced disease, erosions are present on the joint surface. Fractures, devitalized bone, and intraarticular loose bodies may be present. Microscopic fragments of cartilage and bone are seen in the synovial tissue.

At least two underlying mechanisms are believed to be involved in the pathogenesis of neuropathic arthritis. An abnormal autonomic nervous system is thought to be responsible for the increased blood flow to the joint and subsequent resorption of bone. Loss of bone, particularly in the diabetic foot, may be the initial manifestation. With the loss of deep pain, proprioception, and protective neuromuscular reflexes, the joint is subjected to repeated injuries including ligamental tears and bone fractures. The mechanism of injury that occurs following frequent intraarticular glucocorticoid injections is thought to be due to the analgesic effect of glucocorticoids leading to overuse of an already damaged joint, which results in accelerated cartilage damage. It is not understood why only a few patients with neuropathies develop neuropathic arthritis.

Clinical Manifestations Neuropathic joint disease usually begins in a single joint and then progresses to involve other joints, depending on the underlying neurologic disorder. The involved joint progressively becomes enlarged from bony overgrowth and synovial effusion. Loose bodies may be palpated in the joint cavity. Joint instability, subluxation, and crepitus occur as the disease progresses. Neuropathic joints may develop rapidly, and a totally disorganized joint with multiple bony fragments may evolve in a patient within weeks or months. The amount of pain experienced by the patient is less than would be anticipated based on the degree of joint involvement. Patients may experience sudden joint pain from intraarticular fractures of osteophytes or condyles.

Neuropathic arthritis is encountered most often in patients with diabetes mellitus, with the incidence estimated in the range of 0.5%. The usual age of onset is³50 years following several years of diabetes, but exceptions occur. The tarsal and tarsometatarsal joints are most often affected, followed by the metatarsophalangeal and talotibial joints. The knees and spine are occasionally involved. In about 20%, neuropathic arthritis may be present in both feet. Patients often attribute the onset of foot pain to antecedent trauma such as twisting their foot. Neuropathic changes may develop rapidly following a foot fracture or dislocation. Swelling of the foot and ankle are often present. Downward collapse of the tarsal bones leads to convexity of the sole, referred to as a "rocker foot." Large osteophytes may protrude from the top of the foot. Calluses frequently form over the metatarsal heads and may lead to infected ulcers and osteomyelitis. Radiographs may show resorption and tapering of the distal metatarsal bones. The term *Lisfranc fracture-dislocation* is sometimes used to describe the destructive changes at the tarsometatarsal joints.

Diagnosis The diagnosis of neuropathic arthritis is based on the clinical features and characteristic radiographic findings in a patient with an underlying sensory neuropathy. The differential diagnosis of neuropathic arthritis includes osteomyelitis, osteonecrosis, advanced osteoarthritis, stress fractures, and calcium pyrophosphate dihydrate (CPDD) deposition disease. Radiographs in neuropathic arthritis initially show changes of osteoarthritis with joint space narrowing, subchondral bone sclerosis, osteophytes, and joint effusions followed later by marked destructive and hypertrophic changes. Soft tissue swelling, bone resorption, fractures, large osteophytes, extraarticular bone fragments, and subluxation are present with advanced arthropathy. The radiographic

findings of neuropathic arthritis may be difficult to differentiate from those of osteomyelitis, especially in the diabetic foot. The joint margins in a neuropathic joint tend to be distinct, while in osteomyelitis, they are blurred. Imaging studies and cultures of fluid and tissue from the joint are often required to exclude osteomyelitis. Magnetic resonance imaging is helpful in differentiating these disorders. Another useful study is a bone scan using indium 111-labeled white blood cells or indium 111-labeled immunoglobulin G, which will show an increased uptake in osteomyelitis but not in a neuropathic joint. A technetium bone scan will not distinguish osteomyelitis from neuropathic arthritis as increased uptake is observed in both. The joint fluid in neuropathic arthritis is noninflammatory; may be xanthochromic or even bloody; and may contain fragments of synovium, cartilage, and bone. The finding of CPPD crystals suggests the diagnosis of a crystal associated neuropathic-like arthropathy. In the absence of CPPD crystals, the presence of increased number of leukocytes may indicate osteomyelitis.

TREATMENT

The primary focus of treatment is to provide stabilization of the joint. Treatment of the underlying disorder, even if successful, does not usually alter the joint disease. Braces and splints are helpful. Their use requires close surveillance, since patients may be unable to appreciate pressure from a poorly adjusted brace. In the diabetic patient, early recognition and treatment of a Charcot's foot by prohibiting weight bearing of the foot for at least 8 weeks may possibly prevent severe disease from developing. Fusion of a very unstable joint may improve function, but nonunion is frequent, especially when immobilization of the joint is inadequate.

HYPERTROPHIC OSTEOARTHROPATHY AND CLUBBING

Hypertrophic osteoarthropathy (HOA) is characterized by clubbing of digits and, in more advanced stages, by periosteal new bone formation and synovial effusions. HOA occurs in primary and familial forms and usually begins in childhood. The secondary form of HOA is associated with intrathoracic malignancies, suppurative lung disease, congenital heart disease, and a variety of other disorders and is more common in adults. Clubbing is almost always a feature of HOA but can occur as an isolated manifestation (Fig. 325-1). The presence of clubbing in isolation is generally considered to represent either an early stage or an element in the spectrum of HOA. The presence of only clubbing in a patient usually has the same clinical significance as HOA.

Pathology and Pathophysiology InHOA, the bone changes in the distal extremities begin as periostitis followed by new bone formation. At this stage, a radiolucent area may be observed between the new periosteal bone and subjacent cortex. As the process progresses, multiple layers of new bone are deposited, which become contiguous with the cortex and result in cortical thickening. The outer portion of bone is laminated in appearance, with an irregular surface. Initially, the process of periosteal new bone formation involves the proximal and distal diaphyses of the tibia, fibula, radius, and ulna and, less frequently, the femur, humerus, metacarpals, metatarsals, and phalanges. Occasionally, scapulae, clavicles, ribs, and pelvic bones are also affected. In long-standing disease, these changes extend to involve metaphyses and musculotendinous insertions. The adjacent interosseous membranes may become

ossified. The distribution of the bone manifestations is usually bilateral and symmetric. The soft tissue overlying the distal third of the arms and legs may be thickened. Mononuclear cell infiltration may be present in the adjacent soft tissue. Proliferation of connective tissue occurs in the nail bed and volar pad of digits, giving the distal phalanges a clubbed appearance. Small blood vessels in the clubbed digits are dilated and have thickened walls. In addition, the number of arteriovenous anastomoses is increased. The synovium of involved joints shows edema, varying degrees of synovial cell proliferation, thickening of the subsynovium, vascular congestion, vascular obliteration with thrombi, and small numbers of lymphocyte infiltrates.

Several theories have been suggested for the pathogenesis ofHOA. Most have either been disproved or have not explained the development in all clinical disorders associated with HOA. Previously proposed neurogenic and humoral theories are no longer considered likely explanations for HOA. The neurogenic theory was based on the observation that vagotomy resulted in symptomatic improvement in a small number of patients with lung tumors and HOA. It was postulated that vagal stimuli from the tumor site led via a neural reflex to efferent nerve impulses to the distal extremities, resulting in HOA. This theory, however, did not explain HOA in conditions where vagal stimulation did not occur, as in cyanotic congenital heart disease or arterial aneurysms. The humoral theory postulated that soluble substances that are normally inactivated or removed during passage through the lung reached the systemic circulation in an active form and stimulated the changes of HOA. Substances proposed included prostaglandins, ferritin, bradykinin, estrogen, and growth hormone. These substances seemed unlikely candidates, since their blood levels in HOA patients overlapped those in individuals without HOA. Furthermore, these substances did not explain the development of localized HOA associated with arterial aneurysms or infected arterial grafts.

Recent studies have suggested a role for platelets in the development ofHOA. It has been observed that megakaryocytes and large platelet particles, present in venous circulation, were fragmented in their passage through normal lung. In patients with cyanotic congenital heart disease and in other disorders associated with right-to-left shunts, these large platelet particles may bypass the lung and reach the distal extremities, where they can interact with endothelial cells. Platelet clumps have been demonstrated to form on an infected heart valve in bacterial endocarditis, in the wall of arterial aneurysms, and on infected arterial grafts. These platelet particles may also reach the distal extremities and interact with endothelial cells. Platelet-endothelial activation in the distal portion of extremities would then result in the release of platelet-derived growth factor (PDGF) and other factors leading to the proliferation of connective tissue and periosteum. Stimulation of fibroblasts by PDGF and transforming growth factor b(TGF-b) results in cell growth and collagen synthesis. Elevated plasma levels of von Willebrand factor antigen have been found in patients with both primary and secondary forms of HOA, indicating endothelial activation or damage. Abnormalities of collagen synthesis have been demonstrated in the involved skin of patients with primary HOA. Fibroblasts from affected skin were shown to have increased collagen synthesis, increaseda1(I) procollagen mRNA, and evidence for upregulation of collagen transcription. Other factors are undoubtedly involved in the pathogenesis of HOA, and further studies are needed to better understand this disorder.

Clinical Manifestations PrimaryHOA, also referred to as *pachydermoperiostitis* or *Touraine-Solente-Gole syndrome*, usually begins insidiously at puberty. In a smaller number of patients, the onset is in the first year of life. The disorder is inherited as an autosomal dominant trait with variable expression and is nine times more common in boys than in girls. Approximately one-third of patients have a family history of primary HOA.

PrimaryHOA is characterized by clubbing, periostitis, and unusual skin features. A small number of patients with this syndrome do not express clubbing. The skin changes and periostitis are prominent features of this syndrome. The skin becomes thickened and coarse. Deep nasolabial folds develop, and the forehead may become furrowed. Patients may have heavy-appearing eyelids and ptosis. The skin is often greasy, and there may be excessive sweating of the hands and feet. Patients may also experience acne vulgaris, seborrhea, and folliculitis. In a few patients, the skin over the scalp becomes very thick and corrugated, a feature that has been descriptively termed *cutis verticis gyrata*. The distal extremities, particularly the legs, become thickened owing to proliferation of new bone and soft tissue; when the process is extensive, the distal lower extremities resemble those of an elephant. The periostitis is usually not painful, as it may be in secondary HOA. Clubbing of the fingers may be extensive, producing large, bulbous deformities and clumsiness. Clubbing also affects the toes. Patients may experience articular and periarticular pain, especially in the ankles and knees, and joint motion may be mildly restricted owing to periarticular bone overgrowth. Noninflammatory effusions occur in the wrists, knees, and ankles. Synovial hypertrophy is not found. Associated abnormalities observed in patients with primary HOA include hypertrophic gastropathy, bone marrow failure, female escutcheon, gynecomastia, and cranial suture defects. In patients with primary HOA, the symptoms disappear when adulthood is reached.

HOAsecondary to an underlying disease occurs more frequently than primary HOA. It accompanies a variety of disorders and may precede clinical features of the associated disorder by months. Clubbing is more frequent than the full syndrome of HOA in patients with associated illnesses. Because clubbing evolves over months and is usually asymptomatic, it is often recognized first by the physician and not the patient. Patients may experience a burning sensation in their fingertips. Clubbing is characterized by widening of the fingertips, enlargement of the distal volar pad, convexity of the nail contour, and the loss of the normal 15° angle between the proximal nail and cuticle. The thickness of the digit at the base of the nail is greater than the thickness at the distal interphalangeal joint. An objective measurement of finger clubbing can be made by determining the diameter at the base of the nail and at the distal interphalangeal joint of all 10 digits. Clubbing is present when the sum of the individual digit ratios is >10. At the bedside, clubbing can be appreciated by having the patient place the dorsal surface of the fourth fingers together. Normally, an open area is visible between the opposing fingers; when clubbing is present, this open space is no longer visible. The base of the nail feels spongy when compressed, and the nail can be easily rocked on its bed. Marked periungual erythema is usually present. When clubbing is advanced, the finger may have a drumstick appearance, and the distal interphalangeal joint can be hyperextended. Periosteal involvement in the distal extremities may produce a burning or deep-seated aching pain. The pain can be quite incapacitating and is aggravated by dependency and relieved by elevation of the affected limbs. The overlying soft tissue

may be swollen, and the skin slightly erythematous. Pressure applied over the distal forearms and legs may be quite painful.

Patients may also experience joint pain, most often in the ankles, wrists, and knees. Joint effusions may be present; usually they are small and noninflammatory. The small joints of the hands are rarely affected. Severe joint or bone pain may be the presenting symptom of an underlying lung malignancy and may precede the appearance of clubbing. In addition, the progression ofHOAtends to be more rapid when associated with malignancies, most notably bronchogenic carcinoma. Unlike primary HOA, excessive sweating and oiliness of the skin and thickening of the facial skin are uncommon in secondary HOA.

HOAoccurs in 5 to 10% of patients with intrathoracic malignancies, the most common being bronchogenic carcinoma and pleural tumors (Table 325-3). Lung metastases infrequently cause HOA. HOA is also seen in patients with intrathoracic infections, including lung abscesses, empyema, bronchiectasis, chronic obstructive lung disease, and, uncommonly, pulmonary tuberculosis. HOA may also accompany chronic interstitial pneumonitis, sarcoidosis, and cystic fibrosis. In the latter, clubbing is more common than the full syndrome of HOA. Other causes of clubbing include congenital heart disease with right-to-left shunts, bacterial endocarditis, Crohn's disease, ulcerative colitis, sprue, and neoplasms of the esophagus, liver, and small and large bowel. In patients with congenital heart disease with right-to-left shunts, clubbing alone occurs more often than the full syndrome of HOA.

Unilateral clubbing has been found in association with aneurysms of major extremity arteries, infected arterial grafts, and with arteriovenous fistulas of brachial vessels. Clubbing of the toes but not fingers has been associated with an infected abdominal aortic aneurysm and patent ductus arteriosus. Clubbing of a single digit may follow trauma and has been reported in tophaceous gout and sarcoidosis. While clubbing occurs more commonly than the full syndrome in most diseases, periostitis in the absence of clubbing has been observed in the affected limb of patients with infected arterial grafts.

Hyperthyroidism (Graves' disease), treated or untreated, is occasionally associated with clubbing and periostitis of the bones of the hands and feet. This condition is referred to as *thyroid acropachy*. Periostitis is asymptomatic and occurs in the midshaft and diaphyseal portion of the metacarpal and phalangeal bones. The long bones of the extremities are seldom affected. Elevated levels of long-acting thyroid stimulator (LATS) are found in the serum of these patients.

Laboratory Findings The laboratory abnormalities reflect the underlying disorder. The synovial fluid of involved joints has <500 white cells per microliter, and the cells are predominantly mononuclear. Radiographs show a faint radiolucent line beneath the new periosteal bone along the shaft of long bones at their distal end. These changes are observed most frequently at the ankles, wrists, and knees. The ends of the distal phalanges may show osseous resorption. Radionuclide studies show pericortical linear uptake along the cortical margins of long bones that may be present before any radiographic changes.

TREATMENT

The treatment ofHOA is to identify the associated disorder and treat it appropriately. The symptoms and signs of HOA may disappear completely with removal or effective chemotherapy of a tumor or with antibiotic therapy and drainage of a chronic pulmonary infection. Vagotomy or percutaneous block of the vagus nerve leads to symptomatic relief in some patients. Aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), or analgesics may help control symptoms of HOA.

FIBROMYALGIA

Fibromyalgia is a commonly encountered disorder characterized by widespread musculoskeletal pain, stiffness, paresthesia, nonrestorative sleep, and easy fatigability along with multiple tender points which are widely and symmetrically distributed. Fibromyalgia affects predominantly women in a ratio of 8 or 9 to 1 compared to men. This disorder is found in most countries, in most ethnic groups, and in all types of climates. The prevalence of fibromyalgia in the general population of a community in the United States using the 1990 American College of Rheumatology (ACR) classification criteria was reported to be 3.4%in women and 0.5% in men. Contrary to some previous reports, fibromyalgia was not found to be present mainly in young women but, rather, to be most prevalent in women ³50 years. The prevalence increased with age, being 7.4% in women between the ages of 70 and 79. Although not common, fibromyalgia also occurs in children. The reported prevalence of fibromyalgia in some rheumatology clinics has been as high as 20%.

Pathogenesis Several causative mechanisms for fibromyalgia have been postulated. Disturbed sleep has been implicated as a factor in the pathogenesis. Nonrestorative sleep or awakening unrefreshed has been observed in most patients with fibromyalgia. Sleep electroencephalographic studies in patients with fibromyalgia have shown disruption of normal stage 4 sleep [non-rapid eye movement (NREM) sleep] by many repeated a-wave intrusions. The idea that stage 4 sleep deprivation has a role in causing this disorder was supported by the observation that symptoms of fibromyalgia developed in normal subjects whose stage 4 sleep was disrupted artificially by induceda-wave intrusions. This sleep disturbance, however, has been demonstrated in healthy individuals; in emotionally distressed individuals; and in patients with sleep apnea, fever, osteoarthritis, or rheumatoid arthritis. Low levels of serotonin metabolites have been reported in the cerebrospinal fluid of patients with fibromyalgia, suggesting that a deficiency of serotonin, a neurotransmitter that regulates pain and NREM sleep, might also be involved in the pathogenesis of fibromyalgia. Drugs that affect serotonin metabolism have not had a dramatic effect on fibromyalgia, however. Since patients experience pain from muscle and musculotendinous sites, many studies have been done to examine muscle, both structurally and physiologically. Inflammation or diagnostic muscle abnormalities have not been found. Evidence indicates deconditioning of muscles, and patients experience a greater degree of postexertional pain than do unaffected persons. Fibromyalgia patients as a group have been reported by some investigators to have reduced levels of growth hormone, which is important for muscle repair and strength. Growth hormone is secreted normally during stage 4 sleep, which is disturbed in patients with fibromyalgia. The reduction of growth hormone may explain the extended periods of muscle pain following exertion in these patients. The

level of the neurotransmitter substance P has been reported to be increased in the cerebrospinal fluid of fibromyalgia patients and may play a role in spreading muscle pain. Patients with fibromyalgia have a decreased cortisol response to stress. Low urinary free cortisol and a diminished cortisol response to corticotropin-releasing hormone suggest an abnormal hypothalamic-pituitary-adrenal axis. Disturbances of the autonomic and peripheral nervous systems may account for the cold sensitivity and Raynaud's-like symptoms seen in patients with fibromyalgia.

Many patients with fibromyalgia have psychological abnormalities; there has been disagreement as to whether some of these abnormalities represent reactions to the chronic pain or whether the symptoms of fibromyalgia are a reflection of psychiatric disturbance. Many patients fit a psychiatric diagnosis, the most common being depression, anxiety, somatization, and hypochondriases. Studies have also shown a high prevalence of sexual and physical abuse and eating disorders. However, fibromyalgia also occurs in patients without significant psychiatric problems. Patients with fibromyalgia may have a lower pain threshold than usual, although not all investigators in the field agree on this point. A better understanding of fibromyalgia awaits further studies.

Clinical Manifestations Symptoms are generalized aching and stiffness of the trunk, hip, and shoulder girdles. Other patients complain of generalized muscle aching and weakness. Patients may complain of low back pain, which may radiate into the buttocks and legs. Others complain of pain and tightness in the neck and across the upper posterior shoulders. Patients complain of muscle pain after even mild exertion. Some degree of pain is always present. The pain has been described as a burning or gnawing pain or as soreness, stiffness, or aching. While pain may begin in one region, such as the shoulders, neck, or lower back, it eventually becomes widespread. Patients may complain of joint pain and perceive that their joints are swollen; however, joint examination yields normal findings. Stiffness is usually present on arising in the morning; usually it improves during the day, but in some patients it lasts all day. Patients may complain of numbness of their hands and feet. They may also feel colder overall than others in the home, and some may experience Raynaud's-like phenomena or actual Raynaud's phenomenon. Patients complain of feeling fatigued and exhausted and wake up tired. They also awaken frequently at night and have trouble falling back to sleep. Symptoms are made worse by stress or anxiety, cold, damp weather, and overexertion. Patients often feel better during warmer weather and vacations.

The characteristic feature on physical examination is the demonstration of specific tender points, which are exclusively more tender or painful than adjacent areas. TheACRCriteria for Fibromyalgia defines 18 tender points (Fig. 325-2). These points of tenderness are remarkably constant in location. A moderate degree of pressure should be used in digital palpation of these tender points. Some workers recommend that the tender site be palpated using a rolling motion, which may be more effective in eliciting the tenderness. The tender sites can also be examined using a dolorimeter, which is a spring-loaded pressure gauge. Digital palpation appears to be as effective and accurate for the diagnosis of fibromyalgia as dolorimetry. The amount of pressure applied by the examiner introduces variability in the interpretation, however. If too much pressure is applied, the pain will be produced even in normal subjects. Likewise, tenderness will not be appreciated if too little pressure is applied or the site is missed on palpation. Some

investigators have quantitated their response, but the number of tender point sites is more diagnostic. Some patients are tender all over and not just at the specific tender point sites. These patients are still more tender over the specific tender point sites, however. Sites where there is usually no tenderness and which can be used as controls are the dorsum of the third digit between the proximal interphalangeal and distal interphalangeal joints, the medial third of the clavicle, the medial malleolus, and the forehead. If tenderness at these sites is also present, the diagnosis of fibromyalgia should be questioned and possible psychiatric disorders investigated. Whether such patients can be diagnosed as also having fibromyalgia is debatable.

Skinfold tenderness may be present, particularly over the upper scapular region. Subcutaneous nodules may be felt at sites of tenderness. Nodules in similar locations are present in normal persons but are not tender.

Fibromyalgia may be triggered by emotional stress, medical illness, surgery, hypothyroidism, and trauma. It has appeared in some patients with human immunodeficiency virus (HIV) infection, parvovirus B19 infection, or Lyme disease. In the latter situation, fibromyalgia persisted despite adequate antibiotic treatment for Lyme disease. Disorders commonly associated with fibromyalgia include irritable bowel syndrome, irritable bladder, headaches (including migraine headaches), dysmenorrhea, premenstrual syndrome, restless legs syndrome, temporomandibular joint pain, and sicca syndrome.

The course of fibromyalgia is variable. Symptoms wax and wane in some patients, while in others pain and fatigue are persistent regardless of therapy. Studies from tertiary medical centers indicate a poor prognosis for most patients. The prognosis may be better in community-treated patients. In a community-based study reported after 2 years of treatment, 24% of patients were in remission, and 47% no longer fulfilled theACRcriteria for fibromyalgia.

Diagnosis Fibromyalgia is diagnosed by a history of widespread pain and the demonstration of at least 11 of the 18 tender point sites on digital palpation (Fig. 325-2). TheACRcriteria are useful for standardizing the diagnosis; however, not all patients with fibromyalgia meet these criteria (Table 325-4). Some patients have fewer tender sites and more regional pain and may be considered to have probable fibromyalgia.

Results of joint and muscle examinations are normal in fibromyalgia patients, and there are no laboratory abnormalities. Fibromyalgia may occur in patients with rheumatoid arthritis, other connective tissue diseases, or other medical illness. A distinction is no longer made between primary and secondary fibromyalgia (concomitant with other disease), as the signs and symptoms are similar. Fibromyalgia and chronic fatigue syndrome have many similarities (Chap. 384). Both are associated with fatigue, abnormal sleep, musculoskeletal pain, and psychiatric conditions such as less severe forms of depression and anxiety. Patients with chronic fatigue syndrome, however, are more likely to have symptoms suggesting a viral illness. These include mild fever, sore throat, and pain in the axillary and anterior and posterior cervical lymph nodes. The onset of chronic fatigue syndrome is usually sudden; patients are usually able to date the onset. Patients also have impaired memory and concentration. While many patients with chronic fatigue syndrome have tender points, the diagnosis does not require their

presence. Polymyalgia rheumatica is distinguished from fibromyalgia in an elderly patient by the presence of more proximal muscle stiffness and pain and an elevated erythrocyte sedimentation rate. Patients should be evaluated for hypothyroidism, which may have symptoms similar to fibromyalgia or may accompany fibromyalgia.

The diagnosis of fibromyalgia has taken on a more complex significance in regard to labor and industry issues. This has become a significant issue since it has been reported that 10 to 25% of patients are not able to work in any capacity, while others require modification of their work. Disability evaluation in fibromyalgia is controversial. The diagnosis of fibromyalgia is not accepted by all. It is hard to evaluate patients' perceptions of their inability to function. The determination of tender points can also be subjective, on the part of both the physician and the patient, particularly when issues of compensation are pending. Patients also encounter difficulty in having their illness recognized as a disability. Physicians have been placed in the inappropriate role of assessing the patient's disability. Physicians are not in a position to quantitate disability at the workplace; that is better done by a work evaluation specialist. Better instruments are clearly needed for measuring disability, particularly in patients with fibromyalgia.

TREATMENT

Patients should be informed that they have a condition that is not crippling, deforming, or degenerative, and that treatment is available. Salicylates or other NSAIDs only partially improve symptoms. Glucocorticoids have been of little benefit and should not be used in these patients. Opiate analgesics should be avoided. Local measures such as heat, massage, injection of tender sites with steroids or lidocaine, and acupuncture provide only temporary relief of symptoms. Other therapies that may help to varying degrees including biofeedback, behavioral modification, hypnotherapy, and stress management and relaxation response training. The use of tricyclics such as amitriptyline (10 to 50 mg) and doxepin (10 to 25 mg) or a pharmacologically similar drug, cyclobenzaprine (10 to 40 mg), 1 to 2 h before bedtime will give the patient restorative sleep (stage 4 sleep), resulting in clinical improvement. Patients should be started on a low dose, which is increased gradually as needed. Side effects of these tricyclics and cyclobenzoprine limit their use; these include constipation, dry mouth, weight gain, drowsiness, and difficulty thinking. Depression and anxiety should be treated with appropriate drugs and, when indicated, with psychiatric counseling. Alprazolam and lorazepam can be used for anxiety, while trazodone, sertraline, fluoxetine, paroxetine or other newer selective serotonin reuptake inhibitors can be used as antidepressants. Patients may also benefit by regular aerobic exercises. Exercise should be of a low-impact type and begun at a low level. Eventually, the patient should be exercising 20 to 30 min 3 to 4 days a week. Regular stretching exercises are also very important. Life stresses should be identified and discussed with the patient, and the patient should be provided with help on how to cope with these stresses. Patients may benefit from a multidisciplinary team approach involving a mental health professional, a physical therapist, and a physical medicine and rehabilitation specialist. Group therapy may be beneficial. Patients should be well educated about their disorder and taught the importance of self help. There are patient support groups in many communities. While treatment of fibromyalgia is effective in some patients, others continue to have chronic disease, which is relieved only partially if at all.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is characterized by localized musculoskeletal pain and tenderness in association with trigger points. The pain is deep and aching and may be accompanied by a burning sensation. Myofascial pain may follow trauma, overuse, or prolonged static contraction of a muscle or muscle group, which may occur when reading or writing at a desk or working at a computer. In addition, this syndrome may be associated with underlying osteoarthritis of the neck or low back. Trigger points are a diagnostic feature of this syndrome. Pain is referred from trigger points to defined areas distant from the original tender points. Palpation of the trigger point reproduces or accentuates the pain. The trigger points are usually located in the center of a muscle belly, but they can occur at other sites, such as costosternal junctions, the xyphoid process, ligamentous and tendinous insertions, fascia, and fatty areas. Trigger point sites in muscle have been described as feeling indurated and taut, and palpation may cause the muscle to twitch. These findings, however, have been shown not to be unique for myofascial pain syndrome, since in a controlled study they were also present in fibromyalgia patients and normal subjects. Myofascial pain most often involves the posterior neck, low back, shoulders, and chest. Chronic pain in the muscles of the posterior neck may involve referral of pain from the trigger point in the erector neck muscle or upper trapezius to the head, leading to persistent headaches which may last for days. Trigger points in the paraspinal muscles of the low back may refer pain to the buttock. Pain may be referred down the leg from a trigger point in the gluteus medius and can mimic sciatica. A trigger point in the infraspinatus muscle may produce local and referred pain over the lateral deltoid and down the outside of the arm into the hand. Injection of a local anesthetic such as 1% lidocaine into the trigger point site often results in pain relief. Another useful technique is first to spray from the trigger point toward the area of referred pain with an agent such as ethyl chloride and then to stretch the muscle. This maneuver may need to be repeated several times. Massage and application of ultrasound to the affected area may also be beneficial. Patients should be instructed in methods to prevent muscle stresses related to work and recreation. Posture and resting positions are important in preventing muscle tension. The prognosis in most patients is good. In some patients, myofascial pain syndrome may evolve into fibromyalgia. Patients at risk for developing fibromyalgia are thought to be those with anxiety, depression, nonrestorative sleep, and fatigue.

PSYCHOGENIC RHEUMATISM

Patients may experience severe joint pain involving a few to several joints without physical findings of arthritis. These patients are often convinced that they have rheumatoid arthritis,SLE, or another connective tissue disease. This disorder is recognized by the inconsistencies, exaggerations, and emotional lability of the patient during the history and physical examination. Results of laboratory studies are normal. Organic disease needs to be excluded, which necessitates seeing the patient at regular intervals. This condition also needs to be distinguished from fibromyalgia. Anti-inflammatory or other drugs are not helpful.

REFLEX SYMPATHETIC DYSTROPHY SYNDROME

The reflex sympathetic dystrophy syndrome (RSDS) is now referred to as *complex*

regional pain syndrome, type 1, by the new Classification of the International Association for the Study of Pain. It is characterized by pain and swelling, usually of a distal extremity, accompanied by vasomotor instability, trophic skin changes, and the rapid development of bony demineralization. RSDS occasionally involves an isolated site such as a knee, hip, or one or two digits of a foot or hand. The contralateral side is affected clinically in ~25% of patients and may be involved in virtually all patients with RSDS, as shown by scintigraphic studies. A precipitating event can be identified in at least two-thirds of cases. These events include trauma, such as fractures and crush injuries; myocardial infarction; strokes; peripheral nerve injury; and use of certain drugs, including barbiturates, anti-tuberculous drugs, and, more recently, cyclosporine administered to patients undergoing renal transplantation. The pathogenesis of RSDS is poorly understood and is thought to involve abnormal activity of the sympathetic nervous system following a precipitating event.

RSDSevolves through three clinical phases. The first phase is characterized by an intense burning pain and swelling of a distal extremity. The involved extremity is warm, edematous, and very tender, especially around joints. Sweating and hair growth are increased. Light touch causes pain, which may continue after the stimulus is removed. Passive or active motion of joints is very painful, and the joints are stiff. In the first phase, especially when both sides are involved, the clinical findings may suggest early rheumatoid arthritis. Redness and swelling over a distal extremity such as an ankle or wrist may also mimic inflammatory arthritis, or even an infectious arthritis. In 3 to 6 months, the skin gradually becomes thin, shiny, and cool. This is the second phase of the disease. The clinical features of the first and second phases often overlap. In another 3 to 6 months (third phase), the skin becomes atrophic and dry, and irreversible flexion contractures, palmar fibromatosis, and Dupuytren's contractures develop, resulting in a clawlike hand deformity. Similar changes occur in the feet. When RSDS occurs in the upper extremity, motion of the shoulder on the affected side may be painful and restricted, a condition referred to as *shoulder-hand syndrome* (see "Adhesive Capsulitis," below).**Reflex sympathetic dystrophy syndrome, including its treatment, is covered in greater detail in Chap. 366.*

TIETZE'S SYNDROME AND COSTOCHONDRITIS

Tietze's syndrome is manifested by painful swelling of one or more costochondral articulations. The age of onset is usually before 40, and both sexes are affected equally. In most patients only one joint is involved, usually the second or third costochondral joint. The onset of anterior chest pain may be sudden or gradual. The pain may radiate to the arms or shoulder and is aggravated by sneezing, coughing, deep inspirations, or twisting motions of the chest. The term *costochondritis* is often used interchangeably with *Tietze's syndrome*, but some workers restrict the former term to pain of the costochondral articulations without swelling. Costochondritis is observed in patients over age 40; tends to affect the third, fourth, and fifth costochondral joints; and occurs more often in women. Both syndromes may mimic cardiac or upper abdominal causes of pain. Rheumatoid arthritis, ankylosing spondylitis, and Reiter's syndrome may involve costochondral joints but are distinguished easily by their other clinical features. Other skeletal causes of anterior chest wall pain are xiphoidalgia and the slipping rib syndrome, which usually involves the tenth rib. Malignancies such as breast cancer, prostate cancer, plasma cell cytoma, and sarcoma can invade the ribs, thoracic spine,

or chest wall and produce symptoms suggesting Tietze's syndrome. They should be easily distinguishable by radiographs and biopsy. Analgesics, anti-inflammatory drugs, and local glucocorticoid injections usually relieve symptoms.

MUSCULOSKELETAL DISORDERS ASSOCIATED WITH HYPERLIPIDEMIA (See alsoChap. 344)

Musculoskeletal manifestations may be the first indication of a hereditary disorder of lipoprotein metabolism. Patients with familial hypercholesterolemia (previously referred to as type II hyperlipoproteinemia) may have recurrent migratory polyarthritis involving knees and other large peripheral joints and, to a lesser degree, peripheral small joints. In a few patients, the arthritis is monarticular. Fever may accompany the arthritis. Pain ranges from moderate to very severe to incapacitating. The involved joints can be warm, erythematous, swollen, and tender. Arthritis usually has a sudden onset, lasts from a few days to 2 weeks, and does not cause joint damage. Episodes may suggest acute gout attacks. Several attacks occur a year. Synovial fluid from involved joints is not inflammatory and contains few white cells and no crystals. Joint involvement may actually represent inflammatory periarthritis or peritendinitis and not intraarticular disease. The recurrent, transient nature of the arthritis may suggest rheumatic fever, especially since patients with lipoproteinemia have an elevated erythrocyte sedimentation rate, and a falsely elevated antistreptolysin O titer. Patients may also experience Achilles tendinitis, which can be very painful. Attacks of tendinitis come on gradually and last only a few days. Fever is not present. Patients may be asymptomatic between attacks. During an attack the Achilles tendon is warm, erythematous, swollen, and tender to palpation. Achilles tendinitis and other joint manifestations often precede the appearance of xanthomas and may be the first clinical indication of hyperlipoproteinemia. Attacks of tendinitis may occur following treatment with a lipid-lowering drug. Patients also have tendinous xanthomas in the Achilles, patellar, and extensor tendons of the hands over the knuckles and feet. Xanthomas have also been reported in the peroneal tendon, the plantar aponeurosis, and the periosteum overlying the distal tibia. These xanthomas are located within tendon fibers. Tuberous xanthomas are soft subcutaneous masses located over the extensor surfaces of the elbows, knees, and hands, as well as on the buttocks. They appear in childhood in homozygous patients and after the age of 30 in heterozygous patients. Patients with elevated plasma levels of very low density lipoprotein (VLDL) and triglyceride (previously referred to as type IV hyperlipoproteinemia) may also have a mild inflammatory arthritis affecting large and small peripheral joints, usually in an asymmetric pattern with only a few joints involved at a time. The onset of arthritis is usually in middle age. Arthritis may be persistent or recurrent, with episodes lasting a few days to weeks. Joint pain is severe in some patients. Patients may experience morning stiffness. Joint tenderness and periarticular hyperesthesia may also be present, as may synovial thickening. Joint fluid is usually noninflammatory and without crystals, but may have increased white blood cell counts with predominantly mononuclear cells. The fluid is occasionally lactescent. Radiographs may show juxtaarticular osteopenia and cystic lesions. Large bone cysts have been noted in a few patients. Xanthoma and bone cysts are also observed in other lipoprotein disorders. The pathogenesis of arthritis in patients with familial hypercholesterolemia or with elevated levels of VLDL and triglyceride is not well understood. Salicylates, otherNSAIDs, or analgesics usually provide relief of symptoms. Clinical improvement also may occur in patients treated with

lipid lowering agents. Patients, however, treated with a HMG CoA reductase agent may experience myalgias and a few patients may develop polymysitis or even rhabdomyolysis (Chap. 382).

ARTHROPATHY OF ACROMEGALY

Acromegaly is the result of excessive production of growth hormone by an adenoma in the anterior pituitary gland (Chap. 328). Middle-aged persons are most often affected. The excessive secretion of growth hormone along with insulin-like growth factor I stimulates proliferation of cartilage, periarticular connective tissue, and bone, resulting in several musculoskeletal abnormalities, including osteoarthritis, back pain, muscle weakness, and carpal tunnel syndrome.

An arthropathy resembling osteoarthritis is a common feature, affecting most often the knees, shoulders, hips, and hands. Single or multiple joints may be affected. The overgrowth of cartilage initially produces widening of the joint space. The newly synthesized cartilage is not developed in an organized manner, making it susceptible to fissuring, ulceration, and destruction. Ligamental laxity of the joint resulting from the growth of connective tissue also contributes to the development of osteoarthritis. With breakdown and loss of cartilage, the joint space narrows, and subchondral sclerosis and osteophytes appear on radiographs. Joint examination reveals marked crepitus and hypermobility. Joint fluid is noninflammatory. Calcium pyrophosphate dihydrate crystals are found in the cartilage in some cases of acromegaly arthropathy and, when shed into the joint, can produce attacks of pseudogout. Chondrocalcinosis may also be observed radiographically. Approximately half of the patients with acromegaly experience back pain, which is predominantly lumbosacral. Hypermobility of the spine may be a contributing factor in back pain. Radiograph of the spine shows normal or increased intervertebral disk spaces, hypertrophic anterior osteophytes, and ligamental calcification. These changes are similar to those observed in patients with diffuse idiopathic skeletal hyperostosis. Dorsal kyphosis in conjunction with elongation of the ribs contributes to the development of the barrel chest seen in acromegalic patients. The hands and feet become enlarged owing to soft tissue proliferation. The fingers are thickened and have spadelike distal tufts. One-third of patients have a thickened heel pad. Approximately 25% of patients have Raynaud's phenomenon.

Carpal tunnel syndrome occurs in about half of patients. The median nerve is compressed by the excessive growth of connective tissue in the carpal tunnel. The median nerve also becomes enlarged. Patients with acromegaly also develop proximal muscle weakness, which is thought to be caused by the effect of growth hormone on muscle. Results of muscle enzyme assays and electromyography are normal. Muscle biopsy specimens show muscle fibers of varying size and no inflammatory changes.

ARTHROPATHY OF HEMOCHROMATOSIS

Hemochromatosis is a disorder of iron storage. Excessive amounts of iron are absorbed from the intestine, leading to iron deposition in parenchymal cells, which results in tissue damage and impairment of organ function (Chap. 345). Symptoms of hemochromatosis usually begin between the ages of 40 and 60 but can occur earlier. Arthritis, which occurs in 20 to 40% of patients, usually begins after the age of 50 and may be the first

clinical feature of hemochromatosis. The arthropathy is an inflammatory osteoarthritis-like disorder affecting the small joints of the hands, followed later by larger joints such as knees, ankles, shoulders, and hips. The second and third metacarpophalangeal joints of both hands are often the first joints affected; they can provide an important clue to the possibility of hemochromatosis. Patients experience stiffness and pain. Morning stiffness usually lasts less than half an hour. The affected joints are enlarged and mildly tender. Synovial tissue is not appreciatively increased. Radiographs show irregular narrowing of the joint space, subchondral sclerosis, and subchondral cysts. There is juxtaarticular proliferation of bone, with frequent hooklike osteophytes. The synovial fluid is noninflammatory. The synovium shows mild to moderate proliferation of lining cells, fibrosis, and a low number of inflammatory cells, which are mononuclear. In approximately half of patients, there is evidence of calcium pyrophosphate deposition disease. Iron can be demonstrated in the lining cells of the synovium and also in chondrocytes.

Iron may damage the articular cartilage in several ways. Promotion by iron of superoxide-dependent lipid peroxidation may play a role in joint damage. In animal models, ferric iron has been shown to interfere with collagen formation. Iron has also been shown to increase the release of lysosomal enzymes from cells in the synovial membrane. Iron may also play a role in the development of chondrocalcinosis. Iron inhibits synovial tissue pyrophosphatase in vitro and, therefore, may inhibit pyrophosphatase in vivo, resulting in chondrocalcinosis. Iron in synovial cells may also inhibit the clearance of calcium pyrophosphate from the joint.

TREATMENT

The treatment of hemochromatosis is repeated phlebotomy. Unfortunately, this treatment has little effect on the arthritis, which, along with chondrocalcinosis, usually continues to progress. Treatment of the arthritis consists of administration of acetaminophen and NSAIDs. Placement of a hip or knee prosthesis has been successful in advanced disease.

HEMOPHILIC ARTHROPATHY

Hemophilia is a sex-linked recessive genetic disorder characterized by the absence or deficiency of factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease) (Chap. 117). Hemophilia A is by far the more common type, constituting 85% of cases. Spontaneous hemarthrosis is a common problem with both types of hemophilia and can lead to a chronic deforming arthritis. The frequency and severity of hemarthrosis are related to the degree of clotting factor deficiency. Hemarthrosis is not common in other inherited disorders of coagulation, such as von Willebrand's disease or factor V deficiency.

Hemarthrosis becomes evident after 1 year of age, when the child begins to walk and run. In order of frequency, the joints most commonly affected are the knees, ankles, elbows, shoulders, and hips. Small joints of the hands and feet are occasionally involved.

In the initial stage of arthropathy, hemarthrosis produces a warm, tensely swollen, and

painful joint. The patient holds the affected joint in flexion and guards against any movement. Blood in the joint remains liquid because of the absence of intrinsic clotting factors and the absence of tissue thromboplastin in the synovium. The blood in the joint space is resorbed over a period of a week or longer, depending on the size of the hemarthrosis. Joint function usually returns to normal or baseline in about 2 weeks.

Recurrent hemarthrosis leads to the development of a chronic arthritis. The involved joints remain swollen, and flexion deformities develop. In the later stages of arthropathy, joint motion is restricted and function is severely limited. Joint ankylosis, subluxation, or laxity are features of end-stage disease.

Bleeding into muscle and soft tissue also causes musculoskeletal disorders. When bleeding into the iliopsoas muscle occurs, the hip is held in flexion because of the pain, resulting in a hip flexion contracture. Rotation of the hip is preserved, which distinguishes this problem from intraarticular hemorrhage. Expansion of the hematoma may place pressure on the femoral nerve, resulting in a femoral neuropathy. Another problem is shortening of the heel cord secondary to bleeding into the gastrocnemius. Hemorrhage into a closed compartment space, such as the volar compartment in the forearm, can result in muscle necrosis and flexion deformities of the wrist and fingers. When bleeding involves periosteum or bone, a pseudotumor forms. These occur distal to the elbows or knees in children and improve with treatment of the hemophilia. Surgical removal is indicated if the pseudotumor continues to enlarge. In adults, they occur in the femur and pelvis and are usually refractory to treatment. When bleeding occurs in muscle, cysts may develop within the muscle. Needle aspiration of a cyst is contraindicated because it can induce bleeding.

Septic arthritis can occur in hemophilia and is difficult at times to distinguish from acute hemarthrosis. Whenever there is suspicion of an infected joint, the joint should be aspirated immediately, the fluid cultured, and the patient started on a broad-spectrum antibiotic. The patient should be infused with the deficient clotting factor before the joint is tapped to decrease the risk of further bleeding.

Radiographs of joints reflect the stage of disease. In early stages there is only capsule distention; later, juxtaarticular osteopenia, marginal erosions, and subchondral cysts develop. In late disease, the joint space is narrowed and there is bony overgrowth. The changes are similar to those observed in osteoarthritis. Unique features of hemophilic arthropathy are widening of the femoral intercondylar notch, enlargement of the proximal radius, and squaring of the distal end of the patella.

Recurrent hemarthrosis produces synovial hyperplasia and hypertrophy. A pannus covers the cartilage. Cartilage is damaged by collagenase and other degradative enzymes released by mononuclear cells in the overlying synovium. Hemosiderin is found in synovial lining cells, the subsynovium, and chondrocytes and may also play a role in cartilage destruction.

TREATMENT

The treatment of hemarthrosis is initiated with the immediate infusion of factor VIII or IX at the first sign of joint or muscle hemorrhage. The patient is placed at bed rest, with the

involved joint in as much extension as the patient can tolerate. AnalgesicNSAIDsand local icing may help with the pain. NSAIDs can be given safely for short periods even though they have a stabilizing effect on platelets. Studies have shown no significant abnormalities in platelet function or bleeding time in hemophiliacs receiving ibuprofen. The new cyclooxygenase-2 inhibitors celecoxib and rofecoxib do not interfere with platelet function and can be safely given for pain. Synovectomy, open or arthroscopic, may be indicated in patients with chronic synovial proliferation and recurrent hemarthrosis. Hypertrophied synovium is very vascular and subject to bleeding. Both types of synovectomy reduce the number of hemarthroses and slow the roentgenographic progression of hemophilic arthropathy. Open surgical synovectomy, however, is associated with some loss of range of motion. Radiosynovectomy with either yttrium 90 silicate or phosphorus 31 colloid has also been effective and may be a useful alternative when surgical synovectomy is not practical. Total joint replacement is indicated for severe joint destruction and incapacitating pain. Because of the young age of hemophilic patients, total-joint prostheses may need to be replaced more than once during their lives.

ARTHROPATHIES ASSOCIATED WITH HEMOGLOBINOPATHIES

Sickle Cell Disease Sickle cell disease (Chap. 106) is associated with several musculoskeletal abnormalities (Table 325-5). Children under the age of 5 may develop diffuse swelling, tenderness, and warmth of the hands and feet lasting from 1 to 3 weeks. The condition, referred to as *sickle cell dactylitis* or *hand-foot syndrome* has also been observed in sickle cell disease and sickle cell thalassemia. Dactylitis is believed to result from infarction of the bone marrow and cortical bone leading to periostitis and soft tissue swelling. Radiographs show periosteal elevation, subperiosteal new bone formation, and areas of radiolucency and increased density involving the metacarpals, metatarsals, and proximal phalanges. These bone changes disappear after several months. The syndrome leaves little or no residual damage. Because hematopoiesis ceases in the small bones of hands and feet with age, the syndrome is rarely seen after age 4 or 5 and does not occur in adults.

Sickle cell crisis is often associated with periarticular pain and joint effusions. The joint and periarticular area are warm and tender. Knees and elbows are most often affected, but other joints can be involved. Joint effusions are noninflammatory, with white cell counts<1000/uL; mononuclear cells predominate. There have been a few reports of sterile inflammatory effusion with high cell counts consisting of mostly polymorphonuclear white cells. Synovial biopsies have shown mild lining cell proliferation and microvascular thrombosis. Scintigraphic studies have shown decreased marrow uptake adjacent to the involved joint. The joint effusion and periarticular pain are considered to be the result of ischemia and infarction of the synovium and adjacent bone and bone marrow. The treatment is that for sickle cell crisis (Chap. 106).

Patients with sickle cell disease may also develop osteomyelitis, which commonly involves the long tubular bones (Chap. 129). These patients are particularly susceptible to bacterial infections, especially *Salmonella* infections, which are found in more than half of cases (Chap. 156). Radiographs of the involved site show periosteal elevation initially, followed by disruption of the cortex. Treatment of the infection results in healing

of the bone lesion. Sickle cell disease is also associated with bone infarction resulting from thrombosis secondary to the sickling of red cells. Bone infarction also occurs in hemoglobin S-C disease and sickle cell thalassemia (Chap. 106). The bone pain in sickle cell crisis is due to bone and bone marrow infarction. In children, infarction of the epiphyseal growth plate interferes with normal growth of the affected extremity. Radiographically, infarction of the bone cortex results in periosteal elevation and irregular thickening of the bone cortex. Infarction in the bone marrow leads to lysis, fibrosis, and new bone formation.

Avascular necrosis of the head of the femur is seen in ~5% of patients. It also occurs in the humeral head and less commonly in the distal femur, tibial condyles, distal radius, vertebral bodies, and other juxtaarticular sites. The mechanism for avascular necrosis is most likely the same as for bone infarction. Subchondral hemorrhage may play a role in the deterioration of articular cartilage. Irregularity of the femoral head or of other bone surfaces affected by avascular necrosis eventually results in degenerative joint disease. Radiograph of the affected joint may show patchy radiolucency and density followed by flattening of the bone. Magnetic resonance imaging is a sensitive technique for detecting early avascular necrosis as well as bone infarction elsewhere. Total hip replacement and placement of prostheses in other joints may improve function and relieve pain in those patients with severe joint destruction.

Septic arthritis is occasionally encountered in sickle cell disease (Chap. 323). Multiple joints may be infected. Joint infection may result from hematogenous spread or from spread of contiguous osteomyelitis. Microorganisms identified include staphylococcus, *Streptococcus*, *Escherichia coli*, and *Salmonella*. The latter is not seen as frequently in septic arthritis as it is in osteomyelitis. Acute gouty arthritis is uncommon in sickle cell disease, even though 40% of patients are hyperuremic. Hyperuricemia is due to overproduction of uric acid secondary to increased red cell turnover. Attacks may be polyarticular.

The bone marrow hyperplasia in sickle cell disease results in widening of the medullary cavities, thinning of the cortices, and coarse trabeculations and central cupping of the vertebral bodies. These changes are also seen to a lesser degree in hemoglobin S-C disease and sickle cell thalassemia. In normal individuals, red marrow is located mostly in the axial skeletal, but in sickle cell disease, red marrow is found in the bones of the extremities and even in the tarsal and carpal bones. Vertebral compression may lead to dorsal kyphosis, and softening of the bone in the acetabulum may result in protrusio acetabuli.

Thalassemia b-Thalassemia is a congenital disorder of hemoglobin synthesis characterized by impaired production of bchains (Chap. 106). Bone and joint abnormalities occur inb-thalassemia, being most common in the major and intermedia groups. In one study, approximately 50% of patients with b-thalassemia had evidence of symmetric ankle arthropathy, characterized by a dull aching pain aggravated by weight bearing. The onset was most often in the second or third decade of life. The degree of ankle pain in these patients varied. Some patients experienced self-limited ankle pain, which occurred only after strenuous physical activity and lasted several days to weeks. Other patients had chronic ankle pain, which became worse with walking. Symptoms eventually abated in a few patients. Compression of the ankle, calcaneus, or forefoot

was painful in some patients. Synovial fluid from two patients was noninflammatory. Radiographs of ankle showed osteopenia, widened medullary spaces, thin cortices, and coarse trabeculations. These findings were largely the result of bone marrow expansion. The joint space was preserved. Specimens of bone from three patients revealed osteomalacia, osteopenia, and microfractures. Increased osteoblasts as well as increased foci of bone resorption were present on the bone surface. Iron staining was found in the bone trabeculae, in osteoid, and in the cement line. Synovium showed hyperplasia of lining cells which contained deposits of hemosiderin. This arthropathy was considered to be related to the underlying bone pathology. The role of iron overload or abnormal bone metabolism in the pathogenesis of this arthropathy is not known. The arthropathy was treated with analgesics and splints. Patients were also transfused to decrease hematopoiesis and bone marrow expansion.

Patients withb-thalassemia major and intermedia also have involvement of other joints, including the knees, hips, and shoulders. Acquired hemochromatosis with arthropathy has been described in a patient with thalassemia. Gouty arthritis and septic arthritis can occur. Avascular necrosis is not a feature of thalassemia because there is no sickling of red cells leading to thrombosis and infarction.

b-Thalassemia minor (trait) is also associated with joint manifestations. Chronic seronegative oligoarthritis affecting predominantly ankles, wrists, and elbows has been described. These patients had mild persistent synovitis without large effusions. Joint erosions were not seen. Recurrent episodes of an acute asymmetric arthritis also have been reported; episodes last less than a week and may affect knees, ankles, shoulders, elbows, wrists, and metacarpal phalangeal joints. The mechanism for this arthropathy is unknown. Treatment with nonsteroidal drugs was not particularly effective.

TUMORS OF JOINTS

Primary tumors and tumor-like disorders of synovium are uncommon but should be considered in the differential diagnosis of monarticular joint disease. In addition, metastases to bone and primary bone tumors adjacent to a joint may produce joint symptoms.**For further discussion, see Chap. 98.*

Pigmented villonodular synovitis is characterized by the slowly progressive, exuberant, benign proliferation of synovial tissue, usually involving a single joint. The most common age of onset is in the third decade, and women are affected slightly more often than men. The cause of this disorder is unknown.

The synovium has a brownish color and numerous large, finger-like villi that fuse to form pedunculated nodules. There is marked hyperplasia of synovial cells in the stroma of the villi. Hemosiderin granules and lipids are found in the cytoplasm of macrophages and in the interstitial tissue. Multinucleated giant cells may be present. The proliferative synovium grows into the subsynovial tissue and invades adjacent cartilage and bone.

The clinical picture of pigmented villonodular synovitis is characterized by the insidious onset of swelling and pain in one joint, most commonly the knee. Other joints affected include the hips, ankles, calcaneocuboid joints, elbows, and small joints of the fingers or toes. The disease may also involve the common flexor sheath of the hand or fingers.

Less commonly, tendon sheaths in the wrist, ankle, or foot may be involved. Symptoms may be mild and intermittent and may be present for years before the patient seeks medical attention. Radiographs may show joint space narrowing, erosions, and subchondral cysts. The joint fluid contains blood and is dark red or almost black in color. Lipid-containing macrophages may be present in the fluid. The joint fluid may be clear if hemorrhages have not occurred.

The treatment of pigmented villonodular synovitis is complete synovectomy. With incomplete synovectomy, the villonodular synovitis recurs, and the rate of tissue growth may be faster than originally. Irradiation of the involved joint has been successful in some patients.

Synovial chondromatosis is a disorder characterized by multiple focal metaplastic growths of normal-appearing cartilage in the synovium or tendon sheath. Segments of cartilage break loose and continue to grow as loose bodies. When calcification and ossification of loose bodies occur, the disorder is referred to as *synovial osteochondromatosis*. The disorder is usually monarticular and affects young to middle-aged individuals. The knee is most often involved, followed by hip, elbow, and shoulder. Symptoms are pain, swelling, and decreased motion of the joint. Radiographs may show several rounded calcifications within the joint cavity. Treatment is synovectomy; however, the tumor may recur.

Hemangiomas occur in synovium and in tendon sheaths. The knee is affected most commonly. Recurrent episodes of joint swelling and pain usually begin in childhood. The joint fluid is bloody. Treatment is excision of the lesion. *Lipomas* occur most often in the knee, originating in the subsynovial fat on either side of the patellar tendon. Lipomas also appear in tendon sheaths of the hands, wrists, feet, and ankles. In some instances, surgical removal is necessary.

Synovial sarcoma is a malignant neoplasm often found near a large joint of both upper and lower extremities, being more common in the lower extremity. It seldom arises within the joint itself. Synovial sarcomas comprise 10% of sarcomas. The tumor is believed to arise from primitive mesenchymal tissue which differentiates into epithelial cells and/or spindle cells. Small foci of calcification may be present in the tumor mass. It occurs most often in young adults and is more common in men. The tumor presents as a slowly growing deep seated mass near a joint, without much pain. The area of the knee is the most common site, followed by the foot, ankle, elbow, and shoulder. Other primary sites include the buttocks, abdominal wall, retioperitoneum and mediastinum. The tumor spreads along tissue planes. The most common site of visceral metastasis is lung. The diagnosis is made by biopsy. Treatment is wide resection of the tumor including adjacent muscle and regional lymph nodes, followed by chemotherapy and radiation therapy. Currently used chemotherapeutic agents are doxorubicin, ifosfamide, and cisplatin. Amputation of the involved distal extremity may be required. Chemotherapy may be beneficial in some patients with metastatic disease. Isolated pulmonary mitostasis can be surgically removed. The 5-year survival with treatment has been reported as high as 88%.

326. PERIARTICULAR DISORDERS OF THE EXTREMITIES - *Bruce Gilliland*

A number of periarticular disorders have become increasingly common over the past two to three decades, due in part to greater participation in recreational sports by individuals of a wide range of ages. This chapter discusses some of the more common periarticular disorders of the extremities.

BURSITIS

Bursitis is inflammation of a bursa, which is a thin-walled sac lined with synovial tissue. The function of the bursa is to facilitate movement of tendons and muscles over bony prominences. Excessive frictional forces, trauma, systemic disease (e.g., rheumatoid arthritis, gout), or infection may cause bursitis. *Subacromial bursitis* (subdeltoid bursitis) is the most common form of bursitis. The subacromial bursa, which is contiguous with the subdeltoid bursa, is located between the undersurface of the acromion and the humeral head, and is covered by the deltoid muscle. Bursitis is caused by repetitive overhead motion and often accompanies rotator cuff tendinitis. Another frequently encountered form is *trochanteric bursitis*, which involves the bursa around the insertion of the gluteus medius onto the greater trochanter of the femur. Patients experience pain over the lateral aspect of the hip and upper thigh and have tenderness over the posterior aspect of the greater trochanter. External rotation and resisted abduction of the hip elicit pain. *Olecranon bursitis* occurs over the posterior elbow, and when the area is acutely inflamed, infection should be excluded by aspirating and culturing fluid from the bursa. *Achilles bursitis* involves the bursa located above the insertion of the tendon to the calcaneus and results from overuse and wearing tight shoes. *Retrocalcaneal bursitis* involves the bursa that is located between the calcaneus and posterior surface of the Achilles tendon. The pain is experienced at the back of the heel, and swelling appears on the medial and/or lateral side of the tendon. It occurs in association with spondyloarthropathies, rheumatoid arthritis, gout, or trauma. *Ischial bursitis* (weaver's bottom) affects the bursa separating the gluteus medius from the ischial tuberosity and develops from prolonged sitting and pivoting on hard surfaces. *Iliopsoas bursitis* affects the bursa that lies between the iliopsoas muscle and hip joint and is lateral to the femoral vessels. Pain is experienced over this area and is made worse by hip extension and flexion. Bursitis results from trauma or overuse but can also be seen in patients with rheumatoid arthritis. *Anserine bursitis* is an inflammation of the sartorius bursa located over the medial side of the tibia just below the knee and under the conjoint tendon and is manifested by pain on climbing stairs. Tenderness is present over the insertion of the conjoint tendon of the sartorius, gracilis, and semitendinosus. *Prepatellar bursitis* (housemaid's knee) occurs in the bursa situated between the patella and overlying skin and is caused by kneeling on hard surfaces. Treatment of bursitis consists of prevention of the aggravating situation, rest of the involved part, administration of a nonsteroidal anti-inflammatory drug (NSAID), or local glucocorticoid injection.

ROTATOR CUFF TENDINITIS AND IMPINGEMENT SYNDROME

Tendinitis of the rotator cuff is the major cause of a painful shoulder and is currently thought to be caused by inflammation of the tendon(s). The rotator cuff consists of the tendons of the supraspinatus, infraspinatus, subscapularis, and teres minor muscles,

and inserts on the humeral tuberosities. Of the tendons forming the rotator cuff, the supraspinatus tendon is the most often affected, probably because of its repeated impingement (impingement syndrome) between the humeral head and the undersurface of the anterior third of the acromion and coracoacromial ligament above as well as the reduction in its blood supply that occurs with abduction of the arm (Fig. 326-1). The tendon of the infraspinatus or the long head of the biceps is less commonly involved. The process begins with edema and hemorrhage of the rotator cuff, which evolves to fibrotic thickening and eventually to rotator cuff degeneration with tendon tears and bone spurs. Subacromial bursitis also accompanies this syndrome. Symptoms usually appear after injury or overuse, especially with activities involving elevation of the arm with some degree of forward flexion. Impingement syndrome occurs in persons participating in baseball, tennis, swimming, or occupations that require repeated elevation of the arm. Those over age 40 are particularly susceptible. Patients complain of a dull aching in the shoulder, which may interfere with sleep. Severe pain is experienced when the arm is actively abducted into an overhead position. The arc between 60 and 120° is especially painful. Tenderness is present over the lateral aspect of the humeral head just below the acromion.NSAIDs, local glucocorticoid injection, and physical therapy may relieve symptoms.

Patients may tear the supraspinatus tendon acutely by falling on an outstretched arm or lifting a heavy object. Symptoms are pain, along with weakness of abduction and external rotation of the shoulder. Atrophy of the supraspinatus muscles develops. The diagnosis is established by arthrogram or ultrasound. Surgical repair may be necessary in patients who fail to respond to conservative measures. In patients with moderate to severe tears and functional loss, surgery is indicated.

CALCIFIC TENDINITIS

This condition is characterized by deposition of calcium salts, primarily hydroxyapatite, within a tendon. The exact mechanism of calcification is not known but may be initiated by ischemia or degeneration of the tendon. The supraspinatus tendon is most often affected because it is frequently impinged on and has a reduced blood supply when the arm is abducted. The condition usually develops after age 40. Calcification within the tendon may evoke acute inflammation, producing sudden and severe pain in the shoulder. However, it may be asymptomatic or not related to the patient's symptoms.

BICIPITAL TENDINITIS AND RUPTURE

Bicipital tendinitis, or tenosynovitis, is produced by friction on the tendon of the long head of the biceps as it passes through the bicipital groove. When the inflammation is acute, patients experience anterior shoulder pain that radiates down the biceps into the forearm. Abduction and external rotation of the arm are painful and limited. The bicipital groove is very tender to palpation. Pain may be elicited along the course of the tendon by resisting supination of the forearm with the elbow at 90° (Yergason's supination sign). Acute rupture of the tendon may occur with vigorous exercise of the arm and is often painful. In a young patient, it should be repaired surgically. Rupture of the tendon in an older person may be associated with little or no pain and is recognized by the presence of persistent swelling of the biceps ("Popeye" muscle) produced by the retraction of the long head of the biceps. Surgery is usually not necessary in this setting.

ADHESIVE CAPSULITIS

Often referred to as "frozen shoulder," adhesive capsulitis is characterized by pain and restricted movement of the shoulder, usually in the absence of intrinsic shoulder disease. Adhesive capsulitis, however, may follow bursitis or tendinitis of the shoulder or be associated with systemic disorders such as chronic pulmonary disease, myocardial infarction, and diabetes mellitus. Prolonged immobility of the arm contributes to the development of adhesive capsulitis, and reflex sympathetic dystrophy is thought to be a pathogenic factor. The capsule of the shoulder is thickened, and a mild chronic inflammatory infiltrate and fibrosis may be present.

Adhesive capsulitis occurs more commonly in women after age 50. Pain and stiffness usually develop gradually over several months to a year but progress rapidly in some patients. Pain may interfere with sleep. The shoulder is tender to palpation, and both active and passive movement are restricted. Radiographs of the shoulder show osteopenia. The diagnosis is confirmed by arthrography, in that only a limited amount of contrast material, usually <15 mL, can be injected under pressure into the shoulder joint.

In most patients, the condition improves spontaneously 1 to 3 years after onset, but some have permanent restriction of movement. Early mobilization of the arm following an injury to the shoulder may prevent the development of this disease. Slow but forceful injection of contrast material into the joint may lyse adhesions and stretch the capsule, resulting in improvement of shoulder motion. Manipulation under anesthesia may be helpful in some patients. Once the disease is established, therapy may have little effect on its natural course. Local injections of glucocorticoids,NSAIDs, and physical therapy may provide relief of symptoms.

LATERAL EPICONDYLITIS (TENNIS ELBOW)

Lateral epicondylitis, or tennis elbow, is a painful condition involving the soft tissue over the lateral aspect of the elbow. The pain originates at or near the site of attachment of the common extensors to the lateral epicondyle and may radiate into the forearm and dorsum of the wrist. This painful condition is thought to be caused by small tears of the extensor aponeurosis resulting from repeated resisted contractions of the extensor muscles. The pain usually appears after work or recreational activities involving repeated motions of wrist extension and supination against resistance. Most patients with this disorder injure themselves in activities other than tennis, such as pulling weeds, carrying suitcases or briefcases, or using a screwdriver. The injury in tennis usually occurs when hitting a backhand with the elbow flexed. Shaking hands and opening doors can reproduce the pain. Striking the lateral elbow against a solid object may also induce pain.

The treatment is usually rest along with administration of anNSAID. Ultrasound, icing, and friction massage may also help relieve pain. When pain is severe, the elbow is placed in a sling or splinted at 90° of flexion. When the pain is acute and well localized, injection of a glucocorticoid using a small-gauge needle may be effective. Following injection, the patient should be advised to rest the arm for at least 1 month and avoid

activities that would aggravate the elbow. Once symptoms have subsided, the patient should begin rehabilitation to strengthen and increase flexibility of the extensor muscles before resuming physical activity involving the arm. A forearm band placed 2.5 to 5.0 cm (1 to 2 in) below the elbow may help to reduce tension on the extensor muscles at their attachment to the lateral epicondyle. The patient should be advised to restrict activities requiring forcible extension and supination of the wrist. Improvement may take several months. The patient may continue to experience mild pain but, with care, can usually avoid the return of debilitating pain. In an occasional patient, surgical release of the extensor aponeurosis may be necessary.

MEDIAL EPICONDYLITIS

Medial epicondylitis is an overuse syndrome resulting in pain over the medial side of the elbow with radiation into the forearm. The cause of this syndrome is considered to be repetitive resisted motions of wrist flexion and pronation, which lead to microtears and granulation tissue at the origin of the pronator teres and forearm flexors, particularly the flexor carpi radialis. This overuse syndrome is usually seen in patients >35 years and is much less common than lateral epicondylitis. It occurs most often in work-related repetitive activities but also occurs with recreational activities such as swinging a golf club (golfer's elbow) or throwing a baseball. On physical examination, there is tenderness just distal to the medial epicondyle over the origin of the forearm flexors. Pain can be reproduced by resisting wrist flexion and pronation with the elbow extended. Radiographs are usually normal. The differential diagnosis of patients with medial elbow symptoms include tears of the pronator teres, acute medial collateral ligament tear, and medial collateral ligament instability. Ulnar neuritis has been found in 25 to 50% of patients with medial epicondylitis and is associated with tenderness over the ulnar nerve at the elbow as well as hypesthesia and paresthesia on the ulnar side of the hand.

The initial treatment of medial epicondylitis is conservative, involving rest,NSAIDs, friction massage, ultrasound, and icing. Some patients may require splinting. Injections of glucocorticoids at the painful site may also be effective. Patients should be instructed to rest at least 1 month. Also, patients should be started on physical therapy once the pain has subsided. In patients with chronic debilitating medial epicondylitis that remains unresponsive after at least a year of treatment, surgical release of the flexor muscle at its origin may be necessary and is often successful.

PART THIRTEEN -ENDOCRINOLOGY AND METABOLISM

SECTION 1 -ENDOCRINOLOGY

327. PRINCIPLES OF ENDOCRINOLOGY - *J. Larry Jameson*

The management of endocrine disorders requires an understanding of such disparate areas as intermediary metabolism, reproductive physiology, bone metabolism, and growth. Accordingly, the practice of endocrinology is intimately linked to a conceptual framework for understanding hormone secretion, hormone action, and principles of feedback control systems. The endocrine system is investigated primarily by measuring hormone concentrations, thereby arming the clinician with valuable diagnostic information. Most disorders of the endocrine system are amenable to effective treatment, once the correct diagnosis is determined. Endocrine deficiency disorders are treated with physiologic hormone replacement; hormone excess conditions, usually due to benign glandular adenomas, are managed by removing tumors surgically or by reducing hormone levels medically.

SCOPE OF ENDOCRINOLOGY

The specialty of endocrinology encompasses the study of glands and the hormones they produce. The term *endocrine* was coined by Starling to contrast the actions of hormones secreted internally (endocrine) with those secreted externally (*exocrine*) or into a lumen, such as the gastrointestinal tract. The term *hormone*, derived from a Greek phrase meaning "to set in motion," aptly describes the dynamic actions of these circulating substances as they elicit cellular responses and regulate physiologic processes through feedback mechanisms.

Unlike certain other specialties in medicine, it is not possible to define endocrinology strictly along anatomic lines. The classic endocrine glands -- pituitary, thyroid, parathyroid, pancreatic islets, adrenal, and gonads -- communicate broadly with other organs through the nervous system, hormones, cytokines, and growth factors. In addition to its traditional synaptic functions, the brain produces a vast array of peptide hormones, spawning the discipline of neuroendocrinology. Through the production of hypothalamic releasing factors, the central nervous system exerts a major regulatory influence over pituitary hormone secretion (Chap. 328). The peripheral nervous system modulates adrenal medulla and pancreatic islet hormone production. The immune and endocrine systems are also intimately intertwined. The adrenal glucocorticoid, cortisol, is a powerful immunosuppressant. Cytokines and interleukins (ILs) have profound effects on the functions of the pituitary, adrenal, thyroid, and gonads. Common endocrine diseases, such as autoimmune thyroid disease and type 1 diabetes mellitus, are caused by dysregulation of immune surveillance and tolerance. Less common diseases such as polyglandular failure, Addison's disease, and lymphocytic hypophysitis also have an immunologic basis.

The interdigitation of endocrinology with physiologic processes in other specialties sometimes blurs the role of hormones. For example, hormones play an important role in maintenance of blood pressure, intravascular volume, and peripheral resistance in the cardiovascular system. The heart is the principal source of atrial natriuretic peptide,

which acts in classic endocrine fashion to induce natriuresis at a distant target organ (the kidney). Vasoactive substances such as catecholamines, angiotensin II, endothelin, and nitric oxide are involved in dynamic changes of vascular tone, in addition to their multiple roles in other tissues. Erythropoietin, a traditional circulating hormone, is made in the kidney and stimulates erythropoiesis in the bone marrow (Chap. 104). The kidney is also integrally involved in the renin-angiotensin axis (Chap. 331) and is a primary target of several hormones including parathyroid hormone (PTH), mineralocorticoids, and vasopressin. The gastrointestinal tract produces a surprising number of peptide hormones such as cholecystokinin, gastrin, secretin, and vasoactive intestinal peptide, among many others. Carcinoid and islet tumors can secrete excessive amounts of these hormones, leading to specific clinical syndromes (Chap. 93). Many of these gastrointestinal hormones are also produced in the central nervous system, where their functions remain poorly understood. As new hormones such as inhibin, ghrelin, and leptin are discovered, they become integrated into the science and practice of medicine on the basis of their functional roles rather than through their structures or mechanisms of action.

Characterization of hormone receptors frequently reveals unexpected relationships to factors in nonendocrine disciplines. The growth hormone (GH) receptor, for example, is a member of the cytokine receptor family. The G protein-coupled receptors (GPCRs), which mediate the actions of many peptide hormones, are used in numerous physiologic processes including vision, smell, and neurotransmission.

It is apparent that hormones and growth factors play an important functional role in all organ systems. Though endocrinologists are not usually involved in the administration of the hormones or growth factors used to treat diseases in other specialties (e.g., cardiology, hematology), the principles of endocrinology can be applied in these cases, thus emphasizing the impact of endocrinology across multiple disciplines.

NATURE OF HORMONES

Hormones can be divided into five major classes: (1) *amino acid derivatives* such as dopamine, catecholamines, and thyroid hormone; (2) *small neuropeptides* such as gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), somatostatin, and vasopressin; (3) *large proteins* such as insulin, luteinizing hormone (LH), and PTH produced by classic endocrine glands; (4) *steroid hormones* such as cortisol and estrogen that are synthesized from cholesterol-based precursors; and (5) *vitamin derivatives* such as retinoids (vitamin A) and vitamin D. A variety of *peptide growth factors*, most of which act locally, share actions with hormones. As a rule, amino acid derivatives and peptide hormone interact with cell-surface membrane receptors. Steroids, thyroid hormones, vitamin D, and retinoids are lipid-soluble and interact with intracellular nuclear receptors.

HORMONE AND RECEPTOR FAMILIES

Many hormones and receptors can be grouped into families, reflecting their structural similarities (Table 327-1). The evolution of these families generates diverse but highly selective pathways of hormone action. Recognizing these relationships allows extrapolation of information gleaned from one hormone or receptor to other family

members.

The glycoprotein hormone family, consisting of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), LH, and human chorionic gonadotropin (hCG), illustrates many features of related hormones. The glycoprotein hormones are heterodimers that share the a subunit in common; theb subunits are distinct and confer specific biologic actions. The overall three-dimensional architecture of theb subunits is similar, reflecting the locations of conserved disulfide bonds that restrain protein conformation. The cloning of theb-subunit genes from multiple species suggests that this family arose from a common ancestral gene, probably by gene duplication and subsequent divergence to evolve new biologic functions.

As the hormone families enlarge and diverge, their receptors must co-evolve, if new biologic functions are to be derived. RelatedGPCRs, for example, have evolved for each of the glycoprotein hormones. These receptors are structurally similar, and each is coupled to the $G_s$asignaling pathway. However, there is minimal overlap of hormone binding. For example, TSH binds with high specificity to the TSH receptor but interacts weakly with the LH or the FSH receptor. Nonetheless, there can be subtle physiologic consequences of hormone cross-reactivity with other receptors. Very high levels ofhCGduring pregnancy stimulate the TSH receptor and increase thyroid hormone levels.

Insulin, insulin-like growth factor (IGF) I, and IGF-II share structural similarities that are most apparent when precursor forms of the proteins are compared. In contrast to the high degree of specificity seen with the glycoprotein hormones, there is moderate cross-talk among the members of the insulin/IGF family. High concentrations of an IGF-II precursor produced by certain tumors (e.g., sarcomas) can cause hypoglycemia, partly because of binding to insulin and IGF-I receptors (Chap. 334). High concentrations of insulin also bind to the IGF-I receptor, perhaps accounting for some of the clinical manifestations seen in severe insulin resistance.

Another important example of receptor cross-talk is seen with PTH and parathyroid hormone-related peptide (PTHrP) (Chap. 341). PTH is produced by the parathyroid glands, whereas PTHrP is expressed at high levels during development and by a variety of tumors. These hormones share amino acid sequence similarity, particularly in their amino-terminal regions. Both hormones bind to a single PTH receptor that is expressed in bone and kidney. Hypercalcemia and hypophosphatemia may therefore result from excessive production of either hormone, making it difficult to distinguish hyperparathyroidism from hypercalcemia of malignancy solely on the basis of serum chemistries. However, sensitive and specific assays for PTH now allow these disorders to be separated more readily.

Based on their specificities for DNA binding sites, the nuclear receptor family can be subdivided into type 1 receptors (GR, MR, AR, ER, PR) that bind steroids and type 2 receptors (TR, VDR, RAR, PPAR) that bind thyroid hormone, vitamin D, retinoic acid, or lipid derivatives. Certain functional domains in nuclear receptors, such as the zinc finger DNA-binding domains, are highly conserved. However, selective amino acid differences within this domain confer DNA sequence specificity. The hormone-binding domains are more variable, providing great diversity in the array of small molecules that can bind to

different nuclear receptors. With few exceptions, hormone binding is highly specific for a single type of nuclear receptor. One exception involves the highly related glucocorticoid and mineralocorticoid receptors. Because the mineralocorticoid receptor also binds glucocorticoids with high affinity, an enzyme (11b-hydroxysteroid dehydrogenase) located in renal tubular cells inactivates glucocorticoids, allowing selective responses to mineralocorticoids such as aldosterone. However, when very high glucocorticoid concentrations occur, as in Cushing's syndrome, the glucocorticoid degradation pathway becomes saturated, allowing excessive cortisol levels to exert mineralocorticoid effects (sodium retention, potassium wasting). This phenomenon is particularly pronounced in ectopic adrenocorticotropic hormone (ACTH) syndromes (Chap. 331). Another example of relaxed nuclear receptor specificity involves the estrogen receptor, which can bind an array of compounds, some of which share little structural similarity to the high-affinity ligand estradiol. This feature of the estrogen receptor makes it susceptible to activation by "environmental estrogens" such as resveratrol, octylphenol, and many other aromatic hydrocarbons. On the other hand, this lack of specificity provides an opportunity to synthesize a remarkable series of clinically useful antagonists (e.g., tamoxifen) and selective estrogen response modulators (SERMs), such as raloxifene. These compounds generate distinct conformations that alter receptor interactions with components of the transcription machinery (see below), thereby conferring their unique actions.

HORMONE SYNTHESIS AND PROCESSING

The synthesis of peptide hormones and their receptors occurs through a classic pathway of gene expression: transcription ® mRNA® protein ®posttranslational protein processing ®intracellular sorting, membrane integration, or secretion (Chap. 65). Though endocrine genes contain regulatory DNA elements similar to those found in many other genes, their exquisite control by other hormones also necessitates the presence of specific hormone response elements. For example, the TSH genes are repressed directly by thyroid hormones acting through the thyroid hormone receptor, a member of the nuclear receptor family. Steroidogenic enzyme gene expression requires specific transcription factors such as steroidogenic factor-1 (SF-1), acting in conjunction with signals transmitted by trophic hormones (e.g., ACTH or LH). For some hormones, substantial regulation occurs at the level of translational efficiency. Insulin biosynthesis, while requiring ongoing gene transcription, is regulated primarily at the translational level in response to elevated levels of glucose or amino acids.

Many hormones are embedded within larger precursor polypeptides that are proteolytically processed to yield the biologically active hormone. Examples include: proopiomelanocortin (POMC)® ACTH; proglucagon® glucagon; proinsulin® insulin; pro-PTH ®PTH, among others. In many cases, such as POMC and proglucagon, these precursors generate multiple biologically active peptides. It is provocative that hormone precursors are typically inactive, presumably adding an additional level of regulatory control. This is true not only for peptide hormones but also for certain steroids (testosterone ®dihydrotestosterone) and thyroid hormone (T_4®T_3).

Hormone precursor processing is intimately linked to intracellular sorting pathways that transport proteins to appropriate vesicles and enzymes, resulting in specific cleavage steps, followed by protein folding and translocation to secretory vesicles. Hormones

destined for secretion are translocated across the endoplasmic reticulum under the guidance of an amino-terminal signal sequence that is subsequently cleaved. Cell-surface receptors are inserted into the membrane via short segments of hydrophobic amino acids that remain embedded within the lipid bilayer. During translocation through the Golgi and endoplasmic reticulum, hormones and receptors are also subject to a variety of posttranslational modifications, such as glycosylation and phosphorylation, which can alter protein conformation, modify circulating half-life, and alter biologic activity.

Synthesis of most steroid hormones is based on modifications of the precursor, cholesterol. Multiple regulated enzymatic steps are required for the synthesis of testosterone (Chap. 335), estradiol (Chap. 336), cortisol (Chap. 331), and vitamin D (Chap. 340). This large number of synthetic steps predisposes to multiple genetic and acquired disorders of steroidogenesis (see below).

HORMONE SECRETION, TRANSPORT, AND DEGRADATION

The circulating level of a hormone is determined by its rate of secretion and its circulating half-life. After protein processing, peptide hormones (GnRH, insulin, GH) are stored in secretory granules. As these granules mature, they are poised beneath the plasma membrane for imminent release into the circulation. In most instances, the stimulus for hormone secretion is a releasing factor or neural signal that induces rapid changes in intracellular calcium concentrations, leading to secretory granule fusion with the plasma membrane and release of its contents into the extracellular environment and blood stream. Steroid hormones, in contrast, diffuse into the circulation as they are synthesized. Thus, their secretory rates are closely aligned with rates of synthesis. For example, ACTH and LH induce steroidogenesis by stimulating the activity of *st*eroidogenic *a*cute *r*egulatory (StAR) protein (transports cholesterol into the mitochondrion) along with other rate-limiting steps (e.g., cholesterol side-chain cleavage enzyme, CYP11A1) in the steroidogenic pathway.

Hormone transport and degradation dictate the rapidity with which a hormonal signal decays. Some hormonal signals are evanescent (e.g., somatostatin), whereas others are longer lived (e.g., TSH). Because somatostatin exerts effects in virtually every tissue, a short half-life allows it concentrations and actions to be controlled locally. Structural modifications that impair somatostatin degradation have been useful for generating long-acting therapeutic analogues, such as octreotide (Chap. 328). On the other hand, the actions of TSH are highly specific for the thyroid gland. Its prolonged half-life accounts for relatively constant serum levels, even though TSH is secreted in discrete pulses.

An understanding of circulating hormone half-life is important for achieving physiologic hormone replacement, as the frequency of dosing and the time required to reach steady state are intimately linked to rates of hormone decay. T_4, for example, has a plasma half-life of 7 days. Consequently,>1 month is required to reach a new steady state, but single daily doses are sufficient to achieve constant hormone levels. T_3, in contrast, has a half-life of 1 day. Its administration is associated with more dynamic serum levels and it must be administered two to three times per day. Similarly, synthetic glucocorticoids vary widely in their half-lives; those with longer half-lives (e.g., dexamethasone) are

associated with greater suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Most protein hormones [e.g., ACTH, GH, prolactin (PRL); PTH, LH] have relatively short half-lives (<20 min), leading to sharp peaks of secretion and decay. The only accurate way to profile the pulse frequency and amplitude of these hormones is to measure levels in frequently sampled blood (every 10 min) over long durations (8 to 24 h). Because this is not practical in a clinical setting, an alternative strategy is to pool three to four samples drawn at about 30-min intervals, recognizing that pulsatile secretion makes it difficult to establish a narrow normal range. Rapid hormone decay is useful in certain clinical settings. For example, the short half-life of PTH allows the use of intraoperative PTH determinations to confirm successful removal of an adenoma. This is particularly valuable diagnostically when there is a possibility of multicentric disease or parathyroid hyperplasia, as occurs with multiple endocrine neoplasia (MEN) or renal insufficiency.

Many hormones circulate in association with serum-binding proteins. Examples include: (1) T_4 and T_3binding to thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin (TBPA); (2) cortisol binding to cortisol-binding globulin (CBG); (3) androgen and estrogen binding to sex hormone-binding globulin (SHBG) (also called testosterone-binding globulin, TeBG); (4)IGF-I and -II binding to multiple IGF-binding proteins (IGFBPs); (5) GH interactions with GH-binding protein (GHBP), a circulating fragment of the GH receptor extracellular domain; and (6) activin binding to follistatin. These interactions provide a hormonal reservoir, prevent otherwise rapid degradation of unbound hormones, restrict hormone access to certain sites (e.g., IGFBPs), and modulate the unbound, or "free," hormone concentrations. Although a variety of binding protein abnormalities have been identified, most have little clinical consequence, aside from creating diagnostic problems. For example, TBG deficiency can greatly reduce total thyroid hormone levels, but the free concentrations of T_4 and T_3remain normal. Liver disease and certain medications can also influence binding protein levels (e.g., estrogen increases TBG) or cause displacement of hormones from binding proteins (e.g., salsalate displaces T_4 from TBG). Only free hormone is available to bind receptors and thereby elicit a biologic response. Short-term perturbations in binding proteins change the free hormone concentration, which in turn induces compensatory adaptations through feedback loops. SHBG changes in women are an exception to this self-correcting mechanism. When SHBG decreases because of insulin resistance or androgen excess, the free testosterone concentration is increased, potentially leading to hirsutism (Chap. 53). The increased free testosterone levels does not result in an adequate compensatory feedback correction because estrogen, and not testosterone, is the primary regulator of the reproductive axis.

HORMONE ACTION THROUGH RECEPTORS

Receptors for hormones are divided into two major classes -- membrane and nuclear. *Membrane receptors* primarily bind peptide hormones and catecholamines. *Nuclear receptors* bind small molecules that can diffuse across the cell membrane, such as thyroid hormone, steroids, and vitamin D. Certain general principles apply to hormone-receptor interactions, regardless of the class of receptor. Hormones bind to receptors with specificity and a high affinity that generally coincides with the dynamic range of circulating hormone concentrations. Low concentrations of free hormone (usually $10^{-12}$to 10^{-9}*M*) rapidly associate and dissociate from receptors in a bimolecular

reaction, such that the occupancy of the receptor at any given moment is a function of hormone concentration and the receptor's affinity for the hormone. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of specific cellular responses to circulating hormones. For example, ACTH receptors are located almost exclusively in the adrenal cortex, and FSH receptors are found only in the gonads. In contrast, insulin and thyroid hormone receptors are widely distributed, reflecting the need for metabolic responses in all tissues.

MEMBRANE RECEPTORS

Membrane receptors for hormones can be divided into several major groups: (1) seven transmembraneGPCRs, (2) tyrosine kinase receptors, (3) cytokine receptors, and (4) serine kinase receptors (Fig. 327-1). The *seven transmembrane GPCR* family binds a remarkable array of hormones including large proteins (e.g., LH, PTH), small peptides (e.g.,TRH, somatostatin), catecholamines (epinephrine, dopamine), and even minerals (e.g., calcium). The extracellular domains of GPCRs vary widely in size and are the major binding site for large hormones. The transmembrane-spanning regions are composed of hydrophobic a-helical domains that traverse the lipid bilayer. Like some channels, these domains are thought to circularize and form a hydrophobic pocket into which certain small ligands fit. Hormone binding induces conformational changes in these domains, transducing structural changes to the intracellular domain, which is a docking site for G proteins.

The large family of *G proteins*, so named because they bind guanine nucleotides (GTP, GDP), provides great diversity for coupling to different receptors. G proteins form a heterotrimeric complex that is composed of various aand bg subunits. The asubunit contains the guanine nucleotide-binding site and hydrolyzes GTP® GDP. The bg subunits are tightly associated and modulate the activity of thea subunit, as well as mediating their own effector signaling pathways. G protein activity is regulated by a cycle that involves GTP hydrolysis and dynamic interactions between the a andbg subunits. Hormone binding to the receptor induces GDP dissociation, allowing Ga to bind GTP and dissociate from the bg complex. Under these conditions, the Ga subunit is activated and mediates signal transduction through various enzymes such as adenylate cyclase or phospholipase C. GTP hydrolysis to GDP allows reassociation with thebg subunits and restores the inactive state. As described below, a variety of endocrinopathies result from G protein mutations or from mutations in receptors that modify their interactions with G proteins.

There are more than a dozen isoforms of the Ga subunit. $G_s$astimulates, whereas $G_i$ainhibits adenylate cyclase, an enzyme that generates the second messenger, cyclic AMP, leading to activation of protein kinase A (Table 327-1). $G_q$subunits couple to phospholipase C, generating diacylglycerol and inositol triphosphate, leading to activation of protein kinase C and the release of intracellular calcium.

The *tyrosine kinase receptors* transduce signals for insulin and a variety of growth factors, such asIGF-I, epidermal growth factor (EGF), nerve growth factor, platelet-derived growth factor, and fibroblast growth factor. The cysteine-rich extracellular ligand-binding domains contain growth factor binding sites. After ligand binding, this class of receptors undergoes autophosphorylation, inducing interactions

with intracellular adaptor proteins such as Shc and insulin receptor substrates 1 to 4. In the case of the insulin receptor, multiple kinases are activated including the Raf-Ras-MAPK and the Akt/protein kinase B pathways. The tyrosine kinase receptors play a prominent role in cell growth and differentiation as well as in intermediary metabolism.

The GH and PRL receptors belong to the *cytokine receptor* family (Chap. 305). Analogous to the tyrosine kinase receptors, ligand binding induces receptor binding to intracellular kinases -- the Janus kinases (JAKs), which phosphorylate members of the signal transduction and activators of transcription (STAT) family -- as well as other signaling pathways (Ras, PI3-K, MAPK). The activated STAT proteins translocate to the nucleus and stimulate expression of target genes (Chap. 328).

The *serine kinase receptors* mediate the actions of activins, transforming growth factor b, mullerian-inhibiting substance (MIS, also known as anti-mullerian hormone, AMH), and bone morphogenic proteins (BMPs). This family of receptors (consisting of type I and II subunits) signal through proteins termed *smads* (fusion of terms for *Caenorhabditis elegans* sma + mammalian mad). Like theSTATproteins, the smads serve a dual role of transducing the receptor signal and acting as transcription factors. The pleomorphic actions of these growth factors dictate that they act primarily in a local (paracrine or autocrine) manner. Binding proteins, such as follistatin (which binds activin and other members of this family), function to inactivate the growth factors and restrict their distribution.

NUCLEAR RECEPTORS

The family of nuclear receptors has grown to nearly 100 members, many of which are still classified as orphan receptors because their ligands, if they exist, remain to be identified (Fig. 327-2). Otherwise, most nuclear receptors are classified based on the nature of their ligands. Though all nuclear receptors ultimately act to increase or decrease gene transcription, some (e.g., glucocorticoid receptor) reside primarily in the cytoplasm, whereas others (e.g., thyroid hormone receptor) are always located in the nucleus. After ligand binding, the cytoplasmically localized receptors translocate to the nucleus.

The structures of nuclear receptors have been extensively studied, including by x-ray crystallography. The DNA binding domain, consisting of two zinc fingers, contacts specific DNA recognition sequences in target genes. Most nuclear receptors bind to DNA as dimers. Consequently, each monomer recognizes an individual DNA motif, referred to as a "half-site." The steroid receptors, including the glucocorticoid, estrogen, progesterone, and androgen receptors, bind to DNA as homodimers. Consistent with this twofold symmetry, their DNA recognition half-sites are palindromic. The thyroid, retinoid, PPAR, and vitamin D receptors bind to DNA preferentially as heterodimers in combination with retinoid X receptors (RXRs). Their DNA half-sites are arranged as direct repeats. Receptor specificity for DNA sequences is determined by (1) the sequence of the half-site, (2) the orientation of the half-sites (palindromic, direct repeat), and (3) the spacing between the half-sites. For example, vitamin D, thyroid and retinoid receptors recognize similar tandemly repeated half-sites (TAAGTCA), but these DNA repeats are spaced by three, four, and five nucleotides, respectively.

The carboxy-terminal hormone-binding domain mediates transcriptional control. For type II receptors, such as TR and RAR, co-repressor proteins bind to the receptor in the absence of ligand and silence gene transcription. Hormone binding induces conformational changes, triggering the release of co-repressors and inducing the recruitment of coactivators that stimulate transcription. Thus, these receptors are capable of mediating dramatic changes in the level of gene activity. Certain disease states are associated with defective regulation of these events. For example, mutations in the thyroid hormone receptor prevent co-repressor dissociation, resulting in a dominant form of hormone resistance (Chap. 330). In promyelocytic leukemia, fusion of RARa to other nuclear proteins causes aberrant gene silencing and prevents normal cellular differentiation. Treatment with retinoic acid reverses this repression and allows cellular differentiation and apoptosis to occur (Chap. 111). Type 1 steroid receptors do not interact with co-repressors, but ligand binding still mediates interactions with an array of coactivators. X-ray crystallography shows that variousSERMsinduce distinct receptor conformations. The tissue-specific responses caused by these agents in breast, bone, and uterus appear to reflect distinct interactions with coactivators. The receptor-coactivator complex stimulates gene transcription by several pathways including (1) recruitment of enzymes (histone acetyl transferases) that modify chromatin structure, (2) interactions with additional transcription factors on the target gene, and (3) direct interactions with components of the general transcription apparatus to enhance the rate of RNA polymerase II-mediated transcription.

FUNCTIONS OF HORMONES

The functions of individual hormones are described in detail in subsequent chapters. Nonetheless, it is useful to illustrate how most biologic responses require integration of several different hormonal pathways. The physiologic functions of hormones can be divided into three general areas: (1) growth and differentiation, (2) maintenance of homeostasis, and (3) reproduction.

GROWTH

Multiple hormones and nutritional factors mediate the complex phenomenon of growth (Chap. 328). Short stature may be caused by GH deficiency, hypothyroidism, Cushing's syndrome, precocious puberty, malnutrition or chronic illness, or genetic abnormalities that affect the epiphyseal growth plates (e.g., *FGFR3* or *SHOX* mutations). Many factors (GH,IGF-I, thyroid hormone) stimulate growth, whereas others (sex steroids) lead to epiphyseal closure. Understanding these hormonal interactions is important in the diagnosis and management of growth disorders. For example, delaying exposure to high levels of sex steroids may enhance the efficacy of GH treatment.

MAINTENANCE OF HOMEOSTASIS

Though virtually all hormones affect homeostasis, the most important among these are the following:

1. Thyroid hormone -- controls about 25% of basal metabolism in most tissues (Chap. 330)

2. Cortisol -- exerts a permissive action for many hormones in addition to its own direct effects (Chap. 331)

3. PTH -- regulates calcium and phosphorus levels (Chap. 341)

4. Vasopressin -- regulates serum osmolality by controlling renal free water clearance (Chap. 329)

5. Mineralocorticoids -- control vascular volume and serum electrolyte (Na^+, K^+) concentrations (Chap. 331)

6. Insulin -- maintains euglycemia in the fed and fasted states (Chap. 333)

The defense against hypoglycemia is an impressive example of integrated hormone action (Chap. 334). In response to the fasted state and falling blood glucose, insulin secretion is suppressed, resulting in decreased glucose uptake and enhanced glycogenolysis, lipolysis, proteolysis, and gluconeogenesis to mobilize fuel sources. If hypoglycemia develops (usually from insulin administration or sulfonylureas), an orchestrated counterregulatory response occurs -- glucagon and epinephrine rapidly stimulate glycogenolysis and gluconeogenesis, whereas GH and cortisol act over several hours to raise glucose levels and antagonize insulin action.

Although free water clearance is primarily controlled by vasopressin, cortisol and thyroid hormone are also important for facilitating renal tubular responses to vasopressin effects (Chap. 329). PTH and vitamin D function in an interdependent manner to control calcium metabolism (Chap. 340). PTH stimulates renal synthesis of 1,25 dihydroxyvitamin D, which increases calcium absorption in the gastrointestinal tract and enhances PTH action in bone. Increased calcium, along with vitamin D, feeds back to suppress PTH, thereby maintaining calcium balance.

Depending on the severity of a given stress and whether it is acute or chronic, multiple endocrine and cytokine pathways are activated to mount an appropriate physiologic response (Chap. 328). In severe acute stress such as trauma or shock, the sympathetic nervous system is activated and catecholamines are released, leading to increased cardiac output and a primed musculoskeletal system. Catecholamines also increase mean blood pressure and stimulate glucose production (Chap. 72). Multiple stress-induced pathways converge on the hypothalamus, stimulating several hormones including vasopressin and corticotropin-releasing hormone (CRH). These hormones, in addition to cytokines (tumor necrosis factor a, IL-2, IL-6), increase ACTH and GH production. ACTH stimulates the adrenal gland, increasing cortisol, which in turn helps to sustain blood pressure and dampen the inflammatory response. Increased vasopressin acts to conserve free water.

REPRODUCTION

The stages of reproduction include: (1) sex determination during fetal development (Chap. 338); (2) sexual maturation during puberty (Chap. 8); (3) conception, pregnancy, lactation, and child-rearing (Chap. 336), and (4) cessation of reproductive capability at

menopause. Each of these stages involves an orchestrated interplay of multiple hormones, a phenomenon well illustrated by the dynamic hormonal changes that occur during each 28-day menstrual cycle. In the early follicular phase, pulsatile secretion of LH and FSH stimulate the progressive maturation of the ovarian follicle. This results in a gradual increase of estrogen and progesterone leading to enhanced pituitary sensitivity toGnRH, which, when combined with accelerated GnRH secretion, triggers the LH surge and rupture of the mature follicle. Inhibin, a protein produced by the granulosa cells, enhances follicular growth and feeds back to the pituitary to selectively suppress FSH, without affecting LH. Growth factors, such asEGF andIGF-I modulate follicular responsiveness to gonadotropins. Vascular endothelial growth factor and prostaglandins play a role in follicle vascularization and rupture.

During pregnancy, the increased production of prolactin, in combination with placentally derived steroids (e.g., estrogen and progesterone), prepares the breast for lactation (Chap. 337). Estrogens induce the production of progesterone receptors, allowing for increased responsiveness to progesterone. In addition to these and other hormones involved in lactation, the nervous system and oxytocin mediate the suckling response and milk release.

HORMONAL FEEDBACK REGULATORY SYSTEMS

Feedback control, both negative and positive, is a fundamental feature of endocrine systems. Each of the major hypothalamic-pituitary-hormone axes is governed by negative feedback, a process that maintains hormone levels within a relatively narrow range (Chap. 328). Examples of hypothalamic-pituitary negative feedback include (1) thyroid hormones on theTRH-TSH axis, (2) cortisol on theCRH-ACTH axis, (3) gonadal steroids on theGnRH-LH/FSH axis, and (4)IGF-I on the growth hormone-releasing hormone (GHRH)-GH axis (Fig. 327-3). These regulatory loops include both positive (e.g., TRH, TSH) and negative components (e.g., T_4, T_3), allowing for exquisite control of hormone levels. As an example, a small reduction of thyroid hormone triggers a rapid increase of TRH and TSH secretion, resulting in thyroid gland stimulation and increased thyroid hormone production. When the thyroid hormone reaches a normal level, it feeds back to suppress TRH and TSH, and a new steady state is attained. Feedback regulation also occurs for endocrine systems that do not involve the pituitary gland, such as calcium feedback on PTH, glucose inhibition of insulin secretion, and leptin feedback on the hypothalamus. An understanding of feedback regulation provides important insights into endocrine testing paradigms (see below).

Positive feedback control also occurs but is not well understood. The primary example is estrogen-mediated stimulation of the midcycle LH surge. Though chronic low levels of estrogen are inhibitory, gradually rising estrogen levels stimulate LH secretion. This effect, which is illustrative of an endocrine rhythm (see below), involves activation of the hypothalamicGnRHpulse generator. In addition, estrogen-primed gonadotropes are extroardinarily sensitive to GnRH, leading to a 10- to 20-fold amplification of LH release.

PARACRINE AND AUTOCRINE CONTROL

The aforementioned examples of feedback control involve classic endocrine pathways in which hormones are released by one gland and act on a distant target gland.

However, local regulatory systems, often involving growth factors, are increasingly recognized. *Paracrine regulation* refers to factors released by one cell that act on an adjacent cell in the same tissue. For example, somatostatin secretion by pancreatic islet d cells inhibits insulin secretion from nearby b cells. *Autocrine regulation* describes the action of a factor on the same cell from which it is produced.IGF-I acts on many cells that produce it, including chondrocytes, breast epithelium, and gonadal cells. Unlike endocrine actions, paracrine and autocrine control are difficult to document because local growth factor concentrations cannot be readily measured.

Anatomic relationships of glandular systems also greatly influence hormonal exposure -- the physical organization of islet cells enhances their intercellular communication; the portal vasculature of the hypothalamic-pituitary system exposes the pituitary to high concentrations of hypothalamic releasing factors; testicular seminiferous tubules gain exposure to high testosterone levels produced by the interdigitated Leydig cells; the pancreas receives nutrient information from the gastrointestinal tract; and the liver is the proximal target of insulin action because of portal drainage from the pancreas.

HORMONAL RHYTHMS

The feedback regulatory systems described above are superimposed on hormonal rhythms that are used for adaptation to the environment. Seasonal changes, the daily occurrence of the light-dark cycle, sleep, meals, and stress are examples of the many environmental events that affect hormonal rhythms. The *menstrual cycle* is repeated on average every 28 days, reflecting the time required to follicular maturation and ovulation (Chap. 336). Essentially all pituitary hormone rhythms are entrained to sleep and the *circadian cycle*, generating reproducible patterns that are repeated approximately every 24 h. TheHPAaxis, for example, exhibits characteristic peaks of ACTH and cortisol production in the early morning, with a nadir in the afternoon and evening. Recognition of these rhythms is important for endocrine testing and treatment. Patients with Cushing's syndrome characteristically exhibit increased midnight cortisol levels when compared to normal individuals (Chap. 331). In contrast, morning cortisol levels are similar in these groups, as cortisol is normally high at this time of day in normal individuals. The HPA axis is more susceptible to suppression by glucocorticoids administered at night as they blunt the early morning rise of ACTH. Understanding these rhythms allows glucocorticoid replacement that mimics diurnal production by administering larger doses in the morning than in the afternoon (Chap. 331).

Other endocrine rhythms occur on a more rapid time scale. Many peptide hormones are secreted in discrete bursts every few hours. LH and FSH secretion are exquisitely sensitive toGnRHpulse frequency. Intermittent pulses of GnRH are required to maintain pituitary sensitivity, whereas continuous exposure to GnRH causes pituitary gonadotrope desensitization. This feature of the hypothalamic-pituitary-gonadotrope (HPG) axis forms the basis for using long-acting GnRH agonists to treat central precocious puberty or to decrease testosterone levels in the management of prostate cancer.

It is important to be aware of the pulsatile nature of hormone secretion and the rhythmic patterns of hormone production when relating serum hormone measurements to normal values. For some hormones, integrated markers have been developed to circumvent

hormonal fluctuations. Examples include 24-h urine collections for cortisol,IGF-I as a biologic marker of GH action, and HbA1c as an index of long-term (weeks to months) blood glucose control.

Often, one must interpret endocrine data only in the context of other hormonal results. For example, parathyroid hormone levels are typically assessed in combination with serum calcium concentrations. A high serum calcium level in association with elevated PTH is suggestive of hyperparathyroidism, whereas a suppressed PTH in this situation is more likely to be caused by hypercalcemia of malignancy or other causes of hypercalcemia. Similarly, TSH should be elevated when T_4 and T_3concentrations are low, reflecting reduced feedback inhibition. When this is not the case, it is important to consider other abnormalities in the hormonal axis, such as secondary hypothyroidism, which is caused by a defect at the level of the pituitary.

PATHOLOGIC MECHANISMS OF ENDOCRINE DISEASE

Endocrine diseases can be divided into three major types of conditions: (1) hormone excess, (2) hormone deficiency, and (3) hormone resistance (Table 327-2).

CAUSES OF HORMONE EXCESS

Syndromes of hormone excess can be caused by neoplastic growth of endocrine cells, autoimmune disorders, and excess hormone administration. Benign endocrine tumors, including parathyroid, pituitary, and adrenal adenomas, often retain the capacity to produce hormones, perhaps reflecting the fact that they are relatively well differentiated. Many endocrine tumors exhibit relatively subtle defects in their "set points" for feedback regulation. For example, in Cushing's disease, impaired feedback inhibition of ACTH secretion is associated with autonomous function. However, the tumor cells are not completely resistant to feedback, as revealed by the fact that ACTH is ultimately suppressed by higher doses of dexamethasone (e.g., high-dose dexamethasone test) (Chap. 331). Similar set point defects are also typical of parathyroid adenomas and autonomously functioning thyroid nodules.

The molecular basis of some endocrine tumors, such as theMENsyndromes (MEN-1, -2A, -2B), have provided important insights into tumorigenesis (Chap. 339). MEN-1 is characterized primarily by the triad of parathyroid, pancreatic islet, and pituitary tumors. MEN-2 predisposes to medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. The *MEN1* gene, located on chromosome 11q13, encodes a putative tumor-suppressor gene. Analogous to the paradigm first described for retinoblastoma, the affected individual inherits a mutant copy of the *MEN1* gene, and tumorigenesis ensues after a somatic "second hit" leads to loss of function of the normal *MEN1* gene (through deletion or point mutations).

In contrast to inactivation of a tumor-suppressor gene, as occurs inMEN-1 and most other inherited cancer syndromes, MEN-2 is caused by activating mutations in a single allele. In this case, activating mutations of the *RET* proto-oncogene, which encodes a receptor tyrosine kinase, leads to thyroid C-cell hyperplasia in childhood before the development of medullary thyroid carcinoma. Elucidation of the pathogenic mechanism has allowed early genetic screening for *RET* mutations in individuals at risk for MEN-2,

permitting identification of those who may benefit from prophylactic thyroidectomy and biochemical screening for pheochromocytoma and hyperparathyroidism.

Mutations that activate hormone receptor signaling have been identified in severalGPCRs(Table 327-3). For example, activating mutations of the LH receptor causes a dominantly transmitted form of male-limited precocious puberty, reflecting premature stimulation of testosterone synthesis in Leydig cells (Chap. 335). Activating mutations in these GPCRs are located primarily in the transmembrane domains and induce receptor coupling to G_sa, even in the absence of hormone. Consequently, adenylate cyclase is activated and cyclic AMP levels increase in a manner that mimics hormone action. A similar phenomenon results from activating mutations in G_sa. When these occur early in development, they cause McCune-Albright syndrome. When they occur only in somatotropes, the activating $G_s$amutations cause GH-secreting tumors and acromegaly (Chap. 328).

In autoimmune Graves' disease, antibody interactions with the TSH receptor mimic TSH action, leading to hormone overproduction (Chap. 330). Analogous to the effects of activating mutations of the TSH receptor, these stimulating autoantibodies induce conformational changes that release the receptor from a constrained state, thereby triggering receptor coupling to G proteins.

CAUSES OF HORMONE DEFICIENCY

Most examples of hormone deficiency states can be attributed to glandular destruction caused by autoimmunity, surgery, infection, inflammation, infarction, hemorrhage, or tumor infiltration (Table 327-2). Autoimmune damage to the thyroid gland (Hashimoto's thyroiditis) and pancreatic islet b cells (type 1 diabetes mellitus) are prevalent causes of endocrine disease. Mutations in a number of hormones, hormone receptors, transcription factors, enzymes, and channels can also lead to hormone deficiencies (Table 327-3).

HORMONE RESISTANCE

Most severe hormone resistance syndromes are due to inherited defects in membrane receptors, nuclear receptors, or in the pathways that transduce receptor signals (Table 327-3). These disorders are characterized by defective hormone action, despite the presence of increased hormone levels. In complete androgen resistance, for example, mutations in the androgen receptor cause genetic (XY) males to have a female phenotypic appearance, even though LH and testosterone levels are increased (Chap. 338). In addition to these relatively rare genetic disorders, more common acquired forms of functional hormone resistance include insulin resistance in type 2 diabetes mellitus, leptin resistance in obesity, and GH resistance in catabolic states. The pathogenesis of functional resistance involves receptor downregulation and postreceptor desensitization of signaling pathways; functional forms of resistance are generally reversible.

Approach to the Patient

Because endocrinology interfaces with numerous physiologic systems, there is no standard endocrine history and examination. Moveover, because most glands are

relatively inaccessible, the examination usually focuses on the manifestations of hormone excess or deficiency, as well as direct examination of palpable glands, such as the thyroid and gonads. For these reasons, it is important to evaluate patients in the context of their presenting symptoms, review of systems, family and social history, and exposure to medications that may affect the endocrine system. Astute clinical skills are required to detect subtle symptoms and signs suggestive of underlying endocrine disease. For example, a patient with Cushing's syndrome may manifest specific findings, such as central fat redistribution, striae, and proximal muscle weakness, in addition to features seen commonly in the general population, such as obesity, plethora, hypertension, and glucose intolerance. Similarly, the insidious onset of hypothyroidism -- with mental slowing, fatigue, dry skin, and other features -- can be difficult to distinguish from similar, nonspecific findings in the general population. Clinical judgment, based on knowledge of pathophysiology and experience, is required to decide when to embark on more extensive evaluation of these disorders. As described below, laboratory testing plays an essential role in endocrinology by allowing quantitative assessment of hormone levels and dynamics. Radiologic imaging tests, such as CT scan, MRI, thyroid scan, and ultrasound, are also used for the diagnosis of endocrine disorders. However, these tests are generally employed only after a hormonal abnormality has been established by biochemical testing.

Hormone Measurements and Endocrine Testing Radioimmunoassays are the most important diagnostic tool in endocrinology, as they allow sensitive, specific, and quantitative determination of steady-state and dynamic changes in hormone concentrations. Radioimmunoassays use antibodies to detect specific hormones. For many peptide hormones, these measurements are now configured as immunoradiometric assays (IRMAs), which use two different antibodies to increase binding affinity and specificity. There are many variations of these assays -- a common format involves using one antibody to capture the antigen (hormone) onto an immobilized surface and a second antibody, labeled with a fluorescent or radioactive tag, to detect the antigen. These assays are sensitive enough to detect plasma hormone concentrations in the picomolar to nanomolar range, and they can readily distinguish structurally related proteins, such as PTH fromPTHrP. A variety of other techniques are used to measure specific hormones, including mass spectroscopy, various forms of chromatography, and enzymatic methods; bioassays are now used rarely.

Most hormone measurements are based on plasma or serum samples. However, urinary hormone determinations remain useful for the evaluation of some conditions. Urinary collections over 24 h provide an integrated assessment of the production of a hormone or metabolite, many of which vary during the day. It is important to assure complete collections of 24-h urine samples; simultaneous measurement of creatinine provides an internal control for the adequacy of collection and can be used to normalize some hormone measurements. A 24-h urine free cortisol measurement largely reflects the amount of unbound cortisol, thus providing a reasonable index of biologically available hormone. Other commonly used urine determinations include: 17-hydroxycorticosteroids, 17-ketosteroids, vanillylmandelic acid (VMA), metanephrine, catecholamines, 5-hydroxyindoleacetic acid (5-HIAA), and calcium.

The value of quantitative hormone measurements lies in their correct interpretation in a

clinical context. The normal range for most hormones is relatively broad, often varying by a factor of two- to tenfold. The normal ranges for many hormones are gender- and age-specific. Thus, using the correct normative database is an essential part of interpreting hormone tests. The pulsatile nature of hormones and factors that can affect their secretion, such as sleep, meals, and medications, must also be considered. Cortisol values increase fivefold between midnight and dawn; reproductive hormone levels vary dramatically during the female menstrual cycle.

For many endocrine systems, much information can be gained from basal hormone testing, particularly when different components of an endocrine axis are assessed simultaneously. For example, low testosterone and elevated LH levels suggest a primarily gonadal problem, whereas a hypothalamic-pituitary disorder is likely if both LH and testosterone are low. Because TSH is a sensitive indicator of thyroid function, it is generally recommended as a first-line test for thyroid disorders. An elevated TSH level is almost always the result of primary hypothyroidism, whereas a low TSH is most often caused by thyrotoxicosis. These predictions can be confirmed by determining the free thyroxine level. Elevated calcium and PTH levels suggest hyperparathyroidism, whereas PTH is suppressed in hypercalcemia caused by malignancy or granulomatous diseases. A suppressed ACTH in the setting of hypercortisolemia, or increased urine free cortisol, is seen with hyperfunctioning adrenal adenomas.

It is not uncommon, however, for baseline hormone levels associated with pathologic endocrine conditions to overlap with the normal range. In this circumstance, dynamic testing is useful to further separate the two groups. There are a multitude of dynamic endocrine tests, but all are based on principles of feedback regulation, and most responses can be remembered based on the pathways that govern endocrine axes. *Suppression tests* are used in the setting of suspected endocrine hyperfunction. An example is the dexamethasone suppression test used to evaluate Cushing's syndrome (Chaps. 328 and331). *Stimulation tests* are generally used to assess endocrine hypofunction. The ACTH stimulation test, for example, is used to assess the adrenal gland response in patients with suspected adrenal insufficiency. Other stimulation tests use hypothalamic-releasing factors such asTRH,GnRH,CRH, andGHRH to evaluate pituitary hormone reserve (Chap. 328). Insulin-induced hypoglycemia evokes pituitary ACTH and GH responses. Stimulation tests based on reduction or inhibition of endogenous hormones are less commonly used. Examples include metyrapone inhibition of cortisol synthesis and clomiphene inhibition of estrogen feedback.

Screening and Assessment of Common Endocrine Disorders Because many endocrine disorders are prevalent in the adult population (Table 327-4), most are diagnosed and managed by general internists, family practitioners, or other primary health care providers. The high prevalence and clinical impact of certain endocrine diseases justifies vigilance for features of these disorders during routine physical examinations; laboratory screening is indicated in selected high-risk populations.

328. DISORDERS OF THE ANTERIOR PITUITARY AND HYPOTHALAMUS - *Shlomo Melmed*

The anterior pituitary is often referred to as the "master gland" because, together with the hypothalamus, it orchestrates the complex regulatory functions of multiple other endocrine glands. The anterior pituitary gland produces six major hormones: (1) prolactin (PRL), (2) growth hormone (GH), (3) adrenocorticotropin hormone (ACTH), (4) luteinizing hormone (LH), (5) follicle-stimulating hormone (FSH), and (6) thyroid-stimulating hormone (TSH) (Table 328-1). Pituitary hormones are secreted in a pulsatile manner, reflecting stimulation by an array of specific hypothalamic releasing factors. Each of these pituitary hormones elicits specific responses in peripheral target tissues. The hormonal products of these peripheral glands, in turn, exert feedback control at the level of the hypothalamus and pituitary to modulate pituitary function (Fig. 328-1). Pituitary tumors cause characteristic hormone excess syndromes. Hormone deficiency may be inherited or acquired. Fortunately, efficacious treatments exist for the various pituitary hormone excess and deficiency syndromes. Nonetheless, these diagnoses are often elusive, emphasizing the importance of recognizing subtle clinical manifestations and performing the correct laboratory diagnostic tests.**For discussion of disorders of the posterior pituitary, or neurohypophysis, see Chap. 329.*

ANATOMY AND DEVELOPMENT

Anatomy The pituitary gland weighs ~600 mg and is located within the sella turcica ventral to the diaphragma sella; it comprises anatomically and functionally distinct anterior and posterior lobes. The sella is contiguous to vascular and neurologic structures, including the cavernous sinuses, cranial nerves, and optic chiasm. Thus, expanding intrasellar pathologic processes may have significant central mass effects in addition to their endocrinologic impact.

Hypothalamic neural cells synthesize specific releasing and inhibiting hormones that are secreted directly into the portal vessels of the pituitary stalk. Blood supply of the pituitary gland is derived from the superior and inferior hypophyseal arteries (Fig. 328-2). The hypothalamic-pituitary portal plexus provides the major blood source for the anterior pituitary, allowing reliable transmission of hypothalamic peptide pulses without significant systemic dilution; consequently, pituitary cells are exposed to sharp spikes of releasing factors and in turn release their hormones as discrete pulses (Fig. 328-3).

The posterior pituitary is supplied by the inferior hypophyseal arteries. In contrast to the anterior pituitary, the posterior lobe is directly innervated by hypothalamic neurons (supraopticohypophyseal and tuberohypophyseal nerve tracts) via the pituitary stalk (Chap. 329). Thus, posterior pituitary production of vasopressin (antidiuretic hormone; ADH) and oxytocin is particularly sensitive to neuronal damage by lesions that affect the pituitary stalk or hypothalamus.

Pituitary Development The embryonic differentiation and maturation of anterior pituitary cells have been elucidated in considerable detail. Pituitary development from Rathke's pouch involves a complex interplay of lineage-specific transcription factors expressed in pluripotential stem cells and gradients of locally produced growth factors (Table 328-1). The transcription factor Pit-1 determines cell-specific expression

ofGH,PRL, andTSH in somatotropes, lactotropes, and thyrotropes. Expression of high levels of estrogen receptors in cells that contain Pit-1 favors PRL expression, whereas thyrotrope embronic factor (TEF) induces TSH expression. Pit-1 binds to GH, PRL, and TSH gene regulatory elements, as well as to recognition sites on its own promoter, providing a mechanism for perpetuating selective pituitary phenotypic stability. The transcription factor Prop-1 induces the pituitary development of Pit-1-specific lineages, as well as gonadotropes. Gonadotrope cell development is further defined by the cell-specific expression of the nuclear receptors, steroidogenic factor (SF-1) and DAX-1. Development of corticotrope cells, which express the proopiomelanocortin (POMC) gene, requires corticotropin upstream transcription element (CUTE) and the PTX-1 transcription factor. Abnormalities of pituitary development caused by mutations of Pit-1, Prop-1, SF-1, and DAX-1 result in a series of rare, selective or combined, pituitary hormone deficits.

HYPOTHALAMIC AND ANTERIOR PITUITARY INSUFFICIENCY

Hypopituitarism results from impaired production of one or more of the anterior pituitary trophic hormones. Reduced pituitary function can result from inherited disorders; more commonly, it is acquired and reflects the mass effects of tumors or the consequences of inflammation or vascular damage. These processes may also impair synthesis or secretion of hypothalamic hormones, with resultant pituitary failure (Table 328-2).

DEVELOPMENTAL AND GENETIC CAUSES OF HYPOPITUITARISM

Pituitary Dysplasia Pituitary dysplasia may result in aplastic, hypoplastic, or ectopic pituitary gland development. Because pituitary development requires midline cell migration from the nasopharyngeal Rathke's pouch, midline craniofacial disorders, such as cleft lip and palate, basal encephalocele, hypertelorism, and optic nerve hypoplasia, may be associated with pituitary dysplasia. Acquired pituitary failure in the newborn can also be caused by birth trauma, including cranial hemorrhage, asphyxia, and breech delivery.

Septo-optic Dysplasia Hypothalamic dysfunction and hypopituitarism may result from dysgenesis of the septum pellucidum or corpus callosum. Affected children have mutations in the *HESX1* gene, which is involved in early development of the ventral prosencephalon. These children exhibit cleft palate, syndactyly, ear deformities, hypertelorism, optic atrophy, micropenis, and anosmia. Pituitary dysfunction leads to diabetes insipidus,GHdeficiency and short stature, and, occasionally,TSHdeficiency.

Tissue-Specific Factor Mutations Several pituitary cell-specific transcription factors, such as Pit-1 and Prop-1, are critical for determining the development and function of specific anterior pituitary cell lineages. Autosomal dominant or recessive Pit-1 mutations cause combinedGH,PRL, andTSHdeficiencies. These patients present with growth failure and varying degrees of hypothyroidism. The pituitary may appear hypoplastic on magnetic resonance imaging (MRI).

Prop-1 is expressed early in pituitary development and appears to be required for Pit-1 function. Familial and sporadic *PROP1* mutations result in combinedGH,PRL,TSH, and gonadotropin deficiency, with preservation ofACTH. Over 80% of these patients have

growth retardation and, by adulthood, all are deficient in TSH and gonadotropins. Because of gonadotropin deficiency, they do not enter puberty spontaneously (Fig. 328-4).

Developmental Hypothalamic Dysfunction

Kallmann Syndrome This syndrome results from defective hypothalamic gonadotropin-releasing hormone (GnRH) synthesis and is associated with anosmia or hyposmia due to olfactory bulb agenesis or hypoplasia (Chap. 335). The syndrome may also be associated with color blindness, optic atrophy, nerve deafness, cleft palate, renal abnormalities, cryptorchidism, and neurologic abnormalities such as mirror movements. Defects in the *KAL* gene, which maps to chromosome Xp22.3, prevent embryonic migration of GnRH neurons from the hypothalamic olfactory placode to the hypothalamus. Genetic abnormalities, in addition to *KAL* mutations, can also cause isolated GnRH deficiency, as autosomal recessive and dominant modes of transmission have been described. GnRH deficiency prevents progression through puberty. Males present with delayed puberty and pronounced hypogonadal features, including micropenis, probably the result of low testosterone levels during infancy (Chap. 335). Female patients present with primary amenorrhea and failure of secondary sexual development.

Kallmann syndrome and other causes of congenitalGnRHdeficiency are characterized by lowLH andFSHlevels and low concentrations of sex steroids (testosterone or estradiol). In sporadic cases of isolated gonadotropin deficiency, the diagnosis is often one of exclusion after eliminating other causes of hypothalamic-pituitary dysfunction. Repetitive GnRH administration restores normal pituitary gonadotropin responses, pointing to a hypothalamic defect.

Long-term treatment of males with human chorionic gonadotropin (hCG) or testosterone restores pubertal development and secondary sex characteristics; females can be treated with cyclic estrogen and progestin. Fertility may also be restored by the administration of subcutaneous, pulsatileGnRHusing a portable infusion pump.

Laurence-Moon-Bardet-Biedl Syndrome This rare autosomal recessive disorder is characterized by mental retardation; obesity; and hexadactyly, brachydactyly, or syndactyly. Central diabetes insipidus may or may not be associated.GnRHdeficiency occurs in 75% of males and half of affected females. Retinal degeneration begins in early childhood, and most patients are blind by age 30.

Frohlich Syndrome (Adipose Genital Dystrophy) A broad spectrum of hypothalamic lesions may be associated with hyperphagia, obesity, and central hypogonadism. DecreasedGnRHproduction in these patients results in attenuated pituitaryFSH andLHsynthesis and release.

Prader-Willi Syndrome Chromosome 15q deletions are associated with hypogonadotropic hypogonadism, hyperphagia-obesity, chronic muscle hypotonia, mental retardation, and adult-onset diabetes mellitus (Chap. 66). Multiple somatic defects also involve the skull, eyes, ears, hands, and feet. Diminished hypothalamic oxytocin- and vasopressin-producing nuclei have been reported.

DeficientGnRHsynthesis is suggested by the observation that chronic GnRH treatment restores pituitaryLH andFSHrelease.

ACQUIRED HYPOPITUITARISM

Hypopituitarism may be caused by accidental or neurosurgical trauma; vascular events such as apoplexy; pituitary or hypothalamic neoplasms such as pituitary adenomas, craniopharyngiomas, or metastatic deposits; inflammatory disease such as lymphocytic hypophysitis; infiltrative disorders such as sarcoidosis, hemochromatosis (Chap. 345), and tuberculosis; or irradiation. It is often difficult to localize the site of hormonal dysfunction as many processes, including hemochromatosis and radiation, may affect both hypothalamic and pituitary function.

Hypothalamic Infiltration Disorders These disorders -- including those associated with sarcoidosis, histiocytosis X, amyloidosis, and hemochromatosis -- frequently involve both hypothalamic and pituitary neuronal and neurochemical tracts. Consequently, diabetes insipidus occurs in half of patients with these disorders. Growth retardation is seen if attenuatedGHsecretion occurs before pubertal epiphyseal closure. Hypogonadotropic hypogonadism and hyperprolactinemia are also common.

Inflammatory Lesions Pituitary damage and subsequent dysfunction can be seen with chronic infections such as tuberculosis, opportunistic fungal infections associated with AIDS, and in tertiary syphilis. Other inflammatory processes, such as granulomas or sarcoidosis, may mimic a pituitary adenoma. These lesions may cause extensive hypothalamic and pituitary damage, leading to trophic hormone failure.

Cranial Irradiation Cranial irradiation may result in long-term hypothalamic and pituitary dysfunction, especially in children and adolescents who are more susceptible to damage following whole-brain or head and neck therapeutic irradiation. The development of hormonal abnormalities correlates strongly with irradiation dosage and the time interval after completion of radiotherapy. Up to two-thirds of patients ultimately develop hormone insufficiency afer a median dose of 50 Gy (5000 rad) directed at the skull base. The development of hypopituitarism occurs over 5 to 15 years and usually reflects hypothalamic damage rather than absolute destruction of pituitary cells. Though the pattern of hormone loss is variable,GHdeficiency is most commonly followed by gonadotropin andACTHdeficiency. When deficiency of one or more hormones is documented, the possibility of diminished reserve of other hormones is likely. Accordingly, anterior pituitary function should be evaluated over the long term in previously irradiated patients, and replacement therapy instituted when appropriate (see below).

Lymphocytic Hypophysitis This occurs mainly in pregnant or post-partum women; it usually presents with hyperprolactinemia andMRIevidence of a prominent pituitary mass resembling an adenoma, with mildly elevatedPRLlevels. Pituitary failure caused by diffuse lymphocytic infiltration may be transient or permanent but requires immediate evaluation and treatment. Rarely, isolated pituitary hormone deficiencies have been described, suggesting a selective autoimmune process targeted to specific cell types. Most patients manifest symptoms of progressive mass effects with headache and visual disturbance. The erythrocyte sedimentation rate is often elevated. As the MRI image

may be indistinguishable from that of a pituitary adenoma, hypophysitis should be considered in a post-partum woman with a newly diagnosed pituitary mass before embarking on unnecessary surgical intervention. The inflammatory process often resolves after several months of glucocorticoid treatment, and pituitary function may be restored, depending on the extent of damage.

Pituitary Apoplexy Acute intrapituitary hemorrhagic vascular events can cause substantial damage to the pituitary and surrounding sellar structures. Pituitary apoplexy may occur spontaneously in a preexisting adenoma (usually nonfunctioning); postpartum (Sheehan's syndrome); or in association with diabetes, hypertension, sickle cell anemia, or acute shock. The hyperplastic enlargement of the pituitary during pregnancy increases the risk for hemorrhage and infarction. Apoplexy is an endocrine emergency that may result in severe hypoglycemia, hypotension, central nervous system (CNS) hemorrhage, and death. Acute symptoms include severe headache with signs of meningeal irritation, bilateral visual changes, ophthalmoplegia that varies, and, in severe cases, cardiovascular collapse and loss of consciousness. Pituitary computed tomography (CT) orMRI may reveal signs of intratumoral or sellar hemorrhage, with deviation of the pituitary stalk and compression of pituitary tissue.

Patients with no evident visual loss or impaired consciousness can be observed and managed conservatively with high-dose glucocorticoids. Those with significant or progressive visual loss or loss of consciousness require urgent surgical decompression. Visual recovery after surgery is inversely correlated with the length of time after the acute event. Therefore, severe ophthalmoplegia or visual deficits are indications for early surgery. Hypopituitarism is very common after apoplexy.

Empty Sella A partial or apparently totally empty sella is usually an incidentalMRIfinding. These patients usually exhibit normal pituitary function, implying that the surrounding rim of pituitary tissue is fully functional. Hypopituitarism, however, may develop insidiously. Pituitary masses may undergo clinically silent infarction with development of a partial or totally empty sella by cerebrospinal fluid (CSF) filling the dural herniation. Rarely, functional pituitary adenomas may arise within the rim of pituitary tissue, and these are not always visible on MRI.

PRESENTATION AND DIAGNOSIS

The clinical manifestations of hypopituitarism depend on which hormones are lost and the extent of the hormone deficiency.GHdeficiency causes growth disorders in children and leads to abnormal body composition in adults (see below). Gonadotropin deficiency causes menstrual disorders and infertility in women and decreased sexual function, infertility, and loss of secondary sexual characteristics in men.TSH andACTHdeficiency usually develop later in the course of pituitary failure. TSH deficiency leads to growth retardation in children and features of hypothyroidism in children and in adults. The secondary form of adrenal insufficiency caused by ACTH deficiency leads to hypocortisolism with relative preservation of mineralocorticoid production.PRLdeficiency causes failure of lactation. When lesions involve the posterior pituitary tracts, polyuria and polydipsia reflect loss of vasopressin secretion. Epidemiologic studies have documented an increased mortality rate in patients with longstanding pituitary damage, primarily from increased cardiovascular and cerebrovascular disease.

LABORATORY INVESTIGATION

Biochemical diagnosis of pituitary insufficiency is made by demonstrating low levels of trophic hormones in the setting of low target hormone levels. For example, low free thyroxine in the setting of a low or inappropriately normalTSHlevel suggests secondary hypothyroidism. Similarly, a low testosterone level without elevation of gonadotropins suggests hypogonadotropic hypogonadism. Provocative tests may be required to assess pituitary reserve (Table 328-3).GHresponses to insulin-induced hypoglycemia, arginine, L-dopa, growth hormone-releasing hormone (GHRH), or growth hormone-releasing peptides (GHRPs) can be used to assess GH reserve.PRL and TSH responses to thyrotropin-releasing hormone (TRH) reflect lactotrope and thyrotrope function. Corticotropin-releasing hormone (CRH) administration inducesACTHrelease, and administration of synthetic ACTH (cortrosyn) evokes adrenal cortisol release as an indirect indicator of pituitary ACTH reserve (Chap. 331). ACTH reserve is most reliably assessed during insulin-induced hypoglycemia. However, this test should be performed cautiously in patients with suspected adrenal insufficiency because of increased risk of hypoglycemia and hypotension.

TREATMENT

Hormone replacement therapy, including glucocorticoids, thyroid hormone, sex steroids, growth hormone, and vasopressin, is usually free of complications. Treatment regimens that mimic physiologic hormone production allow for maintenance of satisfactory clinical homeostasis. Effective dosage schedules are outlined inTable 328-4. Patients in need of glucocorticoid replacement require careful dose adjustments during stressful events such as acute illness, dental procedures, trauma, and acute hospitalization (Chap. 331).

HYPOTHALAMIC, PITUITARY, AND OTHER SELLAR MASSES

PITUITARY TUMORS

Pituitary adenomas are the most common cause of pituitary hormone hypersecretion and hyposecretion syndromes in adults. They account for ~10% of all intracranial neoplasms. At autopsy, up to a quarter of all pituitary glands harbor an unsuspected microadenoma (<10 mm diameter). Similarly, pituitary imaging detects small pituitary lesions in at least 10% of normal individuals.

Pathogenesis Pituitary adenomas are benign neoplasms that arise from one of the five anterior pituitary cell types. The clinical and biochemical phenotype of pituitary adenomas depend on the cell type from which they are derived and are described in detail below. Thus, tumors arising from lactotrope (PRL), somatotrope (GH), corticotrope (ACTH), thyrotrope (TSH), or gonadotrope (LH,FSH) cells hypersecrete their respective hormones (Table 328-5). Plurihormonal tumors that express combinations of GH, PRL, TSH, ACTH, and the glycoprotein hormonea subunit may be diagnosed by careful immunocytochemistry or may, in fact, present with mixed clinical features of these hormonal hypersecretory syndromes. Morphologically, these tumors may arise from a single polysecreting cell type or consist of cells with mixed function within the same tumor.

Hormonally active tumors are characterized by autonomous hormone secretion with diminished responsiveness to the normal physiologic pathways of inhibition. Hormone production does not always correlate with tumor size. Small hormone-secreting adenomas may cause significant clinical perturbations, whereas larger adenomas that produce less hormone may be clinically silent and remain undiagnosed (if no central compressive effects occur). About one-third of all adenomas are clinically nonfunctioning and produce no distinct clinical hypersecretory syndrome. Most arise from gonadotrope cells and may secrete a- andb-glycoprotein hormone subunits or, very rarely, intact circulating gonadotropins. True pituitary carcinomas with documented extracranial metastases are exceedingly rare.

Almost all pituitary adenomas are monoclonal in origin, implying the acquisition of one or more somatic mutations that confer a selective growth advantage. In addition to direct studies of oncogene mutations, this idea is supported by X-chromosomal inactivation analyses of tumors in female patients heterozygous for X-linked genes. Consistent with their clonal origin, complete surgical resection of small pituitary adenomas usually cures hormone hypersecretion. Nevertheless, hypothalamic hormones, such asGHRH orCRH, also enhance the mitotic activity of their respective pituitary target cells, in addition to their role in pituitary hormone regulation. Thus, patients harboring rare abdominal or chest tumors elaborating ectopic GHRH or CRH may present with somatotrope or corticotrope hyperplasia.

Several etiologic genetic events have been implicated in the development of pituitary tumors. The pathogenesis of sporadic forms of acromegaly has been particularly informative as a model of tumorigenesis.GHRH, after binding to its G protein-coupled somatotrope receptor, utilizes cyclic AMP as a second messenger to stimulateGHsecretion and somatotrope proliferation. A subset (~35%) of GH-secreting pituitary tumors contain mutations in Gsa (Arg 201® Cys or His; Gln 227® Arg). These mutations inhibit intrinsic GTPase activity, resulting in constitutive elevation of cyclic AMP, Pit-1 induction, and activation of cyclic AMP response element binding protein (CREB), thereby promoting somatotrope cell proliferation.

Characteristic loss of heterozygosity (LOH) in various chromosomes has been documented in large or invasive macroadenomas, suggesting the presence of putative tumor suppressor genes at these loci. LOH of chromosome region on 11q13, 13, and 9 is present in up to 20% of sporadic pituitary tumors includingGH-,PRL-, andACTH-producing adenomas and in some nonfunctioning tumors.

Compelling evidence also favors growth factor promotion of pituitary tumor proliferation. Basic fibroblast growth factor (bFGF) is abundant in the pituitary and has been shown to stimulate pituitary cell mitogenesis. Other factors involved in initiation and promotion of pituitary tumors include loss of negative-feedback inhibition (as seen with primary hypothyroidism or hypogonadism) and estrogen-mediated or paracrine angiogenesis. Growth characteristics and neoplastic behavior may also be influenced by several activated oncogenes, including *RAS* and pituitary tumor transforming gene (*PTTG*).

Genetic Syndromes Associated with Pituitary Tumors Several familial syndromes are associated with pituitary tumors, and the genetic mechanisms for some of these

have been unraveled (Table 328-6).

Multiple endocrine neoplasia (MEN) 1 is an autosomal dominant syndrome characterized primarily by a genetic predisposition to parathyroid, pancreatic islet, and pituitary adenomas (Chap. 339). MEN-1 is caused by inactivating germline mutations in *MENIN*, a constitutively expressed tumor-suppressor gene located on chromosome 11q13. Loss of heterozygosity, or a somatic mutation of the remaining normal *MENIN* allele, leads to tumorigenesis. About half of affected patients develop prolactinomas; acromegaly and Cushing's syndrome are less commonly encountered.

Carney syndrome is characterized by spotty skin pigmentation, myxomas, and endocrine tumors including testicular, adrenal, and pituitary adenomas. Acromegaly occurs in about 20% of patients. This autosomal dominant syndrome is associated with microsatellite alterations on chromosome 2p16.

McCune-Albright syndrome consists of polyostotic fibrous dysplasia, pigmented skin patches, and a variety of endocrine disorders, includingGH-secreting pituitary tumors, adrenal adenomas, and autonomous ovarian function (Chap. 343). Hormonal hypersecretion is due to constitutive cyclic AMP production caused by inactivation of the GTPase activity of Gsa. The Gsa mutations occur postzygotically, leading to a mosaic pattern of mutant expression.

Familial acromegaly is a rare disorder in which family members may manifest either acromegaly or gigantism. The disorder is associated withLOH at a chromosome 11q13 locus distinct from that of *MENIN*.

OTHER SELLAR MASSES

Craniopharyngiomas are derived from Rathke's pouch. They arise near the pituitary stalk and commonly extend into the suprasellar cistern. These tumors are often large, cystic, and locally invasive. Many are partially calcified, providing a characteristic appearance on skull x-ray andCTimages. More than half of all patients present before age 20, usually with signs of increased intracranial pressure, including headache, vomiting, papilledema, and hydrocephalus. Associated symptoms include visual field abnormalities, personality changes and cognitive deterioration, cranial nerve damage, sleep difficulties, and weight gain. Anterior pituitary dysfunction and diabetes insipidus are common. About half of affected children present with growth retardation.

Treatment usually involves transcranial or transsphenoidal surgical resection followed by postoperative radiation of residual tumor. This approach can result in long-term survival and ultimate cure, but most patients require lifelong pituitary hormone replacement. If the pituitary stalk is uninvolved and can be preserved at the time of surgery, the incidence of subsequent anterior pituitary dysfunction is significantly diminished.

Developmental failure of Rathke's pouch obliteration may lead to *Rathke's cysts*, which are small (<5 mm) cysts entrapped by squamous epithelium; these cysts are found in about 20% of individuals at autopsy. Although Rathke's cleft cysts do not usually grow and are often diagnosed incidentally, about a third present in adulthood with

compressive symptoms, diabetes insipidus, and hyperprolactinemia due to stalk compression. Rarely, internal hydrocephalus develops. The diagnosis is suggested preoperatively by visualizing the cyst wall onMRI, which distinguishes these lesions from craniopharyngiomas. Cyst contents range fromCSF-like fluid to mucoid material. *Arachnoid cysts* are rare and generate an MRI image isointense with cerebrospinal fluid.

Sella chordomas usually present with bony clival erosion, local invasiveness, and, on occasion, calcification. Normal pituitary tissue may be visible onMRI, distinguishing chordomas from aggressive pituitary adenomas. Mucinous material may be obtained by fine-needle aspiration.

Meningiomas arising in the sellar region may be difficult to distinguish from nonfunctioning pituitary adenomas. OnMRI they may be asymmetric, and onCT they may show evidence of bony erosion. Meningiomas may cause compressive symptoms.

Histiocytosis X comprises a variety of syndromes associated with foci of eosinophilic granulomas. Diabetes insipidus, exophthalmos, and punched-out lytic bone lesions (*Hand-Schuller-Christian disease*) are associated with granulomatous lesions visible onMRI, as well as a characteristic axillary skin rash. Rarely, the pituitary stalk may be involved.

Pituitary metastases occur in ~3% of cancer patients. Blood-borne metastatic deposits are found almost exclusively in the posterior pituitary. Accordingly, diabetes insipidus can be a presenting feature of lung, gastrointestinal, breast, and other pituitary metastases. About half of pituitary metastases originate from breast cancer; about 25% of patients with breast cancer have such deposits. Rarely, pituitary stalk involvement results in anterior pituitary insufficiency. TheMRIdiagnosis of a metastatic lesion may be difficult to distinguish from an aggressive pituitary adenoma; the diagnosis may require histologic examination of excised tumor tissue. Primary or metastatic lymphoma, leukemias, and plasmacytomas also occur within the sella.

Hypothalamic hamartomas and *gangliocytomas* may arise from astrocytes, oligodendrocytes, and neurons with varying degrees of differentiation. These tumors may overexpress hypothalamic neuropeptides includingGnRH,GHRH, orCRH. In GnRH-producing tumors, children present with precocious puberty, psychomotor delay, and laughing-associated seizures. Medical treatment of GnRH-producing hamartomas with long-acting GnRH analogues effectively suppresses gonadotropin secretion and controls pubertal development. Rarely, hamartomas are also associated with craniofacial abnormalities; imperforate anus; cardiac, renal, and lung disorders; and pituitary failure (*Pallister-Hall syndrome*). Hypothalamic hamartomas are often contiguous with the pituitary, and preoperativeMRIdiagnosis may not be possible. Histologic evidence of hypothalamic neurons in tissue resected at transsphenoidal surgery may be the first indication of a primary hypothalamic lesion.

Hypothalamic gliomas and *optic gliomas* occur mainly in childhood and usually present with visual loss. Adults have more aggressive tumors; about a third are associated with neurofibromatosis.

Brain germ-cell tumors may arise within the sellar region. These include

dysgerminomas, which are associated with diabetes insipidus and visual loss and rarely metastasize. *Germinomas*, *embryonal carcinomas*, *teratomas*, and *choriocarcinomas* may arise in the parasellar region and produce hCG. These germ-cell tumors present with precocious puberty, diabetes insipidus, visual field defects, and thirst disorders. Many patients are GH-deficient with short stature.

METABOLIC EFFECTS OF HYPOTHALAMIC LESIONS

The hypothalamus is subject to injury from mass lesions, granulomatous disorders, infections, and hemorrhage. Lesions involving the anterior and preoptic hypothalamic regions cause paradoxical vasoconstriction, tachycardia, and hyperthermia. Acute hyperthermia is usually due to a hemorrhagic insult, but poikilothermia may also occur. Central disorders of thermoregulation result from posterior hypothalamic damage. The *periodic hypothermia syndrome* comprises episodic attacks of rectal temperatures<30°C, sweating, vasodilation, vomiting, and bradycardia (Chap. 20). Damage to the ventromedial nuclei by craniopharyngiomas, hypothalamic trauma, or inflammatory disorders may be associated with *hyperphagia* and *obesity*. This region appears to contain an energy-satiety center where melanocortin receptors are influenced by leptin, insulin, POMC products, and gastrointestinal peptides (Chap. 77). Median eminence involvement results in diabetes insipidus in about 50% of patients. Hypothalamic gliomas in early childhood may be associated with a diencephalic syndrome characterized by progressive severe emaciation and growth failure. Polydipsia or hypodipsia are associated with damage to central osmo-receptors located in preoptic nuclei (Chap. 329). Slow-growing hypothalamic lesions can cause increased somnolence and disturbed sleep cycles as well as obesity, hypothermia, and emotional outbursts. Lesions of the central hypothalamus may stimulate sympathetic neurons, leading to elevated serum catecholamine and cortisol levels. These patients are predisposed to cardiac arrhythmias, hypertension, and gastric erosions.

EVALUATION

Local Mass Effects Clinical manifestations of sellar lesions vary, depending on the anatomic location of the mass and direction of its extension (Table 328-7). The dorsal roof of the sella presents the least resistance to soft tissue expansion from within the confines of the sella; consequently, pituitary adenomas frequently extend in a suprasellar direction. Bony invasion may ultimately occur as well.

Headaches are common features of small intrasellar tumors, even with no demonstrable suprasellar extension. Because of the confined nature of the pituitary, small changes in intrasellar pressure stretch the dural plate; however, the severity of the headache correlates poorly with adenoma size or extension.

Suprasellar extension can lead to visual loss by several mechanisms, the most common being compression of the optic chiasm, but direct invasion of the optic nerves or obstruction of CSF flow leading to secondary visual disturbances also occur. Pituitary stalk compression by a hormonally active or inactive intrasellar mass may compress the portal vessels, disrupting pituitary access to the hypothalamic hormones and dopamine; this results in hyperprolactinemia and concurrent loss of other pituitary hormones. This "stalk section" phenomenon may also be caused by trauma, whiplash injury with

posterior clinoid stalk compression, or skull base fractures. Lateral mass invasion may impinge on the cavernous sinus and compress its neural contents, leading to cranial nerve III, IV, and VI palsies as well as effects on the ophthalmic and maxillary branches of the fifth cranial nerve (Chap. 367). Patients may present with diplopia, ptosis, ophthalmoplegia, and decreased facial sensation, depending on the extent of neural damage. Extension into the sphenoid sinus indicates that the pituitary mass has eroded through the sellar floor. Aggressive tumors may also invade the palate roof and cause nasopharyngeal obstruction, infection, and, rarely, CSF leakage. Both temporal and frontal lobes may be invaded, leading to uncinate seizures, personality disorders, and anosmia. Direct hypothalamic encroachment by an invasive pituitary mass may cause important metabolic sequelae, precocious puberty or hypogonadism, diabetes insipidus, sleep disturbances, dysthermia, and appetite disorders.

MRISagittal and coronal T1-weighted spin-echo MRI imaging, before and after administration of gadolinium, allow precise visualization of the pituitary gland with clear delineation of the hypothalamus, pituitary stalk, pituitary tissue and surrounding suprasellar cisterns, cavernous sinuses, sphenoid sinus, and optic chiasm. Pituitary gland height ranges from 6 mm in children to 8 mm in adults; during pregnancy and puberty, the height may reach 10 to 12 mm. The upper aspect of the adult pituitary is flat or slightly concave, but in adolescent and pregnant individuals, this surface may be convex, reflecting physiologic pituitary enlargement. The stalk should be vertical.CT scan is indicated to define the extent of bony erosion or the presence of calcification.

The soft tissue consistency of the pituitary gland is slightly heterogeneous onMRI. Anterior pituitary signal intensity resembles that of brain matter on T1-imaging (Fig. 328-5). Adenoma density is usually lower than that of surrounding normal tissue on T1-weighted imaging, and the signal intensity increases with T2-weighted images. The high phospholipid content of the posterior pituitary results in a bright enhancing signal.

Sellar masses are commonly encountered as incidental findings onMRI, and most of these are pituitary adenomas (incidentalomas). This finding is consistent with the observation that clinically silent pituitary microadenomas can be identified in up to 25% of pituitaries in autopsy series. In the absence of hormone hypersecretion, these small lesions can be safely monitored by MRI, which is performed annually and then less often if there is no evidence of growth. Resection should be considered for incidentally discovered macroadenomas, as about one-third become invasive or cause local pressure effects. If hormone hypersecretion is evident, specific therapies are indicated. When larger masses (>1 cm) are encountered, they should also be distinguished from nonadenomatous lesions. Meningiomas are often associated with bony hyperostosis; craniopharyngiomas may be calcified and are usually hypodense, whereas gliomas are hyperdense on T2-weighted images.

Ophthalmologic Evaluation Because optic tracts may be contiguous to an expanding pituitary mass, reproducible visual field assessment that uses perimetry techniques should be performed on all patients with sellar mass lesions that abut the optic chiasm. Loss of red perception is an early sign of optic tract pressure. Bitemporal hemianopia or superior bitemporal defects are classically observed, reflecting the location of these tracts within the inferior and posterior part of the chiasm. Early diagnosis reduces the risk of blindness, scotomas, or other visual disturbances.

Laboratory Investigation The presenting clinical features of functional pituitary adenomas (e.g., acromegaly, prolactinomas, or Cushing's disease) should guide the laboratory studies (see below). However, for a sellar mass with no obvious clinical features of hormone excess, laboratory studies are geared towards determining the nature of the tumor and assessing the possible presence of hypopituitarism. When a pituitary adenoma is suspected based onMRI, initial hormonal evaluation usually includes: (1) basalPRL; (2) insulin-like growth factor (IGF) I; (3) 24-h urinary free cortisol (UFC) and/or overnight oral dexamethasone (1 mg) suppression test; (4)a-subunit,FSH, andLHlevels; and (5) thyroid function tests. Additional hormonal evaluation may be indicated based on the results of these tests. Pending more detailed assessment of hypopituitarism, a menstrual history, testosterone level, 8 A.M. cortisol, and thyroid function tests usually identify patients with pituitary hormone deficiencies that require hormone replacement before further testing or surgery.

Histologic Evaluation Immunohistochemical staining of pituitary tumor specimens obtained at transsphenoidal surgery confirm clinical and laboratory studies and provide a histologic diagnosis when hormone studies are equivocal and in cases of clinically nonfunctioning tumors. Occasionally, ultrastructural assessment by electron microscopy is required for diagnosis.

TREATMENT

Overview Successful management of sellar masses requires accurate diagnosis as well as selection of optimal therapeutic modalities. Most pituitary tumors are benign and slow-growing. Clinical features result from local mass effects and hormonal hypo- or hypersecretion syndromes caused directly by the adenoma or as a consequence of treatment. Thus, lifelong management and follow-up are necessary for these patients.

ImprovedMRItechnology with gadolinium enhancement for pituitary visualization, new advances in transsphenoidal surgery and in stereotactic radiotherapy (including gamma-knife radiotherapy), and novel therapeutic agents have improved pituitary tumor management. The goals of pituitary tumor treatment include normalization of excess pituitary secretion, amelioration of symptoms and signs of hormonal hypersecretion syndromes, and shrinkage or ablation of large tumor masses with relief of adjacent structure compression. Residual anterior pituitary function should be preserved and can sometimes be restored by removing tumor mass. Ideally, adenoma recurrence should be prevented.

Transsphenoidal Surgery Transsphenoidal rather than transfrontal resection is the desired surgical approach for pituitary tumors, except for the rare invasive suprasellar mass surrounding the frontal or middle fossa, the optic nerves, or invading posteriorly behind the clivus. Intraoperative microscopy facilitates visual distinction between adenomatous and normal pituitary tissue, as well as microdissection of small tumors that may not be visible byMRI(Fig. 328-6). Transsphenoidal surgery also avoids the cranial invasion and manipulation of brain tissue required by subfrontal surgical approaches. Endoscopic techniques with three-dimensional intraoperative localization have improved visualization and access to tumor tissue. The endoscopic approach is also less traumatic, as the technique is endonasal and does not require a

transsphenoidal retractor.

In addition to correction of hormonal hypersecretion, pituitary surgery is indicated for mass lesions that impinge on surrounding structures. Surgical decompression and resection are required for an expanding pituitary mass accompanied by pesistent headache, progressive visual field defects, cranial nerve palsies, internal hydrocephalus, and, occasionally, intrapituitary hemorrhage and apoplexy. Repeat surgery may be required for persistent postoperativeCSFleakage. Transsphenoidal surgery is sometimes used for pituitary tissue biopsy and histologic diagnosis.

Whenever possible, the pituitary mass lesion should be selectively excised; normal tissue should be manipulated or resected only when critical for effective dissection. Nonselective hemihypophysectomy or total hypophysectomy may be indicated if no mass lesion is clearly discernible, multifocal lesions are present, or the remaining nontumorous pituitary tissue is obviously necrotic. This strategy increases the likelihood of hypopituitarism and the need for lifelong hormonal replacement.

Preoperative local compression signs, including visual field defects or compromised pituitary function, may be reversed by surgery, particularly when these deficits are not long-standing. For large and invasive tumors, it is necessary to determine the optimal balance between maximal tumor resection and preservation of anterior pituitary function, especially for preserving growth and reproductive function in younger patients. Similarly, tumor invasion outside of the sella is rarely amenable to surgical cure; the surgeon must judge the risk:benefit ratio of extensive tumor resection.

Side Effects Tumor size and the degree of invasiveness largely determine the incidence of surgical complications. Operative mortality is about 1%. Transient diabetes insipidus and hypopituitarism occur in up to 20% of patients. Permanent diabetes insipidus, cranial nerve damage, nasal septal perforation, or visual disturbances may be encountered in up to 10% of patients.CSFleaks occur in 4% of patients. Less common complications include carotid artery injury, loss of vision, hypothalamic damage, and meningitis. Permanent side effects are rarely encountered after surgery for microadenomas.

Radiation Radiation is used either as a primary therapy for pituitary or parasellar masses or, more commonly, as an adjunct to surgery or medical therapy. Focused megavoltage irradiation is achieved by preciseMRIlocalization, using a high-voltage linear accelerator and accurate isocentric rotational arcing. A major determinant of accurate irradiation is to reproduce the patient's head position during multiple visits and to maintain absolute head immobility. A total of <50 Gy (5000 rad) is given as 180-cGy (180 rad) fractions split over about 6 weeks. Stereotactic radiosurgery delivers a large single high-energy dose from a cobalt 60 source (gamma knife), linear accelerator, or cyclotron. Long-term effects of gamma-knife surgery are as yet unknown.

The role of radiation therapy in pituitary tumor management depends on multiple factors including the nature of the tumor, age of the patient, and the availability of surgical and radiation expertise. Because of its relatively slow onset of action, radiation therapy is usually reserved for postsurgical management. As an adjuvant to surgery, radiation is used to treat residual tumor and in an attempt to prevent regrowth. Irradiation offers the

only effective means for ablating significant residual tumor tissue derived from nonfunctioning tumors.PRL-,GH-, andACTH-secreting tumor tissues are also amenable to medical therapy.

Side Effects In the short term, radiation may cause transient nausea and weakness. Alopecia and loss of taste and smell may be more long-lasting. Failure of pituitary hormone synthesis is common in patients who have undergone head and neck or pituitary-directed irradiation. More than 50% of patients develop failure ofGH,ACTH,TSH, and/or gonadotropin secretion within 10 years, usually due to hypothalamic damage. Lifelong follow-up with testing of anterior pituitary hormone reserve is therefore necessary after radiation treatment. Optic nerve damage with impaired vision due to optic neuritis is reported in about 2% of patients who undergo pituitary irradiation. Cranial nerve damage is uncommon now that radiation doses are £2 Gy (200 rad) at any one treatment session and the maximum dose is <50 Gy (5000 rad). The advent of stereotactic radiotherapy may reduce damage to adjacent structures. The cumulative risk of developing a secondary tumor after conventional radiation is 1.3% after 10 years and 1.9% after 20 years.

Medical Medical therapy for pituitary tumors is highly specific and depends on tumor type. For prolactinomas, dopamine agonists are the treatment of choice. For acromegaly andTSH-secreting tumors, somatostatin analogues and, occasionally, dopamine agonists are indicated.ACTH-secreting tumors and nonfunctioning tumors are generally not responsive to medication and require surgery and/or irradiation.

PROLACTIN

SYNTHESIS

PRLconsists of 198 amino acids and has a molecular mass of 21,500 kDa; it is weakly homologous toGH and human placental lactogen (hPL), reflecting the duplication and divergence of a common GH-PRL-hPL precursor gene on chromosome 6. PRL is synthesized in lactotropes, which comprise about 20% of anterior pituitary cells. Lactotropes and somatotropes are derived from a common precursor cell that may give rise to a tumor secreting both PRL and GH. Marked lactotrope cell hyperplasia develops during the last two trimesters of pregnancy and the first few months of lactation. These transient adaptive changes in the lactotrope population are induced by estrogen.

SECRETION

FetalPRLsynthesis begins at 12 weeks' gestation (about 4 weeks afterGH). Normal adult serum PRL levels are about 10 to 25 ug/L in women and 10 to 20 ug/L in men. PRL secretion is pulsatile, with the highest secretory peaks occurring during rapid eye movement sleep. Peak serum PRL levels (up to 30 ug/L) occur between 4:00 and 6:00 A.M. The circulating half-life of PRL is about 50 min.

PRLis unique among the pituitary hormones in that the predominant central control mechanism is inhibitory, reflecting dopamine-mediated suppression of PRL release. This regulatory pathway is exemplified by the spontaneous PRL hypersecretion that occurs after pituitary stalk section, often a consequence of mass lesions at the skull

base.

Dopamine action is mediated by multiple receptor subtypes, each a member of the seven-transmembrane G protein-coupled receptor (GPCR) superfamily. In the pituitary, dopamine type 2 (D_2) receptors are predominant and mediatePRLinhibition. Targeted disruption (gene knockout) of the murine D_2receptor results in hyperprolactinemia and lactotrope proliferation. Activation of D_2receptors inhibits the cyclic AMP pathway, causing membrane hyperpolarization and closing of voltage-gated calcium channels; these events block secretory granule exocytosis by reducing intracellular free calcium. Because of the potent PRL inhibitory effects of dopamine, physiologic, pharmacologic, or pathologic alterations in dopamine action increase PRL levels. As discussed below, dopamine agonists play a central role in the management of hyperprolacinemic disorders.

TRH(pyro Glu-His-Pro-NH2) is a hypothalamic tripeptide that releases prolactin within 15 to 30 min after intravenous injection. The physiologic relevance of TRH forPRLregulation is unclear, as it appears to primarily regulateTSH(Chap. 330). *Vasoactive intestinal peptide* (VIP) also induces PRL release, whereas glucocorticoids and thyroid hormone suppress PRL secretion.

SerumPRLlevels rise after exercise, meals, sexual intercourse, minor surgical procedures, general anesthesia, acute myocardial infarction, and other forms of acute stress. PRL levels also increase significantly (~tenfold) during pregnancy and decline rapidly within 2 weeks of parturition. If breastfeeding is initiated, basal PRL levels remain elevated; suckling stimulates reflex increases in PRL levels that last for about 30 to 45 min. Breast suckling activates neural afferent pathways in the hypothalamus that induce PRL release. With time, the suckling-induced responses diminish and interfeeding PRL levels return to normal.

ACTION

ThePRLreceptor is a member of the type I cytokine receptor family that also includesGH and interleukin (IL) 6 receptors. Ligand binding leads to receptor dimerization followed by intracellular signaling mediated by the Janus kinase (JAK) pathway, which phosphorylates components of the signal transduction and activators of transcription (STAT) family. The STAT proteins translocate to the nucleus, where they act as transcription factors on target genes. In the breast, the lobuloalveolar epithelium proliferates in response to PRL, placental lactogens, elevated progesterone, and local paracrine growth factors; lactogenesis occurs as a result of complex multihormonal interactions (Chap. 337).

PRLacts to induce and maintain lactation, decrease reproductive function, and suppress sexual drive. These functions are geared towards ensuring that maternal lactation is sustained and not interrupted by pregnancy. PRL inhibits reproductive function at multiple levels, including suppression of hypothalamicGnRH and pituitary gonadotropin secretion, as well as impairing gonadal steroidogenesis in both female and male subjects. In the hypothalamus, PRL-mediated suppression of GnRH leads to loss of pulsatileLHsecretion and abrogation of the preovulatory LH surge. In the ovary, PRL blocks folliculogenesis and inhibits granulosa cell aromatase activity, leading to

hypoestrogenism and anovulation. PRL also has a luteolytic effect, generating a shortened, or inadequate, luteal phase of the menstrual cycle. In males, attenuated LH secretion leads to low testosterone levels and decreased spermatogenesis. These hormonal changes decrease libido and reduce fertility in patients with hyperprolactinemia (Chap. 54).

PRLexerts widespread metabolic effects to ensure maintenance of sustained lactation. Gastrointestinal calcium absorption is increased, bone calcium is mobilized, bile acids are elevated, and pancreatic bcell growth is induced by PRL. Centrally, PRL acts on brain centers involved in parenting behavior, appetite stimulation, and analgesia. Concomitant with these effects, maintenance of bone mineral density is abrogated; hyperprolactinemia is associated with enhanced risk for bone loss and the long-term development of osteoporosis. PRL receptors are abundant in the osteoblasts of developing bone, and the accompanying hypoestrogenemia contributes to accelerated bone loss in hyperprolactinemic women.

HYPERPROLACTINEMIA

Etiology Hyperprolactinemia is the most common pituitary hormone hypersecretion syndrome in both males and females.PRL-secreting pituitary adenomas (prolactinomas) are the most common cause of PRL levels>100 ug/L (see below). Less pronounced PRL elevation can also be caused by microprolactinomas but is more commonly caused by drugs, pituitary stalk compression, hypothyroidism, or renal failure (Table 328-8).

Pregnancy and lactation are the important physiologic causes of hyperprolactinemia. Sleep-associated hyperprolactinemia reverts to normal within an hour of awakening. Nipple stimulation and sexual orgasm may also cause acutePRLincreases. Chest wall stimulation or trauma (including chest surgery and herpes zoster) invoke the reflex suckling arc with resultant hyperprolactinemia. Chronic renal failure elevates PRL by decreasing peripheral PRL clearance. Primary hypothyroidism is associated with mild hyperprolactinemia, probably because of enhancedTRHsecretion.

Lesions of the hypothalamic-pituitary region that disrupt hypothalamic dopamine synthesis, portal vessel delivery, or lactotrope responses are associated with hyperprolactinemia. Thus, hypothalamic tumors, cysts, infiltrative disorders, and radiation-induced damage cause elevatedPRLlevels, usually in the range of 30 to 100 ug/L. Plurihormonal adenomas (includingGH andACTHtumors) may directly hypersecrete PRL. Clinically nonfunctioning pituitary tumors commonly cause stalk pressure and hyperprolactinemia.

Drug-induced inhibition or disruption of dopaminergic receptor function results in hyperprolactinemia (Table 328-8). Thus, many antipsychotics and antidepressants cause hyperprolactinemia. Methyldopa inhibits dopamine synthesis and verapamil blocks dopamine release, also leading to hyperprolactinemia. Hormonal agents that inducePRLinclude estrogens, antiandrogens, andTRH.

Presentation and Diagnosis Amenorrhea, galactorrhea, and infertility are the hallmarks of hyperprolactinemia in women. If hyperprolactinemia develops prior to the menarche, primary amenorrhea results. More commonly, hyperprolactinemia develops

later in life and leads to oligomenorrhea and, ultimately, to amenorrhea. Patients present with infertility, vaginal dryness, dyspareunia, and loss of libido. If hyperprolactinemia is sustained, vertebral bone mineral density can be reduced compared to age-matched controls, particularly when associated with pronounced hypoestrogenemia. Galactorrhea is present in up to 80% of hyperprolactinemic women. Though usually bilateral and spontaneous, it may be unilateral or only expressed manually. Patients may also complain of weight gain and mild hirsutism.

In men with hyperprolactinemia, diminished libido or visual loss (from optic nerve compression) are the usual presenting symptoms. Gonadotropin suppression leads to reduced testosterone, impotence, and oligospermia. True galactorrhea is uncommon in men with hyperprolactinemia. If the disorder is longstanding, secondary effects of hypogonadism are evident, including osteopenia, reduced muscle mass, and decreased beard growth.

The diagnosis of idiopathic hyperprolactinemia is made by exclusion of known causes of hyperprolactinemia in the setting of a normal pituitaryMRI. Some of these patients may have small microadenomas below MRI sensitivity (~2 mm).

Laboratory Investigation Basal, fasting morningPRLlevels (normally <20 ug/L) should be measured to assess hypersecretion. Because hormone secretion is pulsatile and levels vary widely in some individuals with hyperprolactinemia, it may be necessary to measure levels on several different occasions when clinical suspicion is high. Both false-positive and false-negative results may be encountered. In patients with markedly elevated PRL levels (>1000 ug/L), results may be falsely lowered because of assay artifacts; sample dilution is required to assess these high values accurately. Falsely elevated values may be caused by aggregated forms of circulating PRL, which are biologically inactive (macroprolactinemia). Hypothyroidism should be excluded by measuringTSH and T_4levels.

TREATMENT

Treatment of hyperprolactinemia depends on the cause of elevatedPRLlevels. Regardless of the etiology, however, treatment should be aimed at normalizing PRL levels to alleviate suppressive effects on gonadal function, halt the galactorrhea, and preserve bone mineral density. Dopamine agonists are effective for many different causes of hyperprolactinemia (see "Treatment" for "Prolactinoma," below).

If the patient is taking a medication known to cause hyperprolactinemia, the drug should be withdrawn, if possible. For psychiatric patients who require neuroleptic agents, dose titration or the addition of a dopamine agonist can help restore normoprolactinemia and alleviate reproductive symptoms. However, dopamine agonists sometimes worsen the underlying psychiatric condition, especially at high doses. Hyperprolactinemia usually resolves after adequate thyroid hormone replacement in hypothyroid patients or after renal transplantation in patients or dialysis. Resection of hypothalamic or sellar mass lesions can reverse hyperprolactinemia caused by reduced dopamine tone. Granulomatous infiltrates rarely respond to glucocorticoid administration. In patients with irreversible hypothalamic damage, no treatment may be warranted. In up to 30% of patients with hyperprolactinemia -- with or without a visible pituitary microadenoma --

the condition resolves spontaneously.

PROLACTINOMA

Etiology and Prevalence Tumors arising from lactotrope cells account for about half of all functioning pituitary tumors, with an annual incidence of ~3/100,000 population. Mixed tumors secreting combinations ofGH andPRL,ACTH and PRL, and rarelyTSH and PRL, are also seen. These plurihormonal tumors are usually recognized by immunohistochemistry, without apparent clinical manifestations from the production of additional hormones. Microadenomas are classified as<1 cm in diameter and do not usually invade the parasellar region. Macroadenomas are >1 cm in diameter, are locally invasive, and may impinge on adjacent structures. The female:male ratio for microprolactinomas is 20:1, whereas the gender ratio is near 1:1 for macroadenomas. Tumor size generally correlates directly with PRL concentrations; values >100 ug/L are usually associated with macroadenomas. Males tend to present with larger tumors than females, possibly because the features of hypogonadism are less readily evident. PRL levels remain stable in most patients, reflecting the slow growth of these tumors. About 5% of microadenomas progress in the long term to macroadenomas. Hyperprolactinemia resolves spontaneously in about 30% of microadenomas.

Presentation and Diagnosis Women usually present with amenorrhea, infertility, and galactorrhea. If the tumor extends outside of the sella, visual field defects or other mass effects may be seen. Men often present with impotence, loss of libido, infertility, or signs of centralCNScompression including headaches and visual defects. Assuming that known physiologic and medication-induced causes of hyperprolactinemia are excluded (Table 328-8), the diagnosis of prolactinoma is likely with aPRLlevel >100 ug/L. PRL levels<100ug/L may be caused by microadenomas, other sellar lesions that decrease dopamine inhibition, or nonneoplastic causes of hyperprolactinemia. For this reason, anMRIshould be performed in all patients with hyperprolactinemia. It is important to remember that hyperprolactinemia caused by the mass effects of nonlactotrope lesions is also corrected by treatment with dopamine agonists. Consequently, PRL suppression by dopamine agonists does not necessarily indicate that the lesion is a prolactinoma.

TREATMENT

As microadenomas rarely progress to become macroadenomas, no treatment may be needed if fertility is not desired. Estrogen replacement is indicated to prevent bone loss and other consequences of hypoestrogenemia and does not appear to increase the risk of tumor enlargement. These patients should be monitored by regular serialPRL andMRImeasurements.

For symptomatic microadenomas, therapeutic goals include control of hyperprolactinemia, reduction of tumor size, restoration of menses and fertility, and improvement of galactorrhea. Dopamine agonists should be titrated to achieve maximalPRLsuppression and restoration of reproductive function (Fig. 328-7). A normalized PRL level does not assure reduced tumor size. However, tumor shrinkage is not usually seen in those who do not respond with lowered PRL levels. For macroadenomas, formal visual field testing should be performed before initiating dopamine agonists.MRI and visual fields should be assessed at 6- to 12-month intervals

until the mass shrinks and annually thereafter until maximum size reduction has occurred.

Medical Oral dopamine agonists (cabergoline or bromocriptine) are the mainstay of therapy for patients with micro- or macroprolactinomas. Dopamine agonists suppressPRLsecretion and synthesis as well as lactotrope cell proliferation.

Bromocriptine The ergot alkaloid bromocriptine mesylate is a dopamine receptor agonist that suppresses prolactin secretion by binding directly to lactotrope D_2dopamine receptors. Bromocriptine is used as initial therapy for both micro- and macroprolactinomas. In microadenomas the drug rapidly lowers serum prolactin levels to normal in up to 70% of patients, decreases tumor size, and restores gonadal function. In patients with macroadenomas, prolactin levels are also normalized in 70% of patients and tumor mass shrinkage (³50%) is achieved in up to 40% of patients. Mass effect symptoms, including headaches and visual disorders, usually improve dramatically within days after bromocriptine initiation; improvement of sexual function requires several weeks of treatment but may occur before complete normalization of prolactin levels. Drug withdrawal usually results in recurrent hyperprolactinemia and tumor reexpansion, with the risk of visual compromise. After initial control ofPRLlevels has been achieved, bromocriptine should be reduced to the lowest effective maintenance dose. In ~5% of treated patients, hyperprolactinemia may resolve and not recur when bromocriptine is discontinued after long-term treatment.

Therapy is initiated by administering a low bromocriptine dose (0.625 to 1.25 mg) at bedtime with a snack, followed by gradually increasing the dose. Most patients are successfully controlled with a daily dose of £7.5 mg (2.5 mg tid). About 20% of patients are resistant to dopaminergic treatment; they may have decreased D_2dopamine receptor numbers or a postreceptor defect. D_2receptor gene mutations in the pituitary have not been reported.

Nausea, vomiting, and postural hypotension with faintness may occur in ~25% of patients after the initial dose. These symptoms may persist in some patients. Other side effects include constipation, nasal stuffiness, dry mouth, nightmares, insomnia, and vertigo; decreasing the dose usually alleviates these problems. For the approximately 15% of patients who cannot tolerate oral bromocriptine, intravaginal administration of tablets is often efficacious.

Auditory hallucinations, delusions, and mood swings have been reported in up to 5% of patients and may be due to the dopamine agonist properties or to the lysergic acid derivative of the compound. Rare reports of leukopenia, thrombocytopenia, pleural fibrosis, cardiac arrhythmias, and hepatitis have been described.

Cabergoline An ergoline derivative, cabergoline is a long-acting dopamine agonist with high D_2receptor affinity. The drug effectively suppressesPRL for>14 days after a single oral dose and induces prolactinoma shrinkage in most patients. Cabergoline (0.5 to 1.0 mg twice weekly) achieves normoprolactinemia and resumption of normal gonadal function in ~80% of patients with microadenomas; galactorrhea improves or resolves in 90% of patients. Cabergoline normalizes PRL and shrinks ~70% of macroprolactinomas. It may also be effective in patients resistant to bromocriptine.

Adverse effects and drug intolerance are encountered less commonly than with bromocriptine.

Other dopamine agonists These include *pergolide mesylate*, an ergot derivative with dopaminergic properties; *lisuride*, an ergot derivative; and *quinagolide* (CV 205-502, Norprolac), a nonergot oral dopamine agonist with specific D_2 receptor activity.

Surgery Indications for surgical debulking include dopamine resistance or intolerance and the presence of an invasive macroadenoma with compromised vision that fails to improve rapidly after drug treatment. InitialPRLnormalization is achieved in about 70% of microprolactinomas after surgical resection, but only 30% of macroadenomas can be successfully resected. However, follow-up studies have shown that recurrence of hyperprolactinemia occurs in up to 20% of patients within the first year after surgery; long-term recurrence rates exceed 50% for macroadenomas. Radiotherapy for prolactinomas is reserved for patients with aggressive tumors that do not respond to maximally tolerated dopamine agonists and/or surgery.

Pregnancy The pituitary increases in size during pregnancy, reflecting the stimulatory effects of estrogen and perhaps other growth factors. About 5% of microadenomas significantly increase in size, but 15 to 30% of macroadenomas may grow during pregnancy. Bromocriptine has been used for over 25 years to restore fertility in women with hyperprolactinemia, without evidence of untoward teratogenic effects. Nonetheless, most authorities recommend strategies to minimize fetal exposure to the drug. For women taking bromocriptine who desire pregnancy, mechanical contraception should be used through three regular menstrual cycles to allow for conception timing. When pregnancy is confirmed, bromocriptine should be discontinued andPRLlevels followed serially, especially if headaches or visual symptoms occur. For women harboring macroadenomas, regular visual field testing is recommended, and the drug should be reinstituted if tumor growth is apparent. Although pituitaryMRI may be safe during pregnancy, this procedure should be reserved for symptomatic patients with severe headache and/or visual field defects. Alternatively, surgical decompression may be indicated if vision is threatened. Though comprehensive data support the efficacy and relative safety of bromocriptine-facilitated fertility, patients should be advised of potential unknown deleterious effects and the risk of tumor growth during pregnancy. At present, the experience with cabergoline is too limited to recommend its routine use when fertility is desired.

GROWTH HORMONE

SYNTHESIS

GHis the most abundant anterior pituitary hormone and is expressed early in fetal life (at 8 weeks' gestation). GH-secreting somatotrope cells constitute up to 50% of the total anterior pituitary cell population. Mammosomatotrope cells, which coexpressPRL with GH, can be identified using double immunostaining techniques. Somatotrope development is determined by expression of the cell-specific Pit-1 nuclear transcription factor. In addition to controlling cell differentiation, it also enhances GH gene expression. Five distinct genes on chromosome 17q22 encode GH and related proteins. The pituitary GH gene (*hGH-N*) produces two alternatively spliced products that give

rise to 22-kDa GH (191 amino acids) and a less abundant, 20-kDa GH molecule, with similar biologic activity. Placental syncytiotrophoblast cells express a GH variant (*hGH-V*) gene; the related hormone human chorionic somatotropin (HCS) is expressed by distinct members of the gene cluster. HCS shares high homology with GH yet exhibits minimal growth-promoting properties.

SECRETION

GHsecretion is controlled by complex hypothalamic and peripheral factors.*GHRH*is a 44 amino acid hypothalamic peptide that stimulates GH synthesis and release. Synthetic agonists of the*GHRP*receptor stimulate GHRH and also directly stimulate GH release, but putative endogenous agonists remain incompletely characterized. *Somatostatin* (SRIF) is synthesized in the medial preoptic area of the hypothalamus and inhibits GH secretion. GHRH is secreted as discrete spikes that elicit GH pulses, whereas SRIF sets basal GH tone. SRIF is also expressed in many extrahypothalamic tissues, including theCNS, gastrointestinal system, and pancreas, where it also acts to inhibit the hormone secretion.*IGF-I*, the peripheral target hormone for GH, feeds back to inhibit GH; estrogens induce GH (Chap. 8), whereas glucocorticoid excess suppresses GH release.

Two distinct surface receptors on the somatotrope regulateGHsynthesis and secretion. TheGHRHreceptor is aGPCRthat signals through the intracellular cyclic AMP pathway. Activation of this receptor stimulates somatotrope cell proliferation as well as hormone production. Inactivating mutations of the GHRH receptor cause profound dwarfism (see below). A distinct surface receptor forGHRP has also been identified. This receptor is expressed in the hypothalamus and pituitary. A natural ligand, termed *ghrelin*, binds to the GHRP receptor; it is produced in large amounts in the stomach, though its physiologic role remains unknown. Hypothalamic somatostatin binds to five distinct receptor subtypes (SSTR1 to SSTR5) that are widely expressed in different tissues, including in the pituitary. SSTR2 and SSTR5 subtypes preferentially suppress GH (andTSH) secretion.

GHsecretion is pulsatile, with greater levels at night generally correlating with the onset of sleep. GH secretory rates decline markedly with age so that hormone production in middle age is about 15% of production during puberty. These changes are paralleled by an age-related decline in lean muscle mass. GH secretion is also reduced in obese individuals, thoughIGF-I levels are preserved, suggesting a change in the setpoint for feedback control. Elevated GH levels occur within an hour of deep sleep onset as well as after exercise, physical stress, trauma, and during sepsis. Integrated 24-h GH secretion is higher in women and is also enhanced by estrogen replacement. Using assays in common clinical use, random GH measurements are undetectable in ~50% of daytime samples obtained from healthy subjects and are undetectable in most obese and elderly subjects. Thus, single random GH measurements do not distinguish patients with adult GH deficiency from normal persons.

GHsecretion is profoundly influenced by nutritional factors. Using newer ultrasensitive chemiluminescence-based GH assays with a sensitivity of 0.002 ug/L, a glucose load can be shown to suppress GH to<0.7 ug/L in female and to<0.07 ug/L in male subjects. Increased GH pulse frequency and peak amplitudes occur with chronic malnutrition or

prolonged fasting. GH is stimulated by high-protein meals and by L-arginine. GH secretion is induced by dopamine and apomorphine (a dopamine receptor agonist), as well as by a-adrenergic pathways.b-Adrenergic blockage induces basal GH and enhancesGHRH- and insulin-evoked GH release.

ACTION

The pattern ofGHsecretion may affect tissue responses. The higher GH pulsatility observed in males, as compared to the relatively continuous GH secretion in females, may be an important biologic determinant of linear growth patterns and liver enzyme induction.

The 70-kD peripheralGHreceptor protein shares structural homology with the cytokine/hematopoietic superfamily. A fragment of the receptor extracellular domain generates a soluble GH binding protein (GHBP) that interacts with GH in the circulation. The liver contains the greatest number of GH receptors. GH binding induces receptor dimerization by making distinct contact through two separate binding domains of the hormone. The dimerized receptor interacts with members of theJAK/STATfamily. The activated STAT proteins translocate to the nucleus, where they modulate expression of GH-regulated target genes. GH analogues that bind to the receptor, but are incapable of mediating receptor dimerization, are potent antagonists of GH action and are being investigated for potential use in the treatment of acromegaly and diabetic microangiopathy.

GHinduces protein synthesis and nitrogen retention and impairs glucose tolerance by antagonizing insulin action. GH also stimulates lipolysis, leading to increased circulating fatty acid levels, reduced omental fat mass, and enhanced lean body mass. GH promotes sodium, potassium, and water retention and elevates serum levels of inorganic phosphate. Linear bone growth occurs as a result of complex hormonal and growth factor actions, including those ofIGF-I. GH stimulates epiphyseal prechondrocyte differentiation. These precursor cells produce IGF-I locally and are also responsive to the growth factor.

INSULIN-LIKE GROWTH FACTORS

ThoughGHexerts direct effects in target tissues, many of its physiologic effects are mediated indirectly throughIGF-I, a potent growth and differentiation factor. The major source of circulating IGF-I is hepatic in origin. Peripheral tissue IGF-I exerts local paracrine actions that appear to be both dependent and independent of GH. Thus, GH administration induces circulating IGF-I level as well as stimulating IGF-I expression in multiple tissues.

BothIGF-I and -II are bound to one of six high-affinity circulating IGF-binding proteins (IGFBPs) that regulate IGF bioactivity. Levels of IGFBP3 areGH-dependent, and it serves as the major carrier protein for circulating IGF-I. GH deficiency and malnutrition are associated with low IGFBP3 levels. IGFBP1 and -2 regulate local tissue IGF action but do not bind appreciable amounts of circulating IGF-I.

SerumIGF-I concentrations are profoundly affected by various physiologic factors.

Levels increase during puberty, peak at 16 years, and subsequently decline by>80% during the aging process. IGF-I concentrations are higher in females than in males. BecauseGH is the major determinant of hepatic IGF-I synthesis, abnormalities of GH synthesis or action (e.g., pituitary failure,GHRHreceptor defect, or GH receptor defect) reduce IGF-I levels. Hypocaloric states are associated with GH resistance; IGF-I levels are therefore low with cachexia, malnutrition, and sepsis. In acromegaly, IGF-I levels are invariably high and reflect a log-linear relationship with GH concentrations.

IGF-I Physiology ThoughIGF-I is not an approved drug, investigational studies provide insight into its physiologic effects. High doses of injected IGF-I (100 ug/kg) induce hypoglycemia, primarily because of actions through the insulin receptor. Low IGF-I doses improve insulin sensitivity in patients with severe insulin resistance and diabetes. In cachectic subjects, IGF-I infusion (12 ug/kg per hour) enhances nitrogen retention and lowers cholesterol levels. Longer-term subcutaneous IGF-I injections exert a marked anabolic effect with enhanced protein synthesis. The impact of long-term IGF-I administration on bone mineral content is as yet unclear. Although bone formation markers are induced, bone turnover may also be stimulated by IGF-I.

Side effects ofIGF-I are dose-dependent. An acute overdose may result in hypoglycemia and hypotension. Fluid retention, temporomandibular jaw pain, and increased intracranial pressure are reversible. Avascular necrosis of the femoral head has been reported. Chronic excess IGF-I would presumably result in features of acromegaly.

DISORDERS OF GROWTH AND DEVELOPMENT

Skeletal Maturation and Somatic Growth Linear growth is a function of endochrondral bone formation whereby cartilage is converted into bony skeleton in the long bones and vertebrae (Chap. 340). Ossification occurs within central diaphyseal and peripheral epiphyseal centers. A cartilaginous growth plate forms between the two centers, and chondrocytes proliferate within the growth plate. Linear bone growth ceases when this cartilage layer ossifies and fuses with epiphyseal and diaphyseal bone.

The growth plate is dependent on a variety of hormonal stimuli includingGH,IGF-I, sex steroids, thyroid hormones, paracrine growth factors, and cytokines. GH directly stimulates prechondrocyte differentiation and clonal expansion, resulting in chondrocytes that express both IGF-I receptors and IGF-I protein. The growth-promoting process also requires caloric energy, amino acids, vitamins, and trace metals and consumes about 10% of normal energy production. Malnutrition impairs chondrocyte activity and reduces circulating IGF-I andIGFBP3 levels.

Bone age is delayed in patients with all forms of trueGHdeficiency or GH receptor defects that result in attenuated GH action. Rarely, GH excess accelerates growth, particularly in the setting of delayed bone age from concomitant hypogonadism. Thyroid hormone is permissive for GH synthesis and secretion as well as for maintaining normal circulatingIGF-I and binding protein levels. Bone age is delayed by thyroid hormone deficiency. Consequently, congenital or acquired hypothyroidism is associated with stunted growth, which is partially reversed by thyroid hormone replacement (Chap. 330). Elevated pubertal sex steroid levels (especially estrogen) induce theGHRH-GH-IGF-I

axis and also directly stimulate epiphyseal growth. High doses of estrogen lead to epiphyseal closure. A mutation of the estrogen receptora prevented epiphyseal closure, confirming the important role of this pathway in bone maturation. Several pathologic conditions accompanied by increased levels of sex steroids, including precocious puberty, androgen exposure (exogenous or endogenous), congenital adrenal hyperplasia, and obesity, are associated with accelerated bone maturation. Thus, children with these conditions have accelerated early growth, but end up with reduced final height. In contrast to sex steroids, glucocorticoid excess inhibits linear growth. Glucocorticoids also stimulate SRIF and inhibit peripheral GH and IGF-I receptor signaling.

Linear bone growth rates are very high in infancy and are pituitary-dependent. Mean growth velocity is ~6 cm/year in later childhood and is usually maintained within a given range on a standardized percentile chart. Peak growth rates occur during midpuberty when bone age is 12 (girls) or 13 (boys) (Chap. 8). Secondary sexual development is associated with elevated sex steroids that cause progressive epiphyseal growth plate closure.

Short stature may occur as a result of constitutive intrinsic growth defects or because of acquired extrinsic factors that impair growth (Table 328-9). Genetic disorders, including pituitary transcription factor defects, mutations in growth-related genes, and pituitary hypoplasia syndromes, may all be associated with growth delay and short stature. In general, delayed bone age in a child with short stature is suggestive of a hormonal or systemic disorder, whereas normal bone age in a short child is more likely to be caused by a genetic growth plate disorder (Chap. 351). Other bone and cartilage dysplasia syndromes are associated with specific limb-body proportion phenotypes, and some involve associated calcium disorders (Chap. 343).

Intrauterine growth retardation results in short stature and may be caused by specific congenital anomalies (e.g.,IGF-I deficiency, *Russell-Silver syndrome*, chromosomal disomy) or maternal factors such as diabetes mellitus, infections, hypoxia, drug addiction, or placental dysfunction. Long-term responses of these children toGHtreatment are currently being evaluated.

Turner syndrome is caused by loss of all, or part, of an X chromosome in females (XO). It is characterized by short stature, in addition to gonadal dysgenesis and other characteristic features (Chap. 338). Short stature may be improved with a combination ofGH and an anabolic steroid (oxandrolone); estrogen is required to induce and sustain sexual development. *Noonan syndrome* resembles Turner syndrome phenotypically, but patients have apparently normal sex chromosomes. These patients have delayed pubertal development but not primary gonadal failure.

GH Deficiency in Children

GH Deficiency Isolated GH deficiency is characterized by short stature, micropenis, increased fat, high-pitched voice, and a propensity to hypoglycemia. The etiology of GH deficiency is not identifiable in most children with the disorder. Familial modes of inheritance are seen in one-third of these individuals and may be autosomal dominant, recessive, or X-linked, indicating that multiple genetic abnormalities can lead to GH

deficiency. About 10% of children with growth hormone deficiency have mutations in the GH-N gene. These include gene deletions and a wide range of point mutations, including some that function in a dominant negative manner (heterozygous mutations) to impair the synthesis or function of GH expressed from the normal allele. Mutations in transcription factors Pit-1 and Prop-1, which control somatotrope development, cause GH deficiency in combination with other pituitary hormone deficiencies. The diagnosis of *idiopathic GH deficiency* (IGHD) should be made only after known molecular defects have been excluded.

GHRH Receptor Mutations Recessive mutations of the GHRH receptor gene have been described in several unrelated families with severe proportionate dwarfism. The low basal GH levels in these patients cannot be stimulated by exogenous GHRH, GHRP, or insulin-induced hypoglycemia, confirming the importance of the GHRH receptor for somatotrope cell proliferation and hormonal responsiveness.

Growth Hormone Insensitivity This is caused by defects of GH receptor structure or signaling. Homozygous or heterozygous exonic and intronic mutations of the GH receptor occur mainly in the extracellular ligand-binding domain and are associated with partial or complete GH insensitivity and growth failure (*Laron syndrome*). The diagnosis of this syndrome is based on normal or high GH levels, with decreased circulating GHBP, and low IGF-I levels. Very rarely, defective IGF-I, IGF-I receptor, or IGF-I signaling defects are also encountered.

Nutritional Short Stature Caloric deprivation and malnutrition, uncontrolled diabetes, and chronic renal failure represent secondary causes of abrogated GH receptor function. These conditions also stimulate the production of proinflammatory cytokines, including tumor necrosis factor (TNF)a and ILs, which can block GH-mediated signal transduction. Children with these conditions typically exhibit features of acquired short stature with elevated GH and low IGF-I levels. Circulating GH receptor antibodies may rarely cause peripheral GH insensitivity.

Psychosocial Short Stature Emotional and social deprivation lead to growth retardation accompanied by delayed speech, discordant hyperphagia, and attenuated response to administered GH. A nurturing environment restores growth rates.

Presentation and Diagnosis Short stature is commonly encountered in clinical practice, but the criteria for biochemical diagnosis of true GH deficiency have been difficult to define. The decision to evaluate these children requires clinical judgement in association with auxologic data and family history. Short stature should be comprehensively evaluated if a patient's height is >3 SD below the mean for age or if the growth rate has decelerated. Skeletal maturation is best evaluated by measuring a radiologic bone age, which is based mainly on the degree of growth plate fusion. Final height can be predicted using standardized scales (Bayley-Pinneau or Tanner-Whitehouse) or estimated by adding 6.5 cm (boys) or subtracting 6.5 cm (girls) from the midparental height.

Laboratory Investigation Because GH secretion is pulsatile, GH deficiency is best assessed by examining the response to provocative stimuli. Random GH measurements do not distinguish normal children from those with true GH deficiency.

Adequate adrenal and thyroid hormone replacement should be assured before testing. Provocative stimuli such as exercise, insulin-induced hypoglycemia, and other pharmacologic tests normally increase GH to >7 ug/L in children. Insulin-induced hypoglycemia testing requires the blood sugar nadir to be<50% of baseline levels. This test should be performed under close supervision and is contraindicated in children with seizure disorders.IGF-I levels are not sufficiently sensitive or specific to make the diagnosis but can be useful to confirm GH deficiency; they must be controlled for age and gender. PituitaryMRI may reveal pituitary mass lesions or structural defects.

TREATMENT

Replacement therapy with recombinantGH (0.02 to 0.05 mg/kg per day subcutaneously) restores growth velocity in GH-deficient children to ~10 cm/year. If pituitary insufficiency is documented, other associated hormone deficits should be corrected -- especially adrenal steroids. GH treatment is also moderately effective for accelerating growth rates in patients with Turner syndrome and chronic renal failure.

In patients withGHinsensitivity and growth retardation due to mutations of the GH receptor, treatment withIGF-I bypasses the dysfunctional GH receptor. Growth rates have been maintained for several years, and this therapy now portends improved final adult stature in this group of patients.

ADULT GH DEFICIENCY (AGHD)

This disorder is usually caused by hypothalamic or pituitary somatotrope damage. Acquired pituitary hormone deficiency follows a typical sequential pattern whereby loss of adequateGHreserve foreshadows subsequent hormone deficits. The sequential order of hormone loss is usually GH ®FSH/LH®TSH®ACTH. The presence of documented central hypogonadism, hypothyroidism, and/or hypoadrenalism invariably assures the presence of GH deficiency. Conversely, ~40% of patients with incipient preclinical pituitary insufficiency already manifest GH deficiency, if rigorously tested.

Presentation and Diagnosis The clinical features ofAGHDinclude changes in body composition, lipid metabolism, and quality of life and cardiovascular dysfunction (Table 328-10). Body composition changes are common and include reduced lean body mass, increased fat mass with selective deposition of intraabdominal visceral fat, and increased waist-to-hip ratio. Hyperlipidemia, left ventricular dysfunction, hypertension, and increase plasma fibrinogen levels may also be present. Bone mineral content is reduced, with resultant increased fracture rates. Patients may exhibit social isolation, depression, and difficulty in maintaining gainful employment. Adult hypopituitarism is associated with a three-fold increased cardiovascular mortality rate in comparison to age- and sex-matched controls, and this may be due toGHdeficiency.

Laboratory Investigation AGHD is rare, and in light of the nonspecific nature of associated clinical symptoms, patients appropriate for testing should be carefully selected on the basis of well-defined criteria. With few exceptions, testing should be restricted to patients with the following predisposing factors: (1) pituitary surgery, (2) pituitary or hypothalamic tumor or granulomas, (3) cranial irradiation, (4) radiologic evidence of a pituitary lesion, (5) childhood requirement forGHreplacement therapy, or,

rarely, (6) unexplained low age- and sex-matchedIGF-I level. The transition of the GH-deficient adolescent to adulthood requires retesting to document adult GH deficiency. Up to 20% of patients treated for childhood-onset GH deficiency are found to be GH-sufficient on repeat testing as adults.

A significant proportion (~25%) of trulyGH-deficient adults have low-normalIGF-I levels. Thus, as in the evaluation of GH deficiency in children, valid age- and gender-matched IGF-I measurements provide a useful index of therapeutic responses but are not sufficiently sensitive for diagnostic purposes.AGHD is diagnosed by demonstrating a subnormal GH response (<3 ug/L) to a standard provocative test. None of the available stimulation tests provides standardized GH responses that clearly discriminate normal subjects from truly GH-deficient adults. The age-related decline of GH blurs this distinction further in elderly individuals. The most validated test to distinguish pituitary-sufficient patients from those with AGHD is insulin-induced (0.05 to 0.1 U/kg) hypoglycemia. After glucose reduction to ~40 mg/dL, most individuals experience neuroglycopenic symptoms (Chap. 334), and peak GH release occurs at 60 min and remains elevated for up to 2 h. About 90% of healthy adults exhibit GH responses>5 ug/L; AGHD is defined by a peak GH response to hypoglycemia of <3 ug/L. An attenuated GH response is observed in patients with pituitary damage, obesity, untreated hypothyroidism, depression, or chronic renal failure. Although an *insulin tolerance test* (ITT) is safe when performed under appropriate supervision, it is contraindicated in patients with diabetes, ischemic heart disease, cerebrovascular disease, or epilepsy and in elderly patients. Alternative stimulatory tests include L-dopa (500 mg orally) and intravenous arginine (30 g), GHRH(1 ug/kg), andGHRP-6 (90 ug). Combinations of these tests may evoke GH secretion in subjects not responsive to a single test.

TREATMENT

Once the diagnosis ofAGHD is unequivocally established, replacement ofGH may be indicated. Contraindications to therapy include the presence of an active neoplasm, intracranial hypertension, or uncontrolled diabetes and retinopathy. The starting dose of 0.15 to 0.3 mg/d should be titrated (up to a maximum of 1.25 mg/d) to maintainIGF-I levels in the mid-normal range for age- and gender-matched controls (Fig. 328-8). Women require higher doses than men, and elderly patients require less GH. Long-term GH maintenance sustains normal IGF-I levels and is associated with persistent body composition changes (e.g., enhanced lean body mass and lower body fat). High-density lipoprotein cholesterol increases, but total cholesterol and insulin levels do not change significantly. Lumbar spine bone mineral density increases, but this response is gradual (>1 year). Many patients note significant improvement in quality of life when evaluated by standardized questionnaires. The effect of GH replacement on mortality rates in GH-deficient patients is currently the subject of long-term prospective investigation.

About 30% of patients exhibit reversible dose-related fluid retention, joint pain, and carpal tunnel syndrome, and up to 40% exhibit myalgias and paresthesias. Patients receiving insulin require careful monitoring for dosing adjustments, asGH is a potent counterregulatory hormone for insulin action. Patients with type 2 diabetes mellitus initially develop further insulin resistance. However, glycemic control improves with the sustained loss of abdominal fat associated with long-term GH replacement. Headache,

increased intracranial pressure, hypertension, atrial fibrillation, and tinnitus occur rarely. Prevalence of pituitary tumor regrowth and potential progression of skin lesions are currently being assessed in long-term surveillance programs. To date, development of these potential side effects does not appear significant. For some patients, the expense of long-term GH replacement is prohibitive.

ACROMEGALY

Etiology GH hypersecretion is usually the result of somatotrope adenomas but is also rarely caused by extrapituitary lesions (Table 328-11). In addition to typical GH-secreting somatotrope adenomas, mixed mammosomatotrope tumors and acidophilic stem-cell adenomas can secrete both GH and PRL. In patients with acidophilic stem-cell adenomas, features of hyperprolactinemia (hypogonadism and galactorrhea) predominate over the less clinically evident signs of acromegaly. Occasionally, mixed plurihormonal tumors are encountered that secrete ACTH, the glycoprotein hormone a subunit, or TSH, in addition to GH. Patients with partially empty sella may present with GH hypersecretion due to a small GH-secreting adenoma within the compressed rim of pituitary tissue; some of these may reflect the spontaneous necrosis of tumors that were previously larger. GH-secreting tumors rarely arise from ectopic pituitary tissue remnants in the nasopharynx or midline sinuses.

There are case reports of ectopic GH secretion by tumors of pancreatic, ovarian, or lung origin. Excess GHRH production may cause acromegaly because of chronic stimulation of somatotropes. These patients present with classic features of acromegaly, elevated GH levels, pituitary enlargement on MRI, and pathologic characteristics of pituitary hyperplasia. The most common cause of GHRH-mediated acromegaly is a chest or abdominal carcinoid tumor. Although these tumors usually express positive GHRH immunoreactivity, clinical features of acromegaly are evident in only a minority of patients with carcinoid disease. Excessive GHRH may also be elaborated by hypothalamic tumors, usually choristomas or neuromas.

Presentation and Diagnosis Protean manifestations of GH and IGF-I hypersecretion are indolent and often are not clinically diagnosed for 10 years or more. Acral bony overgrowth results in frontal bossing, increased hand and foot size, mandibular enlargement with prognathism, and widened space between the lower incisor teeth. In children and adolescents, initiation of GH hypersecretion prior to epiphyseal long bone closure is associated with the development of pituitary gigantism (Fig. 328-9). Soft tissue swelling results in increased heel pad thickness, increased shoe or glove size, ring tightening, characteristic coarse facial features, and a large fleshy nose. Other commonly encountered clinical features include hyperhidrosis, deep and hollow-sounding voice, oily skin, arthropathy, kyphosis, carpal tunnel syndrome, proximal muscle weakness and fatigue, acanthosis nigricans, and skin tags. Generalized visceromegaly occurs, including cardiomegaly, macroglossia, and thyroid gland enlargement.

The most significant clinical impact of GH excess occurs with respect to the cardiovascular system. Coronary heart disease, cardiomyopathy with arrhythmias, left ventricular hypertrophy, decreased diastolic function, and hypertension occur in about 30% of patients. Upper airway obstruction with sleep apnea occurs in about 60% of

patients and is associated with both soft tissue laryngeal airway obstruction and central sleep dysfunction. Diabetes mellitus develops in 25% of patients with acromegaly, and most patients are intolerant of a glucose load (as GH counteracts the action of insulin). Acromegaly is associated with an increased risk of colon polyps and colonic malignancy; polyps are diagnosed in up to one-third of acromegalic patients. Overall mortality is increased about three-fold and is due primarily to cardiovascular and cerebrovascular disorders, malignancy, and respiratory disease. Unless GH levels are controlled, survival is reduced by an average of 10 years compared with an age-matched control population.

Laboratory Investigation Age- and gender-matched serumIGF-I levels are invariably elevated in acromegaly. Consequently, an IGF-I level provides a useful laboratory screening measure when clinical features raise the possibility of acromegaly. Due to the pulsatility ofGHsecretion, measurement of a single random GH level is not useful for the diagnosis or exclusion of acromegaly and does not correlate with disease severity. The diagnosis of acromegaly is confirmed by demonstrating the failure of GH suppression to < 1 ug/L within 1 to 2 h of an oral glucose load (75 g). About 20% of patients exhibit a paradoxical GH rise after glucose. About 60% of patients with GH-secreting tumors may exhibit paradoxical GH responses toTRHadministration.PRLshould be measured as it is elevated in ~25% of patients with acromegaly. Thyroid function, gonadotropins, and sex steroids may be attenuated because of tumor mass effects. Because most patients will undergo surgery with glucocorticoid coverage, tests ofACTHreserve in asymptomatic patients are more efficiently deferred until after surgery.

TREATMENT

Surgical resection ofGH-secreting adenomas is the initial treatment for most patients (Fig. 328-10). Somatostatin analogues are used as adjuvant treatment for preoperative shrinkage of large invasive macroadenomas, immediate relief of debilitating symptoms, and reduction of GH hypersecretion, in elderly patients experiencing morbidity, in patients who decline surgery, or, when surgery fails, to achieve biochemical control. Irradiation or repeat surgery may be required for patients who cannot tolerate or do not respond to adjunctive medical therapy. The high rate of late hypopituitarism and the slow rate (5 to 15 years) of biochemical response are the main disadvantages of radiotherapy. Irradiation is relatively ineffective in normalizingIGF-I levels. Stereotactic ablation of GH-secreting adenomas by gamma-knife radiotherapy is promising, but long-term results are not available and the side effects have not been clearly delineated. Somatostatin analogues may be given while awaiting the full effect of radiotherapy. Systemic sequelae of acromegaly, including cardiovascular disease, diabetes, and arthritis, should also be managed aggressively. Maxillofacial surgery for mandibular repair may also be indicated.

Surgery Transsphenoidal surgical resection by an experienced surgeon is the preferred primary treatment for both microadenomas (cure rate ~70%) and macroadenomas (<50% cured). Soft tissue swelling improves immediately after tumor resection.GHlevels return to normal within an hour, andIGF-I levels are normalized within 3 to 4 days. In ~10% of patients, acromegaly may recur several years after apparently successful surgery; hypopituitarism develops in up to 15% of patients.

Somatostatin Analogues Somatostatin analogues exert their therapeutic effects through SSTR2 and -5 receptors, both of which are expressed byGH-secreting tumors. Octreotide acetate is an 8-amino-acid synthetic somatostatin analogue. In contrast to native somatostatin, the analogue is relatively resistant to plasma degradation. It has a 2-h serum half-life and possesses at least 40-fold greater potency than native somatostatin to suppress GH. These properties often allow effective pharmacologic control of GH hypersecretion without prior surgery or radiotherapy. Octreotide is administered by subcutaneous injection, beginning with 50 ug tid; the dose can be gradually increased up to 1500 ug/d. Fewer than 10% of patients do not respond to the analogue. Octreotide suppresses integrated GH levels to <5 ug/L in ~70% of patients and to<2 ug/L in up to 60% of patients. It normalizesIGF-I levels in ~75% of treated patients (Fig. 328-11). Prolonged use of the analogue is not associated with desensitization, even after ³10 years of treatment. Rapid relief of headache and soft tissue swelling occurs in ~75% of patients within days to weeks of treatment initiation. Subjective clinical benefits of octreotide therapy occur more frequently than biochemical remission, and most patients report symptomatic improvement, including amelioration of headache, perspiration, obstructive apnea, and cardiac failure. Modest pituitary tumor size reduction occurs in about 40% of patients, but this effect is reversed when treatment is stopped.

Two long-acting somatostatin depot formulations, octreotide and lanreotide, are becoming the preferred medical treatment for acromegalic patients. *Sandostatin-LAR* is a sustained-release, long-acting formulation of octreotide incorporated into microspheres that sustain drug levels for several weeks after intramuscular injection.GHsuppression occurs for as long as 6 weeks after a 30-mg injection; long-term monthly treatment sustains GH andIGF-I suppression and reduction of pituitary tumor size. *Lanreotide*, a slow-release depot somatostatin preparation, is a cyclic somatostatin octapeptide analogue that suppresses GH and IGF-I hypersecretion for 10 to 14 days after a 30-mg intramuscular injection. Long-term administration controls GH hypersecretion in two-thirds of treated patients and improves patient compliance because of the long interval required between drug injections.

Side Effects Somatostatin analogues are well tolerated in most patients. Adverse effects are short-lived and mostly relate to drug-induced suppression of gastrointestinal motility and secretion. Nausea, abdominal discomfort, fat malabsorption, diarrhea, and flatulence occur in one-third of patients, though these symptoms usually remit within 2 weeks. Octreotide suppresses postprandial gallbladder contractility and delays gallbladder emptying; up to 30% of patients treated long-term develop echogenic sludge or asymptomatic cholesterol gallstones. Other side effects include mild glucose intolerance due to transient insulin suppression, asymptomatic bradycardia, hypothyroxinemia, and local pain at the injection site. The cost of chronic treatment may be prohibitive.

Dopamine Agonists Bromocriptine may suppressGHsecretion in some acromegalic patients, particularly those with cosecretion ofPRL. High doses (³20 mg/d), administered as three to four daily doses, are usually required to lower GH, and therapeutic efficacy is modest. GH levels are suppressed to <5 ug/L in ~20% of patients, andIGF-I levels are normalized in only 10% of patients. Cabergoline also suppresses GH and decreases adenoma size when given at a relatively high dose of 0.5 mg/d. Combined treatment

with octreotide and bromocriptine induces additive biochemical control compared to either drug alone.

GH Antagonists Investigational GH analogues antagonize endogenous GH action by blocking peripheral GH binding to its receptor. Consequently, serumIGF-I levels are suppressed, potentially reducing the deleterious effects of excess endogenous GH.

Radiation External radiation therapy or high-energy stereotactic techniques are used as adjuvant therapy for acromegaly. An advantage of radiation is that patient compliance with long-term treatment is not required. Tumor mass is reduced, andGHlevels are attenuated over time. However, 50% of patients require at least 8 years for GH levels to be suppressed to <5 ug/L; this suboptimal level of GH reduction is achieved in about 90% of patients after 18 years. Patients may require interim medical therapy for several years prior to attaining maximal radiation benefits. Most patients also experience hypothalamic-pituitary damage, leading to gonadotropin,ACTH, and/orTSHdeficiency within 10 years of therapy.

In summary, surgery is the preferred primary treatment forGH-secreting microadenomas (Fig. 328-10). The high frequency of GH hypersecretion after macroadenoma resection usually necessitates adjuvant or primary medical therapy for these larger tumors. Patients unable to receive or respond to medical treatment can be offered radiation.

ADRENOCORTICOTROPIN HORMONE (See also Chap. 331)

SYNTHESIS

ACTH-secreting corticotrope cells constitute about 20% of the pituitary cell population. ACTH (39 amino acids) is derived from thePOMCprecursor protein (266 amino acids) that also generates several other peptides, including b-lipotropin,b-endorphin, met-enkephalin,a melanocyte-stimulating hormone (MSH), and corticotropin-like intermediate lobe protein (CLIP). The POMC gene is located on chromosome 2 and possesses at least three different promoter regions that account for pituitary and peripheral tissue-specific POMC expression. A proximal promoter mediates POMC expression in corticotropes. The gonads, placenta, gastrointestinal tissues, liver, kidney, adrenal medulla, lung, and lymphocytic tissue express shorter POMC transcripts derived from a downstream promoter region. Tumors arising from peripheral neuroendocrine tissues that secrete ectopic ACTH express the longer form of POMC. The POMC gene is powerfully suppressed by glucocorticoids and induced by CRH, arginine vasopressin (AVP), and gp 130 proinflammatory cytokines, includingIL-6, and leukemia inhibitory factor.

CRH, a 41-amino-acid hypothalamic peptide synthesized in the paraventricular nucleus as well as in higher brain centers, is the predominant stimulator ofACTHsynthesis and release. The CRH receptor is aGPCRthat is expressed on the corticotrope. CRH signaling inducesPOMCtranscription and is mediated by cyclic AMP, as well as mitogen activated protein (MAP) kinase-activator protein-1 (AP-1) cascades.

SECRETION

ACTHsecretion is pulsatile and exhibits a characteristic circadian rhythm, peaking at 6 A.M. and reaching a nadir about midnight. Adrenal glucocorticoid secretion, which is driven by ACTH, follows a parallel diurnal pattern. ACTH circadian rhymicity is determined by variations in secretory pulse amplitude rather than changes in pulse frequency. Superimposed on this endogenous rhythm, ACTH levels are increased byAVP, physical stress, exercise, acute illness, and insulin-induced hypoglycemia.

Loss of cortisol feedback inhibition, as occurs in primary adrenal failure, results in extremely highACTHlevels. Glucocorticoid-mediated negative regulation of the hypothalamo-pituitary-adrenal (HPA) axis occurs as a consequence of both hypothalamicCRHsuppression and direct attenuation of pituitaryPOMCgene expression and ACTH release. HypothalamicAVPstimulates the protein kinase C pathway and acts synergistically with CRH to enhance ACTH production.

Acute inflammatory or septic insults activate theHPA axis through the integrated actions of proinflammatory cytokines, bacterial toxins, and neural signals. The overlapping cascade ofACTH-inducing cytokines (TNF;IL-1, -2, and -6; and leukemia inhibitory factor) activates hypothalamicCRH andAVPsecretion, pituitaryPOMCgene expression, and local paracrine pituitary cytokine networks. The resulting cortisol elevation restrains the inflammatory response and provides host protection. Concomitantly, cytokine-mediated central glucocorticoid receptor resistance impairs glucocorticoid suppression of the HPA. Thus, the neuroendocrine stress response reflects the net result of highly integrated hypothalamic, intrapituitary, and peripheral hormone and cytokine signals.

ACTION

The major function of theHPA axis is to maintain metabolic homeostasis and to mediate the neuroendocrine stress response. Peripheral and central afferent signals, which are integrated by the pituitary corticotrope cell, ultimately affect the pattern and quantity of adrenal cortisol secretion.ACTHinduces cortical steroidogenesis by maintaining adrenal cell proliferation and function. The receptor for ACTH, designated *melanocortin-2 receptor*, is aGPCRthat activates cyclic AMP andMAPkinase pathways; it induces steroidogenesis by stimulating a cascade of steroidogenic enzymes (Chap. 331).

ACTH DEFICIENCY

Presentation and Diagnosis Secondary adrenal insufficiency occurs as a result of pituitary ACTH deficiency. It is characterized by fatigue, weakness, anorexia, nausea, vomiting, and, occasionally, hypoglycemia (due to diminished insulin counterregulation). In contrast to primary adrenal failure, hypocortisolism associated with pituitary failure is not usually accompanied by pigmentation changes or mineralocorticoid deficiency. ACTH deficiency is commonly due to glucocorticoid withdrawal following treatment-associated suppression of theHPAaxis. Isolated ACTH deficiency may occur after surgical resection of an ACTH-secreting pituitary adenoma that has suppressed the HPA axis; this phenomenon is suggestive of a surgical cure. The mass effects of other pituitary adenomas or sellar lesions may lead to ACTH deficiency, but usually in combination with other pituitary hormone deficiencies. Partial ACTH deficiency may be unmasked in the presence of an acute medical or surgical illness, when clinically

significant hypocortisolism reflects diminished ACTH reserve.

Laboratory Diagnosis Inappropriately lowACTHlevels in the setting of low cortisol levels are characteristic of diminished ACTH reserve. Low basal serum cortisol levels are associated with blunted cortisol responses to ACTH provocative stimulation and impaired cortisol response to insulin-induced hypoglycemia, or testing with metyrapone orCRH.*For description of provocative ACTH tests, see "Tests of Pituitary-Adrenal Responsiveness" in Chap. 331.*

TREATMENT

Glucocorticoid replacement therapy improves most features ofACTHdeficiency. The total daily dose of hydrocortisone replacement should not exceed 30 mg daily, divided into two or three doses. Prednisone (5 mg each morning; 2.5 mg each evening) is longer acting and has fewer mineralocorticoid effects than hydrocortisone. Some authorities advocate lower maintenance doses in an effort to avoid cushingoid side effects. Doses should be increased several-fold during periods of acute illness or stress.

CUSHING'S DISEASE (ACTH-PRODUCING ADENOMA) (See also Chap. 331)

Etiology and Prevalence Pituitary corticotrope adenomas account for 70% of patients with endogenous causes of Cushing's syndrome. However, it should be recalled that iatrogenic hypercortisolism is the most common cause of cushingoid features. Ectopic tumorACTHproduction, cortisol-producing adrenal adenomas, carcinoma, and hyperplasia account for the other causes; rarely, ectopic tumorCRHproduction is encountered.

ACTH-producing adenomas account for about 10 to 15% of all pituitary tumors. Because the clinical features of Cushing's syndrome often lead to early diagnosis, most ACTH-producing pituitary tumors are relatively small microadenomas. However, macroadenomas are also seen, and some ACTH-secreting adenomas are clinically silent. Cushing's disease is 5 to 10 times more common in women than in men. These pituitary adenomas exhibit unrestrained ACTH secretion, with resultant hypercortisolemia. However, they retain partial suppressibility in the presence of high doses of administered glucocorticoids, providing the basis for dynamic testing to distinguish pituitary and nonpituitary causes of Cushing's syndrome.

Presentation and Diagnosis The diagnosis of Cushing's syndrome presents two great challenges: (1) to distinguish patients with pathologic cortisol excess from those with physiologic or other disturbances of cortisol production; and (2) to determine the etiology of cortisol excess, which can include iatrogenic administration of glucocorticoids, adrenal adenomas or carcinomas, pituitary adenomas, and ectopic sources ofACTH andCRH.

Typical features of chronic cortisol excess include thin, brittle skin, central obesity, hypertension, plethoric moon facies, purple striae and easy bruisability, glucose intolerance or diabetes mellitus, gonadal dysfunction, osteoporosis, proximal muscle weakness, signs of hyperandrogenism (acne, hirsutism), and psychologic disturbances (depression, mania, and psychoses) (Table 328-12). Hematopoietic features of

hypercortisolism include leukocytosis, lymphopenia, and eosinopenia. Immune suppression includes delayed hypersensitivity. The protean manifestations of hypercortisolism make it challenging to decide which patients mandate formal laboratory evaluation. Certain features make pathologic causes of hypercortisolism more likely -- these include characteristic central redistribution of fat, thin skin with striae and bruising, and proximal muscle weakness. In children and in young females, early osteoporosis may be particularly prominent. The primary cause of death is cardiovascular disease, but infections and risk of suicide are also increased.

Rapid development of features of hypercortisolism associated with skin hyperpigmentation and severe myopathy suggests the possibility of ectopic sources ofACTH. Hypertension, hypokalemic alkalosis, glucose intolerance, and edema are also more pronounced in these patients. Serum potassium levels<3.3 mmol/L are evident in ~70% of patients with ectopic ACTH secretion but are seen in <10% of patients with pituitary-dependent Cushing's disease.

Laboratory Investigation The diagnosis of Cushing's syndrome is based on laboratory documentation of endogenous hypercortisolism. Measurements of 24-h urine free cortisol (UFC) is a precise and cost-effective screening test. Alternatively, the failure to suppress plasma cortisol after an overnight 1-mg dexamethasone suppression test can be used to identify patients with hypercortisolism. As nadir levels of cortisol occur at night, elevated midnight samples of cortisol are suggestive of Cushing's syndrome. Basal plasmaACTHlevels often distinguish patients with ACTH-independent (adrenal or exogenous glucocorticoid) from those with ACTH-dependent (pituitary, ectopic ACTH) Cushing's disease. Mean basal ACTH levels are about eight-fold higher in patients with ectopic ACTH secretion compared to those with pituitary ACTH-secreting adenomas. However, extensive overlap of ACTH levels in these two disorders precludes using ACTH to make the distinction. Instead, dynamic testing, based on differential sensitivity to glucocorticoid feedback, or ACTH stimulation in response toCRH or cortisol reduction is used to discriminate ectopic versus pituitary sources of excess ACTH (Table 328-13). Very rarely, circulating CRH levels are elevated, reflecting ectopic tumor-derived secretion of CRH and often ACTH.**For discussion of dynamic testing for Cushing's syndrome, see Chap. 331.*

MostACTH-secreting pituitary tumors are <5 mm in diameter, and about half are undetectable by sensitiveMRI. The high prevalence of incidental pituitary microadenomas diminishes the ability to distinguish ACTH-secreting pituitary tumors accurately by MRI.

Inferior Petrosal Venous Sampling Because pituitaryMRI with gadolinium enhancement is insufficiently sensitive to distinguish small (<2 mm) pituitaryACTH-secreting adenomas from ectopic ACTH-secreting tumors that may have similar clinical and biochemical characteristics, bilateral inferior petrosal sinus ACTH sampling before and afterCRHadministration may be required. Simultaneous assessment of ACTH concentrations in each inferior petrosal vein and in the peripheral circulation provides a strategy for confirming and localizing pituitary ACTH production. Sampling is performed at baseline and 2, 5, and 10 min after intravenous ovine CRH (1 ug/kg) injection. An increased ratio (>2) of inferior petrosal:peripheral vein ACTH confirms pituitary Cushing's disease. After CRH injection, peak petrosal:peripheral ACTH ratios of³3

confirm the presence of a pituitary ACTH-secreting tumor. The sensitivity of this test is 99%, with very rare false-positive results. False-negative results may be encountered in patients with aberrant venous anatomic drainage. Petrosal sinus catheterizations are technically difficult, and about 0.05% of patients develop neurovascular complications. The procedure should not be performed in patients with hypertension or in the presence of a well-visualized pituitary adenoma on MRI.

TREATMENT

Selective transsphenoidal resection is the treatment of choice for Cushing's disease (Fig. 328-12). The remission rate for this procedure is ~80% for microadenomas but <50% for macroadenomas. After successful tumor resection, most patients experience a postoperative period of adrenal insufficiency that lasts for up to 12 months. This usually requires low-dose cortisol replacement, as patients experience steroid withdrawal symptoms as well as having a suppressedHPAaxis. Biochemical recurrence occurs in approximately 5% of patients in whom surgery was initially successful.

When initial surgery is unsuccessful, repeat surgery is sometimes indicated, particularly when a pituitary source forACTH is well documented. In older patients in whom growth and fertility are no longer important, hemi- or total hypophysectomy may be necessary if an adenoma is not recognized. Pituitary irradiation may be used after unsuccessful surgery, but it cures only about 15% of patients. Because radiation is slow and only partially effective in adults, steroidogenic inhibitors are used in combination with pituitary irradiation to block the adrenal effects of persistently high ACTH levels.

Mitotane (*o*, *p*¢-DDD) suppresses cortisol hypersecretion by inhibiting 11b-hydroxylase and cholesterol side-chain cleavage enzymes and by destroying adrenocortical cells. Side effects of mitotane include gastrointestinal symptoms, dizziness, gynecomastia, hyperlipidemia, skin rash, and hepatic enzyme elevation. It may also lead to hypoaldosteronism. *Ketoconazole*, an imidazole derivative antimycotic agent, inhibits several P450 enzymes and effectively lowers cortisol in most patients with Cushing's disease when administered twice daily (600 to 1200 mg/d). Elevated hepatic transaminases, gynecomastia, impotence, gastrointestinal upset, and edema are common side effects. *Metyrapone* (2 to 4 g/d) inhibits 11b-hydroxylase activity and normalizes plasma cortisol in up to 75% of patients. Side effects include nausea and vomiting, rash, and exacerbation of acne or hirsutism. Other agents include *aminoglutethimide* (250 mg tid), *trilostane* (200 to 1000 mg/d), *cyproheptadine* (24 mg/d), and IV *etomidate* (0.3 mg/kg per hour). Glucocorticoid insufficiency is a potential side effect of agents used to block steroidogenesis.

The use of steroidogenic inhibitors has decreased the need for bilateral adrenalectomy. Removal of both adrenal glands corrects hypercortisolism but may be associated with significant morbidity and necessitates permanent glucocorticoid and mineralocorticoid replacement. Adrenalectomy in the setting of residual corticotrope adenoma tissue predisposes to the development of *Nelson's syndrome*, a disorder characterized by rapid pituitary tumor enlargement and increased pigmentation secondary to highACTHlevels. Radiation therapy may be indicated to prevent the development of Nelson's syndrome after adrenalectomy.

GONADOTROPINS: FSH AND LH

SYNTHESIS AND SECRETION

Gonadotrope cells comprise about 10% of anterior pituitary cells and produce two gonadotropins -- LH and FSH. LikeTSH andhCG, LH and FSH are glycoprotein hormones consisting of a andb subunits. The a subunit is common to these glycoprotein hormones; specificity is conferred by theb subunits, which are expressed by separate genes.

Gonadotropin synthesis and release are dynamically regulated. This is particularly true in females, in whom the rapidly fluctuating gonadal steroid levels vary throughout the menstrual cycle. HypothalamicGnRH, a 10-amino-acid peptide synthesized in the preoptic region, regulates the synthesis and secretion of bothLH andFSH. GnRH is secreted in discrete pulses every 60 to 120 min, which in turn elicit LH and FSH pulses (Fig. 328-3). GnRH acts through aGPCR to stimulate phospholipase C, protein kinase C, and calcium signaling pathways. The pulsatile mode of GnRH input is essential to its action; pulses prime gonadotrope responsiveness, whereas continuous GnRH exposure induces desensitization. Based on this phenomenon, long-acting GnRH agonists are used to suppress gonadotropin levels in children with precocious puberty (Chap. 8) and in men with prostate cancer (Chap. 95) and are used in some ovulation-induction protocols to reduce endogenous gonadotropins (Chap. 336). Estrogens act at the hypothalamic and pituitary levels to control gonadotropin secretion. Chronic estrogen exposure is inhibitory, whereas rising estrogen levels, as occurs during the preovulatory surge, exert positive feedback to increase gonadotropin pulse frequency and amplitude. Progesterone slows GnRH pulse frequency but enhances gonadotropin responses to GnRH. Testosterone feedback in males also occurs at the hypothalamic and pituitary levels and partially reflects its conversion to estrogens (Chap. 335).

ThoughGnRH is the main regulator ofLH andFSHsecretion, FSH synthesis is also under separate control by the gonadal peptides inhibin and activin, which are members of the transforming growth factorb (TGF-b) family. Inhibin selectively suppresses FSH, whereas activin stimulates FSH synthesis (Chap. 336).

ACTION

The gonadotropin hormones interact with their respectiveGPCRsexpressed in the ovary and testis, evoking germ-cell development and maturation and steroid hormone biosynthesis. In women,FSHregulates ovarian follicle development and stimulates ovarian estrogen production.LHmediates ovulation and maintenance of the corpus luteum. In men, LH induces Leydig cell testosterone synthesis and secretion and FSH stimulates seminiferous tubule development and regulates spermatogenesis.

GONADOTROPIN DEFICIENCY

Hypogonadism is the most common presenting feature of adult hypopituitarism, even when other pituitary hormones are also deficient. It is often a harbinger of hypothalamic or pituitary diseases that impairGnRHproduction or delivery through the pituitary stalk. As noted above, hypogonadotropic hypogonadism is a common presenting feature of

hyperprolactinemia.

A variety of inherited and acquired disorders are associated with *isolated hypogonadotropic hypogonadism* (IHH) (Chap. 335). Hypothalamic defects associated withGnRHdeficiency include two X-linked disorders, Kallmann syndrome (see above) and mutations in the *DAX1* gene. GnRH receptor mutations and inactivating mutations of theLHb andFSHb subunit genes are rare causes of selective gonadotropin deficiency. Acquired forms of GnRH deficiency leading to hypogonadotropism are seen in association with anorexia nervosa (Chap. 78), stress, starvation, and extreme exercise, but may also be idiopathic. Hypogonadotropic hypogonadism in these disorders is reversed by removal of the stressful stimulus.

Presentation and Diagnosis In premenopausal women, hypogonadotropic hypogonadism presents as diminished ovarian function leading to oligomenorrhea or amenorrhea, infertility, decreased vaginal secretions, decreased libido, and breast atrophy. In hypogonadal adult males, secondary testicular failure is associated with decreased libido and potency, infertility, decreased muscle mass with weakness, reduced beard and body hair growth, soft testes, and characteristic fine facial wrinkles. Osteoporosis occurs in both untreated hyogonadal females and males.

Laboratory Investigation Central hypogonadism is associated with low or inappropriately low serum gonadotropin levels and low sex hormone concentrations (testosterone in males, estradiol in females). Three pooled serum samples drawn 20 min apart are used for accurate measurement of serumLH andFSHlevels, thus allowing for the effects of hormone secretory pulses. Male patients have abnormal semen analysis.

IntravenousGnRH(100 ug) stimulates gonadotropes to secreteLH(which peaks within 30 min) andFSH(which plateaus during the ensuing 60 min). Normal responses vary according to menstrual cycle stage, age, and sex of the patient. Generally, LH levels increase about threefold, whereas FSH responses are less pronounced. In the setting of gonadotropin deficiency, a normal gonadotropin response to GnRH indicates intact gonadotrope function and suggests a hypothalamic abnormality. An absent response, however, cannot reliably distinguish pituitary from hypothalamic causes of hypogonadism. For this reason, GnRH testing usually adds little to the information gained from baseline evaluation of the hypothalamic-pituitary-gonadotrope axis, except in cases of isolated GnRH deficiency (e.g., Kallmann syndrome).

MRIexamination of the sellar region and assessment of other pituitary functions are usually indicated in patients with documented central hypogonadism.

TREATMENT

In males, testosterone replacement is necessary to achieve and maintain normal growth and development of the external genitalia, secondary sex characteristics, male sexual behavior, and androgenic anabolic effects including maintenance of muscle function and bone mass. Testosterone may be administered by intramuscular injections every 1 to 4 weeks or using patches that are replaced daily (Chap. 335). Gonadotropin injections [hCG or human menopausal gonadotropin (hMG)] over 12 to 18 months are used to

restore fertility. PulsatileGnRHtherapy (25 to 150 ng/kg every 2 h), administered by a subcutaneous infusion pump, is also effective for treatment of hypothalamic hypogonadism when fertility is desired.

In premenopausal women, cyclical replacement of estrogen and progesterone maintains secondary sexual characteristics and genitourinary tract integrity and prevents premature osteoporosis and possibly coronary artery disease (Chap. 336). Gonadotropin therapy is used for ovulation induction. Follicular growth and maturation are initiated usinghMG or recombinantFSH;hCG is subsequently injected to induce ovulation. As in men, pulsatileGnRHtherapy can be used to treat hypothalamic causes of gonadotropin deficiency.

NONFUNCTIONING AND GONADOTROPIN-PRODUCING PITUITARY ADENOMAS

Etiology and Prevalence Nonfunctioning pituitary adenomas include those that secrete little or no pituitary hormones, as well as tumors that produce too little hormone to result in recognizable clinical features. They are the most common type of pituitary adenoma and are usually macroadenomas at the time of diagnosis because clinical features are inapparent until tumor mass effects occur. Based on immunohistochemistry, most clinically nonfunctioning adenomas can be shown to originate from gonadotrope cells. These tumors typically produce small amounts of intact gonadotropins (usuallyFSH) as well as uncombined a andLHb and FSH b subunits. Tumor secretion may lead to elevated a and FSHb subunits and, rarely, to increased LHb subunit levels. Some adenomas expressa subunits without FSH or LH.TRHadministration often induces an atypical increase of tumor-derived gonadotropins or subunits.

Presentation and Diagnosis Clinically nonfunctioning tumors may present with optic chiasm pressure and other symptoms of local expansion or be incidentally discovered on anMRIperformed for another indication. Menstrual disturbances or ovarian hyperstimulation rarely occur in women with large tumors that produceFSH andLH. More commonly, adenoma compression of the pituitary stalk or surrounding pituitary tissue leads to attenuated LH and features of hypogonadism. Prolactin levels are usually slightly increased, also because of stalk compression. It is important to distinguish this circumstance from true prolactinomas, as most nonfunctioning tumors respond poorly to treatment with dopamine agonists.

Laboratory Investigation The goal of laboratory testing in clinically nonfunctioning tumors is to classify the type of the tumor, to identify hormonal markers of tumor activity, and to detect possible hypopituitarism. Free a subunit levels may be elevated in 10 to 15% of patients with nonfunctioning tumors. In female patients, peri- or postmenopausal basalFSHconcentrations are difficult to distinguish from tumor-derived FSH elevation. Premenopausal women have cycling FSH levels, also preventing clear-cut diagnostic distinction from tumor-derived FSH. In men, gonadotropin-secreting tumors may be diagnosed because of slightly increased gonadotropins (FSH>LH) in the setting of a pituitary mass. Testosterone levels are usually low, despite the normal or increased LH level, perhaps reflecting reduced LH bioactivity or the loss of normal LH pulsatility. Because this pattern of hormone tests is also seen in primary gonadal failure and, to some extent, with aging (Chap. 335), the increased gonadotropins alone are insufficient for the diagnosis of a gonadotropin-secreting tumor. In the majority of patients with

gonadotrope adenomas,TRHadministration stimulates LH b subunit secretion; this response is not seen in normal individuals.GnRHtesting is not helpful for making the diagnosis. For nonfunctioning and gonadotropin-secreting tumors, the diagnosis usually rests on immunohistochemical analyses of resected tumor tissue, as the mass effects of these tumors usually necessitate resection.

Although acromegaly or Cushing's syndrome usually presents with unique clinical features, clinically inapparent somatotrope or corticotrope adenomas can be excluded by a normalIGF-I value and normal 24-h urinary free cortisol levels. IfPRLlevels are <100 ug/L in a patient harboring a pituitary mass, a nonfunctioning adenoma causing pituitary stalk compression should be considered.

TREATMENT

Asymptomatic small nonfunctioning adenomas with no threat to vision may be followed with regularMRI and visual field testing without immediate intervention. However, for larger macroadenomas, transsphenoidal surgery is the only effective way to reduce tumor size and relieve mass effects (Fig. 328-13). Although it is not usually possible to remove all adenoma tissue surgically, vision improves in 70% of patients with preoperative visual field defects. Preexisting hypopituitarism that results from tumor mass effects commonly improves or may resolve completely. Early postoperative complications include diabetes insipidus and/or inappropriate antidiuretic hormone secretion. Beginning about 6 months postoperatively, MRI scans should be performed yearly to detect tumor regrowth. Within 5 to 6 years following successful surgical resection, ~15% of nonfunctioning tumors recur. When substantial tumor remains after transsphenoidal surgery, adjuvant radiotherapy may be indicated to prevent tumor growth. Radiotherapy may be deferred if no postoperative residual mass is evident.

Nonfunctioning pituitary tumors respond poorly to dopamine agonist treatment, with modest tumor shrinkage occurring in <10% of patients. Although SSTR subtypes 2 and 5 have been identified on nonfunctioning pituitary adenomas, octreotide does not shrink these tumors and only modestly suppresses gonadotropin and a subunit levels. Visual improvement sometimes occurs without evident reduction of tumor size byMRI, presumably reflecting relief of pressure on the optic tracts. The selectiveGnRHantagonist, Nal-Glu GnRH, suppressesFSHhypersecretion but has no effect on adenoma size.

THYROID-STIMULATING HORMONE

SYNTHESIS AND SECRETION

TSH-secreting thyrotrope cells comprise 5% of the anterior pituitary cell population. TSH is structurally related toLH andFSH. It shares a common a subunit with these hormones but contains a specific TSH b subunit.TRH is a hypothalamic tripeptide (pyroglutamyl histidylprolinamide) that acts through aGPCR to stimulate phospholipase C, protein kinase C, and calcium pathways. TRH stimulates TSH synthesis and secretion; it also stimulates the lactotrope cell to secretePRL. TSH secretion is stimulated by TRH, whereas thyroid hormones, dopamine, SRIF, and glucocorticoids suppress TSH by overriding TRH induction.

The thyrotrope is stimulated whenTSH is released from the negative feedback inhibition of thyroid hormones. Thus, thyroid damage, including surgical thyroidectomy, radiation-induced hypothyroidism, chronic thyroiditis, or prolonged goitrogen exposure, are associated with increased TSH. Long-standing untreated hypothyroidism can lead to thyrotrope hyperplasia and pituitary enlargement, which may be evident onMRI.

ACTION

TSHis secreted in pulses, though the excursions are modest in comparison to other pituitary hormones because of the relatively low amplitude of the pulses and the relatively long half-life of TSH. Consequently, single determinations of TSH suffice to assess its circulating levels. TSH binds to aGPCR on thyroid follicular cells to stimulate thyroid hormone synthesis and release (Chap. 330).

TSH DEFICIENCY

Features of central hypothyroidism, due toTSHdeficiency, mimic those seen whith primary hypothyroidism but are generally less severe. Pituitary hypothyroidism is characterized by low basal TSH levels in the setting of low free thyroid hormone. In contrast, patients with hypothyroidism of hypothalamic origin (presumably due to a lack of endogenousTRH) may exhibit normal or even slightly elevated TSH levels. There is evidence that the TSH produced in this circumstance has reduced biologic activity because of altered glycosylation.

TRH(200 ug) injected intravenously causes a two- to threefold increase inTSH (andPRL) levels within 30 min. Although TRH testing can be used to assess TSH reserve, abnormalities of the thyroid axis can usually be detected based on basal free T_4 and TSH levels, without the need for TRH testing.

Thyroid-replacement therapy should be initiated after establishing adequate adrenal function. Dose adjustment is based on thyroid hormone levels and clinical parameters rather than theTSHlevel.

TSH-SECRETING ADENOMAS

TSH-producing macroadenomas are rare but are often large and locally invasive when they occur. Patients usually present with thyroid goiter and hyperthyroidism, reflecting overproduction of TSH. Diagnosis is based on demonstrating elevated serum free T_4levels, inappropriately normal or high TSH secretion, andMRIevidence of a pituitary adenoma. An elevated free asubunit level occurs in about half of patients and supports the diagnosis of a TSH-secreting adenoma.

It is important to exclude other causes of inappropriateTSHsecretion, such as resistance to thyroid hormone, an autosomal dominant disorder caused by mutations in the thyroid hormone b receptor (Chap. 330). The presence of a pituitary mass and elevated a subunit levels are suggestive of a TSH-secreting tumor. Dysalbuminemic hyperthyroxinemia syndromes, caused by various mutations in serum thyroid hormone binding proteins, are also characterized by elevated thyroid hormone levels, but with

normal rather than suppressed TSH levels. However, free thyroid hormone levels are normal in these disorders, most of which are familial.

TREATMENT

The initial therapeutic approach is to remove or debulk the tumor mass surgically, using either a transsphenoidal or subfrontal approach. Total resection is not often achieved as most of these adenomas are large and locally invasive. Normal circulating thyroid hormone levels are achieved in about two-thirds of patients after surgery. Thyroid ablation or antithyroid drugs (methimazole or propylthiouracil) can be used to reduce thyroid hormone levels. Dopamine agonists are rarely effective for suppressingTSHsecretion from these tumors. However, somatostatin analogue treatment effectively normalizes TSH and a subunit hypersecretion, shrinks the tumor mass in 50% of patients, and improves visual fields in 75% of patients; euthyroidism is restored in most patients. In some patients, octreotide markedly suppresses TSH, causing biochemical hypothyroidism that requires concomitant thyroid hormone replacement. Lanreotide (30 mg intramuscularly), a long-acting somatostatin analogue (see above), effectively suppresses TSH and thyroid hormone in patients treated every 14 days.

DIABETES INSIPIDUS

**See Chap. 329 for diagnosis and treatment of diabetes insipidus.*

(Bibliography omitted in Palm version)

Back to Table of Contents

329. DISORDERS OF THE NEUROHYPOPHYSIS - *Gary L. Robertson*

The neurohypophysis, or posterior pituitary gland, is formed by axons that project from large cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus to the posterior portion of the sella turcica. The neurohypophysis produces two hormones: (1) arginine vasopressin (AVP), also known as antidiuretic hormone (ADH); and (2) oxytocin. AVP acts on the renal tubules to induce water retention, leading to concentration of the urine. Oxytocin stimulates postpartum milk letdown in response to suckling. AVP deficiency causes diabetes insipidus (DI), characterized by the production of large amounts of dilute urine. Excessive or inappropriate production of AVP predisposes to hyponatremia, reflecting water retention. There are no known clinical disorders associated with oxytocin deficiency or excess.

VASOPRESSIN

ACTION

AVPis a nonapeptide composed of a six-membered disulfide ring and a tripeptide tail on which the C-terminal carboxy group is amidated (Fig. 329-1). The most important, if not the only, physiologic action of AVP is to influence the rate of water excretion by promoting concentration of urine. This antidiuretic effect is achieved by increasing the hydroosmotic permeability of cells that line the distal tubule and medullary collecting ducts of the nephron. In the absence of AVP, these cells are impermeable to water and reabsorb little, if any, of the relatively large volume of dilute filtrate that enters from the cortical nephron. Low AVP concentration results in the production of large amounts of urine (as much as 0.2 mL/kg per minute) that is maximally dilute (specific gravity and osmolality ~1.000 and 50 mmol/L, respectively), a condition known as a *water diuresis*. In the presence of AVP, the luminal surface of the cells lining the terminal collecting duct becomes selectively permeable to water, allowing it to diffuse back down the osmotic gradient created by the hypertonic renal medulla. As a result, the dilute fluid passing through the tubules is concentrated and the rate of urine flow decreases. The magnitude of this antidiuretic effect varies in direct proportion to the plasma AVP concentration. It is mediated via binding of AVP to G protein-coupled V_2receptors on the serosal surface of the cell, activation of adenyl cyclase, and insertion into the luminal surface of water channels composed of a protein known as *aquaporin 2* (Fig. 329-2). The genes encoding the V_2receptors and aquaporin 2 have been cloned and appear to be expressed exclusively in the distal and collecting tubules of the kidney. Nonpeptide, as well as peptide, AVP analogues with potent agonist or antagonist actions at human V_2receptors have been developed for treating disorders of water metabolism caused by deficient or excessive production of AVP (see below).

At high concentrations,AVP also has several other actions, including contraction of smooth muscle in blood vessels in the skin and gastrointestinal tract, glycogenolysis in the liver, and potentiation of adrenocorticotropic hormone (ACTH) release by corticotropin-releasing factor (CRF). These effects are mediated by V_{1a} or V_{1b}receptors that are coupled to phospholipase C. The genes that encode these receptors have also been cloned and sequenced and are expressed in many organs, including blood vessels, the anterior and posterior pituitary, and certain other areas of brain. Their role, if any, in human physiology/pathophysiology is still uncertain.

SYNTHESIS

AVPis synthesized via a polypeptide precursor that includes a binding protein known as *neurophysin II* and a glycosylated peptide called *copeptin*. The gene encoding the AVP precursor is located on chromosome 20 and has three exons. It is expressed in distinct subpopulations of magno- and parvocellular neurons in the supraoptic and paraventricular nuclei. Like other peptide hormones destined for secretion, newly synthesized AVP-neurophysin II precursor is translocated from the cytosol to the endoplasmic reticulum, where the signal peptide is removed and the prohormone folds and oligomerizes before moving through the Golgi apparatus to the neurosecretory vesicles; there it is transported down the axons and further cleaved to AVP, neurophysin II, and copeptin. Stimulation of the neurons results in an influx of calcium, fusion of the neurosecretory vesicle with the cell membrane, and extrusion of its contents into the systemic circulation.

SECRETION

The secretion ofAVP is regulated primarily by the "effective" osmotic pressure of body fluids. This control is mediated by specialized cells, known as *osmoreceptors*, which appear to be located in the anteromedial hypothalamus near the supraoptic nucleus. These osmoreceptors are extremely sensitive to small changes in the plasma concentration of sodium and certain other effective solutes such as mannitol but show little or no response to other solutes such as urea or glucose. They appear to have inhibitory as well as stimulatory components that function in concert to regulate AVP secretion around a specific set point. Thus, when plasma osmolality/sodium are depressed to a certain minimum or threshold level of ~280 mosmol/kg or 135 meq/L, respectively, plasma AVP is suppressed to low or undetectable levels and a water diuresis ensues. Conversely, when plasma osmolality/sodium rise above this "threshold," plasma AVP rises steeply in direct proportion, reaching a concentration sufficient to produce a maximum antidiuresis when plasma osmolality/sodium reach ~295 mosmol/kg and 143 meq/L. However, the exact "set" and "sensitivity" of this osmoregulatory system vary appreciably from person to person, apparently as a result of genetic influences, and change during pregnancy, the menstrual cycle, and normal aging; they can also be altered or disrupted by various pathologic conditions.

AVPsecretion can also be influenced by acute changes in blood volume or pressure. This baroregulation is mediated largely by neuronal afferents that originate in transmural pressure receptors of the cardiac atria, aorta, and carotid arteries; project via the vagus and glossopharyngeal nerves to the nucleus tractus solitarius of the brain stem; and then ascend to the paraventricular and supraoptic nucleii of the hypothalmus. These pathways regulate AVP release by maintaining a tonic inhibitory tone that decreases when blood volume or pressure falls by >10 to 20%. This baroregulatory system is probably of minor importance in the physiology of AVP secretion because the hemodynamic changes required to affect it are larger than those usually occurring in the course of normal activities. Moreover, moderate hemodynamic stimuli do not disrupt or override the osmoregulatory system but do lower its threshold or set point by an amount proportional to the magnitude of the hypovolemia or hypotension. However, the baroregulatory system undoubtedly plays an important role in AVP secretion in patients

with large, acute disturbances of hemodynamic function.

AVPsecretion can also be stimulated by a variety of other nonosmotic variables including nausea, acute hypoglycemia, glucocorticoid deficiency, smoking, and, possibly, hyperangiotensinemia. The emetic stimuli are extremely potent since they typically elicit immediate, 50- to 100-fold increases in plasma AVP, even when the nausea is transient and unassociated with vomiting or other symptoms. They appear to act via the emetic center in the medulla and can be completely blocked by treatment with antiemetics such as fluphenazine. There is no evidence that pain or other noxious stresses have any affect on AVP unless they elicit a vasovagal reaction with its associated nausea and hypotension.

METABOLISM

From the venous circulation,AVPdistributes rapidly into a space roughly equal in size to the extracellular fluid volume. It is cleared irreversibly from this space with a $t_1/2$ of 10 to 30 min. Most AVP clearance is due to degradation in the liver and kidneys. Urinary clearance of the hormone is normally much less than creatinine clearance but can vary as much as tenfold, depending on individual differences and changes in total solute clearance. Therefore, measurement of urinary AVP excretion rates are not always a reliable indicator of changes in secretion or plasma levels of the hormone. During pregnancy, the metabolic clearance of AVP is increased three- to fourfold due to placental production of an N-terminal peptidase.

THIRST

ThoughAVPregulates the effective osmotic pressure of body fluids by varying the rate of urinary free-water excretion, it cannot reduce insensible or urinary water output below a certain minimum obligatory level. Thus, an additional mechanism -- thirst -- is essential to prevent hypertonic dehydration. Like AVP, thirst is regulated primarily by an osmostat that is located in the anteromedial hypothalamus and is able to detect very small changes in the plasma concentration of sodium and certain other effective solutes. It functions like the AVP osmostat except that it appears to be "set" slightly higher. This arrangement ensures that thirst, polydipsia, and dilution of body fluids do not occur until dehydration and the resultant rise in plasma osmolality start to exceed the defensive capacity of the antidiuretic mechanism.

OXYTOCIN

Oxytocin is also a nonapeptide and differs fromAVP only at positions 3 and 8 (Fig. 329-1). However, it has relatively little antidiuretic effect and seems to act mainly on mammary ducts to facilitate milk letdown during nursing (Chap. 337). It may also help to initiate or facilitate labor by stimulating contraction of uterine smooth muscle, but it is not yet clear if this action is physiologic or necessary for normal delivery. Both the mammary and uterine effects are mediated by a G protein-coupled receptor that is linked to phospholipase C. Antagonists for this receptor have been developed and tested in humans for possible use in treating premature labor.

Oxytocin is also synthesized via a macromolecular precursor that is encoded by a gene

located on chromosome 20, very near theAVPgene. However, it differs in orientation and size and encodes only a signal peptide, the hormone, and its associated neurophysin. Oxytocin is also expressed in different magnocellular neurons than AVP and, in humans, is not subject to any of the same regulatory influences. Indeed, with the possible exception of nipple stimulation in the postpartum period, no other stimuli are known to consistently induce release of the hormone in humans. Plasma oxytocin is not increased during pregnancy or at the initiation of labor, although the latter condition may be facilitated by upregulation of oxytocin receptors. The distribution and clearance of oxytocin are similar to those of AVP. Oxytocin is also degraded by the liver and kidneys and an N-terminal peptidase produced by the placenta.

DEFICIENCIES OF VASOPRESSIN SECRETION AND ACTION

DIABETES INSIPIDUS

Clinical Characteristics Decreased secretion or action ofAVPusually manifests asDI, a syndrome characterized by the production of abnormally large volumes of dilute urine. The 24-h urine volume is >50 mL/kg body weight and the osmolality is <300 mmol/kg. The polyuria produces symptoms of urinary frequency, enuresis, and/or nocturia, which may disturb sleep and cause mild daytime fatigue or somnolence. It is also associated with thirst and a commensurate increase in fluid intake (polydipsia). Clinical signs of dehydration are uncommon unless fluid intake is impaired.

Etiology Deficient secretion of AVPcan be primary or secondary. The primary form usually results from agenesis or irreversible destruction of the neurohypophysis and is variously referred to as *neurohypophyseal DI*, *neurogenic DI*, *pituitary DI*, *cranial DI*, or *central DI*. It can be caused by a variety of congenital, acquired, or genetic disorders but almost half the time it is idiopathic (Table 329-1). The genetic form of neurohypophysealDI is usually transmitted in an autosomal dominant mode and is caused by diverse mutations in the coding region of the AVP-neurophysin II gene. The mutant precursor cannot be processed properly or efficiently and eventually destroys the neuron, thereby accounting for the dominant mode of transmission and the delayed onset of the disorder. An X-linked recessive form also occurs. A primary deficiency of plasma AVP can also result from increased metabolism by an N-terminal aminopeptidase produced by the placenta. It is referred to as *gestational DI* since the signs and symptoms manifest during pregnancy and usually remit several weeks after delivery. However, a subclinical deficiency in AVP secretion can often be demonstrated in the nonpregnant state in these individuals, indicating that damage to the neurohypophysis may also contribute to the AVP deficiency. Finally, a primary deficiency of AVP can also result from malformation or destruction of the neurohypophysis by a variety of diseases or toxins (Table 329-1).

Secondary deficiencies ofAVPresult from inhibition of secretion by excessive intake of fluids. They are referred to as *primary polydipsia* and can be divided into three subcategories. One of them, called *dipsogenicDI*, seems to be caused by an inappropriate increase in thirst caused by a reduction in the "set" of the osmoregulatory mechanism. It sometimes occurs in association with multifocal diseases of the brain such as neurosarcoid, tuberculous meningitis, or multiple sclerosis but is often idiopathic. The second subtype, called *psychogenic polydipsia*, is not associated with

thirst, and the polydipsia seems to be a feature of psychosis. The third subtype, which may be referred to as *iatrogenic polydipsia*, results from recommendations of health professionals or the popular media to increase fluid intake for its presumed preventive or therapeutic benefits for other disorders.

Primary deficiencies in the antidiuretic action ofAVPresult in *nephrogenicDI*(Table 329-1). It can be genetic, acquired, or caused by exposure to various drugs. The genetic form is usually transmitted in an X-linked mode and is caused by mutations in the coding region of the V_2receptor gene. An autosomal recessive form is caused by mutations in the gene encoding the aquaporin protein that forms the water channels in the distal nephron.

Secondary deficiencies in the antidiuretic response toAVPresult from polyuria per se. They appear to be caused by washout of the medullary concentration gradient and/or suppression of aquaporin function. They usually resolve 24 to 48 h after the polyuria is corrected but often complicate interpretation of certain acute tests commonly used for differential diagnosis.

Pathophysiology When the net secretion or antidiuretic effect ofAVP is decreased by >80 to 85%, the amount of hormone produced under basal conditions is insufficient to concentrate the urine and the rate of output increases exponentially to symptomatic levels. If the AVP defect is primary (e.g., the patient has pituitary, gestational, or nephrogenicDI), the polyuria results in a small (1 to 2%) decrease in body water and a commensurate increase in plasma osmolality and sodium concentration that stimulate thirst and a compensatory increase in water intake. As a result, *overt physical or laboratory signs of dehydration do not develop unless the patient also has a defect in thirst* (see below) *or fails to drink for some other reason*.

The severity of the defect in antidiuretic function varies markedly among patients with pituitary, gestational, or nephrogenicDI. In some, the deficiencies inAVPsecretion or action are so severe that basal urine output approximates the maximum (10 to 15 mL/min); even an intense stimulus such as nausea or severe dehydration does not increase plasma AVP enough to concentrate the urine. In others, however, the deficiency in AVP secretion or action is less pronounced, and a modest stimulus such as a few hours of fluid deprivation, smoking, or a vasovagal reaction increases plasma AVP sufficiently to produce a profound antidiuresis. The maximum urine osmolality achieved in these patients is usually less than normal, largely because their maximal concentrating capacity is temporarily impaired by chronic polyuria per se. However, in a few patients with partial pituitary or nephrogenic DI, it can reach levels as high as 800 mosmol/kg (Fig. 329-3).

In primary polydipsia, the pathogenesis of the polydipsia and polyuria is the reverse of that in neurohypophyseal, nephrogenic, and gestationalDI. Thus, the excessive intake of fluids slightly increases body water, thereby reducing plasma osmolality,AVPsecretion, and urinary concentration. The latter results in a compensatory increase in urinary free-water excretion that varies in direct proportion to intake. Therefore, clinically appreciable overhydration is uncommon unless the compensatory water diuresis is impaired by a drug or disease that stimulates or mimics endogenous AVP.

In the dipsogenic form of primary polydipsia, fluid intake is excessive because the osmotic threshold for thirst appears to be reset to the left, often well below that forAVPrelease. As a result, thirst is abnormally increased and cannot be completely relieved because plasma AVP is suppressed and an offsetting water diuresis develops before plasma osmolality is reduced sufficiently to eliminate the dipsogenic stimulus. Typically, therefore, patients with dipsogenicDIpresent with complaints of chronic thirst, polydipsia, and polyuria indistinguishable from those in patients with pituitary, gestational, or nephrogenic DI. When deprived of fluids or subjected to some other acute osmotic or nonosmotic stimulus, they invariably increase plasma AVP normally, but the resultant increase in urine concentration is usually subnormal because their renal capacity to concentrate the urine is also blunted by chronic polyuria. Thus, their antidiuretic response to these stimuli may be indistinguishable from that in patients with partial pituitary, partial gestational, or partial nephrogenic DI (Fig. 329-3).

Differential Diagnosis When symptoms of urinary frequency, enuresis, nocturia, and/or persistent thirst are present, causes other than polyuria should be excluded. A 24-h urine output > 50 mL/kg per day (>3500 mL in a 70-kg man) is suspicious forDI. If the osmolality of the 24-h urine is >300 mosmol/kg, the patient has a solute diuresis and should be evaluated for uncontrolled diabetes mellitus or other less common causes of excessive solute excretion. However, if the 24-h urine osmolality is <300 mosmol/kg, the patient has a water diuresis and should be evaluated further to determine which type of DI is present.

In differentiating between the various types ofDI, the history, physical examination, and routine laboratory tests may be helpful but are rarely sufficient because few, if any, of the findings are pathognomonic. Except in the rare patient who is clearly dehydrated under basal conditions of *ad libitum* fluid intake, this evaluation should begin with a *fluid deprivation test*. To minimize patient discomfort, avoid excessive dehydration, and maximize the information obtained, the test should be started in the morning and water balance should be monitored closely with hourly measurements of body weight, plasma osmolality and/or sodium concentration, and urine volume and osmolality.

If fluid deprivation does not result in urine concentration (osmolality>300 mosmol/kg, specific gravity>1.010) before body weight decreases by 5% or plasma osmolality/sodium exceed the upper limit of normal, primary polydipsia and a partial defect inAVPsecretion or action are largely excluded (Fig. 329-3). In these patients, severe pituitary or nephrogenicDI can usually be distinguished by administering desmopressin (DDAVP, 0.03 ug/kg subcutaneously or intravenously) and repeating the measurement of urine osmolality 1 to 2 h later. An increase of >50% indicates severe pituitary DI, whereas a smaller or absent response is strongly suggestive of nephrogenic DI.

However, these indirect criteria are not useful for diagnosis in patients who concentrate their urine during fluid deprivation, because the changes in urine osmolality are remarkably similar in primary polydipsia and partial pituitary and partial nephrogenicDI(Fig. 329-3). In this situation, the safest and most reliable way to differentiate these conditions is to measure plasma or urineAVPcollected before and during the fluid deprivation test and analyze the result in relation to the concurrent plasma or urine osmolality (Fig. 329-4). This approach invariably differentiates partial

nephrogenic DI from partial pituitary DI and primary polydipsia. It also differentiates pituitary DI from primary polydipsia if the hormone is measured when plasma osmolality or sodium is clearly above the normal range. However, the requisite level of hypertonic dehydration is difficult to produce by fluid deprivation alone when urine concentration occurs. Therefore, it is usually necessary to add an infusion of hypertonic (3%) saline and repeat the AVP measurements when plasma osmolality rises to >300 mmol/kg (Na^+ > 145 mmol/L). This endpoint is usually reached within 30 to 120 min if the hypertonic saline is infused at a rate of 0.1 mL/kg per minute and the fluid deprivation is maintained.

The differential diagnosis ofDI may also be facilitated by magnetic resonance imaging (MRI) of the pituitary and hypothalamus. In most healthy adults and children, the posterior pituitary emits a hyperintense signal in T1 weighted mid-saggital images. This "bright spot" is almost invariably absent or abnormally small in patients with pituitary DI but is present in 80 to 90% of those with primary polydipsia. Thus, the presence of a normal bright spot virtually excludes pituitary DI, whereas its absence supports but does not prove this diagnosis. Therefore, the MRI findings must be interpreted with caution and only in conjunction with other diagnostic studies based on assays ofAVP or the differential responses to treatment.

TREATMENT

The signs and symptoms of uncomplicated pituitaryDI can be eliminated completely by treatment with DDAVP (Fig. 329-5). It is a synthetic analogue ofAVP(Fig. 329-1) that acts selectively at V_2receptors to increase urine concentration and decrease urine flow in a dose-dependent manner. However, it is more resistant to degradation than AVP and has a three- to fourfold longer duration of action. This property makes it particularly useful in the treatment of gestational DI or pituitary DI during pregnancy. DDAVP can be given by intravenous or subcutaneous injection, nasal inhalation, or oral tablet. The doses required to control pituitary DI completely vary widely, depending on the patient and the route of administration. However, they usually range from 1 to 2 ug qd or bid by injection, 10 to 20 ug bid or tid by nasal spray, and 100 to 400 ug bid or tid orally. The onset of action is rapid, ranging from as little as 15 min after injection to 60 min after oral administration. When given in doses sufficient to completely normalize urinary osmolality and flow, DDAVP produces a slight (1 to 3%) increase in total-body water and a commensurate decrease in plasma osmolality and sodium concentration that rapidly eliminates thirst and polydipsia. Consequently, water balance is maintained and hyponatremia does not develop unless the patient has an associated abnormality in the osmoregulation of thirst or ingests/receives excessive amounts of fluid for some other reason. Fortunately, abnormal thirst occurs in <10% of patients with pituitary DI, and the other causes of excessive intake can usually be eliminated by educating the patient about the risks of drinking for reasons other than thirst. Therefore, most patients with pituitary DI can take desmopressin in doses sufficient to maintain a normal urine output continuously and do not need to endure the inconvenience and discomfort of allowing intermittent escape to prevent water intoxication.

PituitaryDI can also be treated with chlorpropamide (Diabinese). The mechanism of its antidiuretic action is uncertain but may involve potentiation of the effect of small amounts ofAVP or direct activation of the V_2receptor. In patients with severe as well as

partial pituitary DI, doses of chlorpropamide similar to those used in the treatment of diabetes mellitus (125 to 500 mg once daily) increase urine concentration and decrease urine flow, thirst, and polydipsia in a manner similar to DDAVP. The antidiuresis is usually less rapid and smaller than that produced by DDAVP but is almost always sufficient to reduce urine output by 30 to 70%. Moreover, its antidiuretic effect can be enhanced appreciably by cotreatment with a thiazide diuretic. The ability of water loading to reduce the antidiuretic effect of chlorpropamide makes it particularly useful in the treatment of patients who have pituitary DI and abnormal thirst since it is less likely than DDAVP to produce water intoxication. However, unlike DDAVP, chlorpropamide can have other side effects including hypoglycemia, which can be precipitated by severe reductions in caloric intake or heavy exercise, and it exhibits a disulfuram (Antabuse)-like reaction to ethanol. Chlorpropamide is contraindicated in the treatment of gestational DI because its teratogenicity is unknown.

Primary polydipsia cannot be treated with DDAVP in the usual way because a sustained inhibition of the compensatory water diuresis almost invariably results in the development of water intoxication within 24 to 48 h. This complication can also be caused by administration of a thiazide diuretic, smoking, or other nonosmotic stimuli to endogenousAVPsecretion. Iatrogenic polydipsia can often be corrected by patient counseling; however, there is no effective treatment for either psychogenic or dipsogenicDI. In the latter, nocturia or nocturnal enuresis can often be controlled safely by administering a single small dose of DDAVP at bedtime. If the dose is adjusted carefully to provide no more than 8 to 10 h of antidiuresis, it will not result in water intoxication, because patients with dipsogenic, as well as other forms of DI, tend to drink less fluid at night than during the day. Family or other caregivers of patients with psychogenic or dipsogenic DI should also be warned about the hazards of water intoxication caused by a variety of diseases or drugs that can stimulate or mimic the antidiuretic effects of endogenous AVP (see below).

The symptoms and signs of nephrogenicDI are not affected by treatment with DDAVP or chlorpropamide but may be reduced by treatment with a thiazide diuretic and/or amiloride in conjunction with a low-sodium diet. Inhibitors of prostaglandin synthesis (e.g., indomethacin) are also effective in many patients.

ADIPSIC HYPERNATREMIA

Clinical Characteristics Adipsic hypernatremia is characterized by chronic or recurrent hypertonic dehydration and a deficientAVPresponse to osmotic stimulation. Despite their dehydration, the patients have little or no thirst and may even resist efforts to increase their oral intake of fluids. The hypernatremia varies in severity and is associated with commensurate signs of hypovolemia such as tachycardia, postural hypotension, azotemia, hyperuricemia, and hypokalemia. Muscle weakness, pain, rhabdomyolysis, hyperglycemia, hyperlipidemia, and acute renal failure may also occur. Most patients remain conscious unless they have severe hyperglycemia and/or hypertonicity or go on to develop hyponatremia as a result of excessive rehydration.

Etiology Adipsic hypernatremia is caused by agenesis or destruction of the hypothalamic osmoreceptors that normally regulate thirst andAVPsecretion. The osmoreceptor deficiency can usually be traced to an identifiable congenital or acquired

disease in the hypothalamus but is sometimes idiopathic (Table 329-2). The neurohypophysis and its other regulatory afferents are usually spared; anMRItypically shows a normal posterior pituitary bright spot, and the AVP response to nonosmotic stimuli is also normal. Occasionally, the neurohypophysis is also affected, resulting in a combined defect in water balance that is particularly severe and difficult to manage.

Pathophysiology Lack of thirst and failure to drink enough water to replenish renal and extrarenal losses decrease total-body water and increase plasma osmolality/sodium. Plasma renin activity and aldosterone secretion also increase, and plasma potassium falls due to increased urinary excretion. The severity, frequency, and speed with which hypertonic dehydration develops vary markedly from patient to patient, or from time to time in the same patient, owing largely to differences in the rate of insensible and/or renal loss.

The osmoregulation ofAVPsecretion is also impaired in nearly all patients with adipsic hypernatremia (Fig. 329-6). This deficiency is obvious when the hormone is measured in the presence of hypertonic dehydration but is rarely severe enough to produceDI. During rehydration, however, some patients exhibit a further decrease in their plasma AVP and develop DI before their hypernatremia is fully corrected. In other patients, the osmoregulatory deficiency appears to be complete because basal plasma AVP remains relatively fixed, irrespective of whether plasma osmolality and sodium are above, within, or below the normal range. Thus, if overhydrated, these patients do not mount a compensatory water diuresis and quickly develop a hyponatremic syndrome that is clinically and biochemically indistinguishable from acute syndrome of inappropriate antidiuretic hormone, which is commonly referred to as SIADH (see below). In all but a few patients, the abnormality of AVP secretion is limited to the osmoregulatory system since the hormone responds normally to all nonosmotic stimuli, such as nausea.

Differential Diagnosis Adipsic hypernatremia should be distinguished from the hypernatremia that results from various other causes. These distinctions can usually be made from the history, physical examination, and routine laboratory tests. If a conscious patient denies thirst and/or does not drink vigorously in the presence of significant hypernatremia, the diagnosis of hypodipsia or adipsia can be made with confidence. This diagnosis is supported by laboratory evidence of hypovolemia (azotemia, hypokalemia, hyperuricemia, hyperreninemia) and a relative deficiency of plasmaAVP. Close monitoring of these variables and urine osmolality during rehydration is useful for differentiating the patients who developDI or SIADH in response to forced hydration. If the patient is obtunded or otherwise unable to answer questions or drink at the time of presentation, the possibility of adipsic hypernatremia can be evaluated after treatment by assessing the thirst and plasma AVP response to a controlled fluid deprivation-hypertonic saline infusion test similar to that described for evaluation of DI.

TREATMENT

Adipsic hypernatremia should be treated by administering water by mouth, if the patient is alert, or 0.45% saline by vein, if the patient is obtunded or uncooperative. The number of liters of free water that will be required to correct the deficit (DFW) can be estimated from body weight in kg (BW) and the serum sodium concentration in mmol/L (S_{Na}) by the formula DFW =0.5BW´[(S_{Na}- 140)/140]. If serum glucose (S_{Glu}) is elevated, the

measured S_{Na}should be corrected (S_{Na}*) by the formula S_{Na}*=S_{Na}+[(S_{Glu}- 90)/36]. This amount plus an allowance for continuing insensible and urinary losses should be given over a 24- to 48-h period. IfDI is present or develops during rehydration, DDAVP should also be given in standard doses to minimize urinary losses. If hyperglycemia and/or hypokalemia are present, insulin and/or potassium supplements should be given. These variables plus urine output and plasma urea/creatinine should be monitored closely during treatment for signs of emerging DI, SIADH, or acute renal failure.

Once the acute fluid and electrolyte imbalances are corrected, anMRI of the brain and tests of anterior pituitary function should be performed. A long-term management plan to prevent or minimize recurrence of the fluid and electrolyte imbalance should also be developed, including a practical method that the patient can use to regulate fluid intake in accordance with day-to-day variations in water balance. The most effective way to accomplish these objectives is to prescribe DDAVP or chlorpropamide to completely controlDI, if it is present, and teach the patient how to use day-to-day changes in body weight as a guide for adjusting fluid intake. Prescribing a constant fluid intake is less satisfactory because it does not take into account the large, uncontrolled variations in insensible loss that inevitably occur.

EXCESS VASOPRESSIN SECRETION AND ACTION

HYPONATREMIA (See also Chap. 49)

Clinical Characteristics Excessive secretion or action ofAVPresults in the production of decreased volumes of more highly concentrated urine. If not accompanied by a commensurate reduction in fluid intake, the reduced suppressibility of AVP results in water retention and a decrease in plasma osmolality/sodium. If the hyponatremia develops gradually or has been present for more than a few days, it may be asymptomatic. However, if it develops acutely, it is almost always accompanied by symptoms and signs of water intoxication that may include mild headache, confusion, anorexia, nausea, vomiting, coma, and convulsions. Severe hyponatremia may be lethal. Depending on the cause of the increased antidiuresis, osmotically inappropriate thirst and/or fluid intake and other disturbances of fluid and electrolyte balance may also be present.

Etiology Osmotically inappropriate antidiuresis can be caused by a primary defect inAVPsecretion or action or can be secondary to a recognized nonosmotic stimulus such as hypovolemia, hypotension, or glucocorticoid deficiency (Table 329-3). The primary forms are generally referred to as SIADH or euvolemic (type III) hyponatremia. They have many different causes, including ectopic production of AVP by lung cancer or other neoplasms, eutopic release by various diseases or drugs, and exogenous administration of AVP, DDAVP, or large doses of oxytocin. The ectopic forms result from abnormal and presumably unregulated expression of the AVP-NPII gene by primary or metastatic malignancies. They do not usually remit unless the ectopic source is eliminated. The eutopic forms manifest most often in patients with acute infections or strokes, but the mechanisms by which these diseases disrupt osmoregulation are not known. A form of acute or chronic hyponatremia very similar to SIADH can also result from stimulation of AVP secretion by protracted nausea or isolated glucocorticoid deficiency. In these patients the excess AVP secretion can be corrected quickly and

completely by specific treatments (antiemetics or glucocorticoids) that are not useful in other forms of SIADH.

The secondary forms of osmotically inappropriate antidiuresis are usually divided into two groups: type I (hypervolemic) and type II (hypovolemic) hyponatremia. Type I occurs in sodium-retaining, edema-forming states such as congestive heart failure, cirrhosis, or nephrosis and is thought to be due to a reduction in "effective" blood volume. Type II occurs in sodium-depleted states such as severe gastroenteritis, diuretic abuse, or mineralocorticoid deficiency and is probably due to a reduction in blood volume and/or pressure.

Pathophysiology In SIADH, interference with the osmotic suppression ofAVPresults in significant expansion and dilution of body fluids only if water intake exceeds the rate of insensible and urinary output. These abnormalities in water intake often result from an associated defect in the osmoregulation of thirst but can also be due to psychogenic or iatrogenic factors, including the administration of intravenous fluids.

In SIADH, the defect in the osmoregulation of antidiuretic function can take any of four distinct forms (Fig. 329-6). In one of them,AVPsecretion remains fully responsive to changes in plasma osmolality/sodium, but the threshold or set point of the osmoregulatory system is abnormally low. Patients with this kind of downward resetting of the osmostat differ from those with the other types of osmoregulatory defect in that they are able to maximally suppress plasma AVP and dilute their urine if their fluid intake is high enough to reduce their plasma osmolality/sodium to the new set point. Another, smaller subgroup (about 10% of the total) do not have a demonstrable defect in the osmoregulation of AVP (Fig. 329-6). Thus, their inappropriate antidiuresis may be due to other abnormalities such as enhanced renal sensitivity to the antidiuretic effect of normally low levels of AVP or activation of aquaporin 2 water channels by a mechanism that is independent of AVP and V_2receptors.

The extracellular volume expansion that results from excessive retention of water in SIADH also produces an increase in atrial natriuretic hormone, suppression of plasma renin activity, and a compensatory increase in urinary sodium excretion that serves to reduce the hypervolemia but aggravates the hyponatremia. Thus, hyponatremia is due to a decrease in total-body sodium as well as an increase in total-body water. The acute retention of water and fall in plasma sodium also cause a rise in intracellular volume. The resultant brain swelling increases intracranial pressure and probably causes the acute symptoms of water intoxication. After several days, this intracellular volume expansion may be reduced by inactivation or elimination of intracellular solutes, resulting in the remission of symptoms that often occur with hyponatremia of this duration.

In type I (edematous) or type II (hypovolemic) hyponatremia, the osmotic inhibition ofAVP and urine concentration is counteracted by a hemodynamic stimulus that results from a substantial reduction in effective or absolute blood volume. In both cases, the inadequate suppression of AVP appears to be due to downward resetting of the osmostat. The resultant antidiuresis is usually enhanced by decreased distal delivery of filtrate that results from increased reabsorption of sodium in proximal nephrons secondary to the hypovolemia. If it is not associated with a commensurate reduction in

water intake, the marked reduction in urine output that ensues also leads to expansion and dilution of body fluids with symptoms of hyponatremia. This attenuates, but does not completely eliminate, the antidiuresis because the amount of water retained is usually insufficient to fully correct the effective or absolute hypovolemia. Unlike SIADH, therefore, plasma renin activity is elevated, causing secondary hyperaldosteronism and hypokalemia. The disturbance in salt and water balance that underlies the hyponatremia also differs from SIADH in that total-body sodium as well as water is increased in type I, whereas both are decreased in type II.

Differential Diagnosis When unexplained symptoms or signs consistent with water intoxication are present, serum sodium should be measured. If it is low and the reduction cannot be accounted for by an increase in plasma glucose or other solutes such as mannitol (e.g., plasma osmolality is also low), the type of hypotonic hyponatremia present can be determined by estimating extracellular fluid volume from the history, physical examination, and routine chemistries. If these findings are ambiguous or contradictory, measuring the rate of urinary sodium excretion or plasma renin activity may be helpful. These measurements can be misleading, however, if SIADH is stable or resolving or if the patient has type II hyponatremia due to a primary defect in renal conservation of sodium, surreptitious diuretic abuse, or hyporeninemic hypoaldosteronism. The latter may be suspected if serum potassium is elevated instead of low as is usually seen in types I and II hyponatremia. Measurements of plasmaAVP are currently of no diagnostic value since they exhibit the same wide variation in abnormalities in all three types of hyponatremia. In patients who fulfill the clinical criteria for SIADH, plasma cortisol should also be measured to rule out unsuspected secondary adrenal insufficiency. If this is normal and there is no other obvious cause for SIADH, a careful search for occult lung cancer should also be undertaken.

TREATMENT

In acute SIADH, the keystone to treatment of hyponatremia is to restrict total fluid intake to less than the sum of insensible losses and urinary output. Total intake should include the water derived from food (300 to 500 mL/d). Because insensible losses in adults usually approximate 500 mL/d total discretionary intake (all water in liquid form) should be at least 500 mL less than urinary output. If achieved, this deficit usually reduces body water and increases serum sodium by about 1 to 2% per day. If more rapid correction of the hyponatremia is desired to eliminate severe symptoms or signs, the fluid restriction can be supplemented by intravenous infusion of hypertonic (3%) saline. This treatment has the advantage of correcting the sodium deficiency that is partly responsible for the hyponatremia as well as producing a solute diuresis that serves to remove some of the excess water. However, if the hyponatremia has been present for more than 24 to 48 h and is corrected too rapidly, the saline infusion also has the potential to produce central pontine myelinolysis, an acute, potentially fatal neurologic syndrome characterized by quadriparesis, ataxia, and abnormal extraocular movements (Chap. 376). The following guidelines appear to minimize, if not eliminate, the risk of this complication: the 3% saline should be infused a rate £0.05 mL/kg body weight per minute; the effect should be monitored continuously by STAT measurements of serum sodium at least once every hour; and the infusion should be stopped as soon as serum sodium increases by 12 mmol/L or to 130 mmol/L, whichever comes first. Urinary output should also be monitored continuously since spontaneous remission of the SIADH can result in an

acute water diuresis that greatly accelerates the rate of rise in serum sodium produced by fluid restriction and 3% saline infusion.

In chronic SIADH, the hyponatremia can be minimized or eliminated by treatment with demeclocycline, 150 to 300 mg orally three or four times a day, or fludrocortisone, 0.05 to 0.2 mg orally twice a day. The effect of the demeclocycline manifests in 7 to 14 days and is due to production of a reversible form of nephrogenicDI. Potential side effects include phototoxicity and azotemia. The effect of fludrocortisone also manifests in 1 to 2 weeks and is partly due to increased retention of sodium and possibly inhibition of thirst. It also increases urinary potassium excretion, which may require replacement through dietary adjustments or supplements. Fludrocortisone may induce hypertension, occasionally necessitating discontinuation of the treatment.

One or more nonpeptideAVPantagonists that block the antidiuretic effect of AVP may soon be approved for use in the United States. Preliminary studies with these antagonists in acute or chronic SIADH indicate that they produce a dose-dependent increase in urinary free-water excretion, which, if combined with a modest restriction of fluid intake, gradually reduces body water and corrects the hyponatremia without any recognized adverse effect. Thus, they may become the treatment of choice for those forms of SIADH in which there is inappropriate secretion of AVP that cannot be corrected by other, more specific therapy such as antiemetics or glucocorticoids.

When an SIADH-like syndrome is due to protracted nausea and vomiting or isolated glucocorticoid deficiency, all abnormalities can be corrected quickly and completely by giving an antiemetic or hydrocortisone. As with other treatments, care must be taken to ensure that serum sodium does not rise too quickly or too far.

In type I hyponatremia, the only treatment currently available is severe fluid restriction, administration of urea or mannitol to produce a solute diuresis, and/or administration of cardiotonics or serum albumin to correct the effective hypovolemia. None of these treatments is particularly effective, and some (e.g., administration of mannitol or albumin) carry significant risks. Infusion of hypertonic saline is contraindicated because it worsens the sodium retention and edema and may precipitate cardiovascular decompensation. However, preliminary studies indicate that theAVPantagonists may be almost as effective and safe in type I hyponatremia as they are in SIADH. Thus, they may become the treatment of choice for this form of hyponatremia also.

In type II hyponatremia, the defect inAVPsecretion and water balance can usually be corrected easily and quickly by stopping the loss of sodium and water and/or replacing the deficits by mouth or intravenous infusion of normal or hypertonic saline. As with the treatment of other forms of hyponatremia, care must be taken to ensure that plasma sodium does not increase too rapidly. Fluid restriction or administration of AVP antagonists is contraindicated as they would only aggravate the underlying volume depletion and could result in cardiovascular decompensation.

330. DISORDERS OF THE THYROID GLAND - *J. Larry Jameson*, *Anthony P. Weetman*

The thyroid gland produces two related hormones, thyroxine (T_4) and triiodothyronine (T_3) (Fig. 330-1). These hormones play a critical role in cell differentiation during development and help to maintain thermogenic and metabolic homeostasis in the adult. Thyroid hormones act through nuclear hormone receptors to modulate gene expression. Disorders of the thyroid gland result primarily from autoimmune processes that either stimulate the overproduction of thyroid hormones (*thyrotoxicosis*) or cause glandular destruction and underproduction of thyroid hormones (*hypothyroidism*). In addition, neoplastic processes in the thyroid gland can lead to benign nodules and various forms of thyroid cancer.

ANATOMY AND DEVELOPMENT

The thyroid gland is located in the neck, anterior to the trachea, between the cricoid cartilage and the suprasternal notch. The thyroid (Greek *thyreos*, shield, plus *eidos*, form) consists of two lobes that are connected by an isthmus. It is normally 12 to 20 g in size, highly vascular, and soft in consistency. Four parathyroid glands, which produce parathyroid hormone (Chap. 341), are located in the posterior region of each pole of the thyroid. The recurrent laryngeal nerves traverse the lateral borders of the thyroid gland and must be identified during thyroid surgery to avoid vocal cord paralysis.

The thyroid gland develops from the floor of the primitive pharynx during the third week of gestation. The gland migrates from the foramen cecum, at the base of the tongue, along the thyroglossal duct to reach its final location in the neck. This feature accounts for the rare ectopic location of thyroid tissue at the base of the tongue (lingual thyroid), as well as for the presence of thyroglossal duct cysts along this developmental tract. Thyroid hormone synthesis normally begins at about 11 weeks' gestation.

The parathyroid glands migrate from the third (inferior glands) and fourth (superior glands) pharyngeal pouches before becoming embedded in the thyroid gland. Neural crest derivatives from the ultimobranchial body give rise to thyroid medullary C cells that produce calcitonin, a calcium-lowering hormone. The C cells are interspersed throughout the thyroid gland, although their density is greatest in the juncture of the upper one-third and lower two-thirds of the gland.

Thyroid gland development is controlled by a series of developmental transcription factors. Thyroid transcription factor (TTF) 1 (also known as NKX2A), TTF-2 (also known as FKHL15), and paired homeobox-8 (PAX-8) are expressed selectively, but not exclusively, in the thyroid gland. In combination, they orchestrate thyroid cell development and the induction of thyroid-specific genes such as thyroglobulin (Tg), thyroid peroxidase (TPO), the sodium iodide symporter (NIS), and the thyroid-stimulating hormone receptor (TSH-R). Mutations in these developmental transcription factors or their downstream target genes are rare causes of thyroid agenesis or dyshormonogenesis and can cause congenital hypothyroidism (Table 330-1). Congenital hypothyroidism is common enough (approximately 1 in 3000 to 4000 newborns) that neonatal screening is now performed in most industrialized countries (see below). Though the underlying causes of most cases of congenital hypothyroidism

are unknown, early treatment with thyroid hormone replacement precludes potentially severe developmental abnormalities.

The mature thyroid gland contains numerous follicles composed of thyroid follicular cells that surround secreted colloid, a proteinaceous fluid that contains large amounts of thyroglobulin, the protein precursor of thyroid hormones (Fig. 330-2). The thyroid follicular cells are polarized -- the basolateral surface is apposed to the bloodstream and an apical surface faces the follicular lumen. Increased demand for thyroid hormone, usually signaled by thyroid-stimulating hormone (TSH) binding to its receptor on the basolateral surface of the follicular cells, leads toTgreabsorption from the follicular lumen and proteolysis within the cell to yield thyroid hormones for secretion into the bloodstream.

REGULATION OF THE THYROID AXIS

TSH, secreted by the thyrotrope cells of the anterior pituitary, plays a pivotal role in control of the thyroid axis and serves as the most useful physiologic marker of thyroid hormone action. TSH is a 31-kDa hormone composed ofa and b subunits; thea subunit is common to the other glycoprotein hormones [luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin (hCG)], whereas the TSH b subunit is unique to TSH. The extent and nature of carbohydrate modification are modulated by thyrotropin-releasing hormone (TRH) stimulation and influence the biologic activity of the hormone. TSH has been produced recombinantly and is approved for use in the detection of residual thyroid cancer (see "Follow-up Whole-Body Scanning and Thyroglobulin Determinations," below).

The thyroid axis is a classic example of an endocrine feedback loop. HypothalamicTRHstimulates pituitary production ofTSH, which, in turn, stimulates thyroid hormone synthesis and secretion. Thyroid hormones feed back negatively to inhibit TRH and TSH production (Fig. 330-2). The "set-point" in this axis is established by TSH, the level of which is a sensitive and specific marker of thyroid function. TRH is the major positive regulator of TSH synthesis and secretion. TRH acts through a seven-transmembrane G protein-coupled receptor (GPCR) that activates phospholipase C to generate phosphatidylinositol turnover and the release of intracellular calcium. Peak TSH secretion occurs ~15 min after administration of exogenous TRH. Dopamine, glucocorticoids, and somatostatin suppress TSH but are not of major physiologic importance except when these agents are administered in pharmacologic doses. Reduced levels of thyroid hormone increase basal TSH production and enhance TRH-mediated stimulation of TSH. High thyroid hormone levels rapidly and directly suppress TSH and inhibit TRH-mediated stimulation of TSH, indicating that thyroid hormones are the dominant regulator of TSH production. Like other pituitary hormones, TSH is released in a pulsatile manner and exhibits a diurnal rhythm; its highest levels occur at night. However, these TSH excursions are modest in comparison to those of other pituitary hormones, in part because TSH has a relatively long plasma half-life (50 min). Consequently, single measurements of TSH are adequate for assessing its circulating level. TSH is measured using immunoradiometric assays that are highly sensitive and specific. These assays are capable of distinguishing between normal and suppressed TSH values, thus allowing TSH to be used for the diagnosis of hyperthyroidism (low TSH) as well as hypothyroidism (high TSH).

THYROID HORMONE SYNTHESIS, METABOLISM, AND ACTION

THYROID HORMONE SYNTHESIS

Thyroid hormones are derived fromTg, a large iodinated glycoprotein. After secretion into the thyroid follicle, Tg is iodinated on selected tyrosine residues that are subsequently coupled via an ether linkage. Reuptake of Tg into the thyroid follicular cell allows proteolysis and the release of T_4 and T_3.

Iodine Metabolism and Transport Iodide uptake is a critical first step in thyroid hormone synthesis. Ingested iodine is bound to serum proteins, particularly albumin. Unbound iodine is excreted in the urine. The thyroid gland extracts iodine from the circulation in a highly efficient manner. For example, 10 to 25% of radioactive tracer (e.g.,^{123}I) is taken up by the normal thyroid gland over 24 h; this value can rise to 70 to 90% in Graves' disease.

Iodide uptake is mediated by the Na^+/I^--symporter (NIS), which is expressed at the basolateral membrane of thyroid follicular cells. NIS is most highly expressed in the thyroid gland but is also expressed at low levels in the salivary glands, lactating breast, and placenta. The iodide transport mechanism is highly regulated, allowing adaptation to variations in dietary supply. Low iodine levels increase the amount of NIS and stimulate uptake, whereas high iodine levels suppress NIS expression and uptake. The selective expression of the NIS in the thyroid allows isotopic scanning, treatment of hyperthyroidism, and ablation of thyroid cancer with radioisotopes of iodine, without significant effects on other organs. Mutation of the *NIS*gene is a rare cause of congenital hypothyroidism, underscoring its importance in thyroid hormone synthesis.

Iodine deficiency is prevalent in many mountainous regions and in central Africa, central South America, and northern Asia. In areas of relative iodine deficiency, there is an increased prevalence of goiter and, when deficiency is severe, hypothyroidism and cretinism. *Cretinism* is characterized by mental and growth retardation and occurs when children who live in iodine-deficient regions are not treated with iodine or thyroid hormone to restore normal thyroid hormone levels during early childhood. These children are often born to mothers with iodine deficiency, suggesting that maternal thyroid hormone deficiency worsens the condition. Concomitant selenium deficiency may also contribute to the neurologic manifestations of cretinism. Iodine supplementation of salt, bread, and other food substances has markedly reduced the prevalence of cretinism. Unfortunately, however, iodine deficiency remains the most common cause of preventable mental deficiency, often because of resistance to the use of food additives or the cost of supplementation. In addition to overt cretinism, mild iodine deficiency can lead to subtle reduction of IQ. Iodine intake is assessed by determination of excretion in a 24-h urine collection. Oversupply of iodine, through supplements or foods enriched in iodine (e.g., shellfish, kelp), is associated with an increased incidence of autoimmune thyroid disease. The recommended average daily intake of iodine is 150 ug/d for adults, 90 to 120 ug/d for children, and 200 ug/d for pregnant women.

Organification, Coupling, Storage, Release After iodide enters the thyroid, it is

trapped and transported to the apical membrane of thyroid follicular cells where it is oxidized in an organification reaction that involvesTPO and hydrogen peroxide. The reactive iodine atom is added to selected tyrosyl residues withinTg, a large (660 kDa) dimeric protein consisting of 2769 amino acids. The iodotyrosines in Tg are then coupled via an ether linkage in a reaction that is also catalyzed by TPO. Either T_4 or T_3 can be produced by this reaction, depending on the number of iodine atoms present in the iodotyrosines. After coupling, Tg is taken back into the thyroid cell where it is processed in lysosomes to release T_4 and T_3. Uncoupled mono- and diiodotyrosines (MIT, DIT) are deiodinated by the enzyme dehalogenase, thereby recycling any iodide that is not converted into thyroid hormones.

Disorders of thyroid hormone synthesis are rare causes of congenital hypothyroidism. The vast majority of these disorders are due to recessive mutations inTPO orTg, but defects have also been identified in theTSH-R, NIS, the pendrin anion transporter, hydrogen peroxide generation, and in dehalogenase. Because of the biosynthetic defect, the gland is incapable of synthesizing adequate amounts of hormone, leading to increasedTSH and a large goiter.

TSH Action TSH regulates thyroid gland function through theTSH-R, a seven-transmembraneGPCR. The TSH-R is coupled to the a subunit of stimulatory G protein (G_{sa}) and activates adenylyl cyclase, leading to increased production of cyclic AMP. TSH also stimulates phosphatidylinositol turnover by activating phospholipase C. The functional role of the TSH-R has been underscored by naturally occurring mutations. Recessive loss-of-function mutations are a rare cause of thyroid hypoplasia and congenital hypothyroidism. Dominant gain-of-function mutations cause sporadic or familial nonautoimmune hyperthyroidism that is characterized by goiter, thyroid cell hyperplasia, and autonomous function. Most of these activating mutations involve in amino acid substitutions in the transmembrane domain of the receptor. They are thought to mimic conformational changes in the receptor similar to those induced by TSH binding or the interactions of thyroid-stimulating immunoglobulins (TSI) in Graves' disease. Activating TSH-R mutations also occur as somatic events and lead to clonal selection and expansion of the affected thyroid follicular cell (see below).

Factors that Influence Hormone Synthesis and Release TSH is the dominant hormonal regulator of thyroid gland growth and function. However, a variety of growth factors, most produced locally in the thyroid gland, also influence thyroid hormone synthesis. These include insulin-like growth factor I (IGF-I), epidermal growth factor, transforming growth factorb (TGF-b), endothelins, and various cytokines. The quantitative roles of these factors are not well understood, but they are important in selected disease states. In acromegaly, for example, increased levels of growth hormone and IGF-I are associated with goiter and predisposition to multinodular goiter. Certain cytokines and interleukins (ILs) produced in association with autoimmune thyroid disease induce thyroid growth, whereas others lead to apoptosis. As noted above, iodine is an important regulator of thyroid function. For example, iodine deficiency increases thyroid blood flow and stimulates uptake by the NIS. Excess iodide transiently inhibits thyroid iodide organification, a phenomenon known as the *Wolff-Chaikoff effect*. In individuals with a normal thyroid, the gland escapes from this inhibitory effect and iodide organification resumes; the suppressive action of high iodide may persist, however, in patients with underlying autoimmune thyroid disease.

THYROID HORMONE TRANSPORT AND METABOLISM

Serum Binding Proteins T_4 is secreted from the thyroid gland in at least 20-fold excess over T_3(Table 330-2). Both hormones circulate bound to plasma proteins, including thyroxine-binding globulin (TBG), transthyretin (TTR, formerly known as thyroxine-binding prealbumin, or TBPA), and albumin. The functions of serum-binding proteins are to increase the pool of circulating hormone, delay hormone clearance, and perhaps to modulate hormone delivery to selected tissue sites. The concentration of TBG is relatively low (1 to 2 mg/dL), but because of its high affinity for thyroid hormones (T_4>T_3), it carries about 80% of the bound hormones. Albumin has relatively low affinity for thyroid hormones but has a high plasma concentration (~3.5 g/dL), and it binds up to 10% of T_4 and 30% of T_3. TTR also carries about 10% of T_4 but little T_3.

When the effects of the various binding proteins are combined, approximately 99.98% of $T_4$and 99.7% of T_3 are protein-bound. Because T_3 is less tightly bound than T_4, the amount of free T_3 is greater than free T_4, even though there is less total T_3 in the circulation. The unbound, or free, concentrations of the hormones are ~$2 \times 10^{-11} M$ for T_4 and ~$6 \times 10^{-12} M$ for T_3, which roughly correspond to the thyroid hormone receptor binding constants for these hormones (see below). Only the free hormone is biologically available to tissues. Therefore, homeostatic mechanisms that regulate the thyroid axis are directed towards maintenance of normal concentrations of free hormones.

Dysalbuminemic Hyperthyroxinemia A number of inherited and acquired abnormalities affect thyroid hormone binding proteins. X-linkedTBGdeficiency is associated with very low levels of total T_4 and T_3. However, because free hormone levels are normal, patients are euthyroid andTSHlevels are normal. The importance of recognizing this disorder is to avoid efforts to normalize total T_4levels, as this leads to thyrotoxicosis and is futile because of rapid hormone clearance in the absence of TBG. TBG levels are elevated by estrogen because of increased sialylation and delayed TBG clearance. Consequently, in women who are pregnant or taking estrogen-containing contraceptives, elevated TBG increases total $T_4$and T_3levels; however, free T_4 and T_3levels are normal. Mutations in TBG,TTR, and albumin that increase binding affinity for $T_4$and/or T_3 cause disorders known as *euthyroid hyperthyroxinemia* or *familial dysalbuminemic hyperthyroxinemia* (FDH) (Table 330-3). These disorders are usually dominantly transmitted and result in increased total $T_4$and/or T_3, but free hormone levels are normal. The familial nature of the disorders, and the fact that TSH levels are normal rather than suppressed, should suggest the diagnosis. Free hormone levels (ideally measured by dialysis) are normal in FDH. The diagnosis can be confirmed, if necessary, by using tests that measure the affinities of radiolabeled hormone binding to specific transport proteins or by performing DNA sequence analyses of the abnormal transport protein genes.

Certain medications, such as salicylates and salsalate, can displace thyroid hormones from circulating binding proteins. Though these drugs transiently perturb the thyroid axis by increasing free thyroid hormone levels,TSH is suppressed until a new steady state is reached, thereby restoring euthyroidism. Circulating factors associated with acute illness may also displace thyroid hormone from binding proteins (see "Sick Euthyroid Syndrome," below).

Deiodinases In many respects, T_4 may be thought of as a precursor for the more potent T_3. T_4 is converted to T_3 by the deiodinase enzymes (Fig. 330-1). Type I deiodinase, which is located primarily in thyroid, liver, and kidney, has a relatively low affinity for T_4. Type II deiodinase has a higher affinity for T_4 and is found primarily in the pituitary gland, brain, brown fat, and thyroid gland. The presence of type II deiodinase allows it to regulate T_3concentrations locally, a property that may be important in the context of levothyroxine (T_4) replacement. Type II deiodinase is also regulated by thyroid hormone -- hypothyroidism induces the enzyme, resulting in enhanced T_4®T_3conversion in tissues such as brain and pituitary. T_4®T_3conversion may be impaired by fasting, systemic illness or acute trauma, oral contrast agents, and a variety of medications (e.g., propylthiouracil, propranolol, amiodarone, glucocorticoids). Type III deiodinase inactivates T_4 and T_3 and is the most important source of reverse T_3(rT_3).

THYROID HORMONE ACTION

Nuclear Thyroid Hormone Receptors Thyroid hormones act by binding to nuclear receptors, termed *thyroid hormone receptors* (TRs) a andb. Both TRa and TRb are expressed in most tissues, but their relative levels of expression vary among organs; TRa is particularly abundant in brain, kidney, gonads, muscle, and heart, whereas TRb expression is relatively high in the pituitary and liver. Both receptors are variably spliced to form unique isoforms. The TRb2 isoform, which has a unique amino terminus, is selectively expressed in the hypothalamus and pituitary, where it appears to play a role in feedback control of the thyroid axis. The TRa2 isoform contains a unique carboxy terminus that prevents thyroid hormone binding; it may function to block the action of other TR isoforms.

TheTRscontain a central DNA-binding domain and a C-terminal ligand-binding domain. They bind to specific DNA sequences, termed *thyroid response elements* (TREs), in the promoter regions of target genes (Fig. 330-3). The activated receptor can either stimulate gene transcription (e.g., myosin heavy chaina) or inhibit transcription (e.g.,TSHb-subunit gene), depending on the nature of the regulatory elements in the target gene. The receptors bind as homodimers or as heterodimers with retinoic acid X receptors (RXRs) (Chap. 327).

Thyroid hormones bind with similar affinities toTRa and TRb. However, T_3 is bound to its receptors with about 10 to 15 times greater affinity than T_4, which explains its increased hormonal potency. Though T_4 is produced in excess of T_3, receptors are occupied mainly by T_3, reflecting T_4®T_3conversion by peripheral tissues, greater T_3bioavailability in the plasma, and receptors' greater affinity for T_3. After binding to TRs, thyroid hormone induces conformational changes in the receptors that modify its interactions with accessory transcription factors. In the absence of thyroid hormone binding, the aporeceptors bind to corepressor proteins that inhibit gene transcription. Hormone binding dissociates the corepressors and allows the recruitment of coactivators that enhance transcription. The discovery of TR interactions with corepressors explains the fact that TR silences gene expression in the absence of hormone binding. Consequently, hormone deficiency has a profound effect on gene expression because it causes active gene repression as well as loss of hormone-induced stimulation. This concept has been corroborated by the finding that targeted deletion of the TR genes in

mice has a less pronounced phenotypic effect than hormone deficiency.

Thyroid Hormone Resistance Resistance to thyroid hormone (RTH) is an autosomal dominant disorder characterized by elevated free thyroid hormone levels and inappropriately normal or elevatedTSH. Individuals with RTH do not, in general, exhibit signs and symptoms that are typical of hypothyroidism, apparently because hormone resistance is compensated by increased levels of thyroid hormone. The clinical features of RTH can include goiter, attention deficit disorder, mild reduction in IQ, delayed skeletal maturation, tachycardia, and impaired metabolic responses to thyroid hormone.

The disorder is caused by mutations in the TRbreceptor gene. These mutations, located in restricted regions of the ligand-binding domain, cause loss of receptor function. However, because the mutant receptors retain the capacity to dimerize withRXRs, bind to DNA, and recruit corepressor proteins, they function as antagonists of the remaining, normal TRb and TRa receptors. This property, referred to as "dominant negative" activity, explains the autosomal dominant mode of transmission. The diagnosis is suspected when free thyroid hormone levels are increased without suppression ofTSH. Similar hormonal abnormalities are common in other affected family members, though the TRb mutation arises de novo in about 20% of patients. DNA sequence analysis of the TRb gene provides a definitive diagnosis.RTH must be distinguished from other causes of euthyroid hyperthyroxinemia (e.g., familial dysalbuminemic hyperthyroxinemia) and inappropriate secretion of TSH by TSH-secreting pituitary adenomas (Chap. 328). In most patients, no treatment is indicated; the importance of making the diagnosis is to avoid inappropriate treatment of mistaken hyperthyroidism and to provide genetic counseling.

PHYSICAL EXAMINATION

In addition to the examination of the thyroid itself, the physical examination should include a search for signs of abnormal thyroid function and the extrathyroidal features of ophthalmopathy and dermopathy (see below). Examination of the neck begins by inspecting the seated patient from the front and side, and noting any surgical scars, obvious masses, or distended veins. The thyroid can be palpated with both hands from behind or the examiner can face the patient, using the thumbs to palpate each lobe. Most often it is best to use a combination of these methods, especially in cases of doubt or when there are small nodules. The patient's neck should be slightly flexed to relax the neck muscles. After locating the cricoid cartilage, the isthmus can be identified and followed laterally to locate either lobe (the right lobe is normally slightly larger than the left). By asking the patient to swallow sips of water, thyroid consistency can be better appreciated as the gland moves beneath the examiner's fingers.

Features to be noted include thyroid size, consistency, nodularity, and any tenderness or fixation. An estimate of thyroid size (normally 12 to 20 g) should be made, and a drawing is often the best way to record findings. However, ultrasound is the method of choice when it is important to determine thyroid size accurately. The size, location, and consistency of any nodules should also be depicted. A bruit over the gland indicates increased vascularity, as occurs in hyperthyroidism. If the lower borders of the thyroid lobes are not clearly felt, a goiter may be retrosternal. Large retrosternal goiters can cause venous distention over the neck and difficulty breathing, especially when the

arms are raised (Pemberton's sign). With any central mass above the thyroid, the patient should be asked to stick out his or her tongue, as thyroglossal cysts then move upward. The thyroid examination is not complete without assessment for lymphadenopathy in the supraclavicular and cervical regions of the neck.

LABORATORY EVALUATION

MEASUREMENT OF THYROID HORMONES

The enhanced sensitivity and specificity of *TSH assays* have greatly improved laboratory assessment of thyroid function. BecauseTSHlevels change dynamically in response to alterations of free T_4 and T_3, a logical approach to thyroid testing is to determine first whether TSH is suppressed, normal, or elevated. With rare exceptions (see below), a normal TSH level excludes a primary abnormality of thyroid function. This strategy depends on the use of immunoradiometric assays (IRMAs) for TSH that are sensitive enough to discriminate between the lower limit of the reference range and the suppressed values that occur with thyrotoxicosis. Extremely sensitive (fourth generation) assays can detect TSH levels £0.004 mU/L, but for practical purposes assays sensitive to£0.1 mU/L are sufficient. The widespread availability of the TSH IRMA has rendered theTRHstimulation test virtually obsolete, as the failure of TSH to rise after an intravenous bolus of 200 to 400 ug TRH has the same implications as a suppressed basal TSH measured by IRMA.

The finding of an abnormalTSHlevel must be followed by measurements of circulating thyroid hormone levels to confirm the diagnosis of hyperthyroidism (suppressed TSH) or hypothyroidism (elevated TSH). Radioimmunoassays are widely available for serum *total* $T_4$and *total* T_3. T_4 and T_3 are highly protein-bound, and numerous factors (illness, medications, genetic factors) can influence protein binding. It is useful, therefore, to measure the free or unbound hormone levels, which correspond to the biologically available hormone pool. Two direct methods are used to measure *free thyroid hormones*: (1) free thyroid hormone competition with radiolabeled T_4 (or an analogue) for binding to a solid-phase antibody, and (2) physical separation of the free hormone fraction by ultracentrifugation or equilibrium dialysis. Though early free hormone immunoassays suffered from artifacts, newer assays agree well with the results of the more technically demanding and expensive physical separation methods. An indirect method to estimate free thyroid hormone levels is to calculate the free T_3 or free T_4index from the total T_4 or T_3concentration and the *thyroid hormone binding ratio* (THBR). The latter is derived from the *T_3-resin uptake test*, which determines the distribution of radiolabeled T_3between an absorbent resin and the unoccupied thyroid hormone binding proteins in the sample. The binding of the labeled T_3 to the resin is increased when there is reduced unoccupied protein binding sites (e.g.,TBGdeficiency) or increased total thyroid hormone in the sample; it is decreased under the opposite circumstances. The product of THBR and total T_3 or T_4provides the *free T_3or T_4index*. In effect, the index corrects for anomalous total hormone values caused by abnormalities in hormone-protein binding.

Total thyroid hormone levels are elevated whenTBG is increased due to estrogens (pregnancy, oral contraceptives, hormone replacement therapy, tamoxifen), and decreased when TBG binding is decreased (androgens, the nephrotic syndrome).

Genetic disorders and acute illness can also cause abnormalities in thyroid hormone binding proteins, and various drugs (phenytoin, carbamazepine, salicylates, and nonsteroidal anti-inflammatory drugs) can interfere with thyroid hormone binding. Because free thyroid hormone levels are normal and the patient is euthyroid in all of these circumstances, assays that measure free hormone are preferable to those for total thyroid hormones.

For most purposes, the free T_4 level is sufficient to confirm thyrotoxicosis, but 2 to 5% of patients have only an elevated T_3 level (T_3toxicosis). Thus, free T_3levels should be measured in patients with a suppressedTSH but normal free T_4levels. Free T_3levels are normal in about 25% of patients with hypothyroidism and provide little useful information in this setting.

There are several clinical conditions in which the use ofTSH as a screening test may be misleading, particularly without simultaneous free T_4determinations. Any severe nonthyroidal illness can cause abnormal TSH levels (see below). Although hypothyroidism is the most common cause of an elevated TSH level, rare causes include a TSH-secreting pituitary tumor (Chap. 328), thyroid hormone resistance, and assay artifact. Conversely, a suppressed TSH level, particularly<0.1 mU/L, usually indicates thyrotoxicosis but may also be seen during the first trimester of pregnancy (due to hCG secretion), after treatment of hyperthyroidism (because TSH remains suppressed for several weeks), and in response to certain medications (e.g., high doses of glucocorticoids or dopamine). Importantly, secondary hypothyroidism, caused by hypothalamic-pituitary disease, is associated with a variable (low to high-normal) TSH level, which is inappropriate for the low free T_4level. Thus, *TSH should not be used to assess thyroid function in patients with suspected or known pituitary disease*.

Tests for the end-organ effects of thyroid hormone excess or depletion, such as estimation of basal metabolic rate, tendon reflex speed, or serum cholesterol, are not useful as clinical determinants of thyroid function.

TESTS TO DETERMINE THE ETIOLOGY OF THYROID DYSFUNCTION

Autoimmune thyroid disease is detected most easily by measuring circulating antibodies againstTPO andTg. As antibodies to Tg alone are rare, it is reasonable to measure only TPO antibodies. About 5 to 15% of euthyroid women and up to 2% of euthyroid men have thyroid antibodies; such individuals are at increased risk of developing thyroid dysfunction. Almost all patients with autoimmune hypothyroidism, and up to 80% of those with Graves' disease, have TPO antibodies, usually at high levels.

TSIare antibodies that stimulate theTSH-R in Graves' disease. They can be measured in bioassays or indirectly in assays that detect antibody binding to the receptor. The main use of these assays is to predict neonatal thyrotoxicosis caused by high maternal levels of TSI in the last trimester of pregnancy.

Serum Tg levels are increased in all types of thyrotoxicosis except thyrotoxicosis factitia. The main role forTgmeasurement, however, is in the follow-up of thyroid cancer patients. After total thyroidectomy and radioablation, Tg levels should be undetectable; measurable levels (>1 to 2 ng/mL) suggest incomplete ablation or recurrent cancer.

RADIOIODINE UPTAKE AND THYROID SCANNING

The thyroid gland selectively transports radioisotopes of iodine (^{123}I,^{125}I,^{131}I) and ^{99m}Tc pertechnetate, allowing thyroid imaging and quantitation of radioactive tracer fractional uptake.

Graves' disease is characterized by an enlarged gland and increased tracer uptake that is distributed homogeneously. Toxic adenomas appear as focal areas of increased uptake, with suppressed tracer uptake in the remainder of the gland. In toxic multinodular goiter, the gland is enlarged -- often with distorted architecture -- and there are multiple areas of relatively increased or decreased tracer uptake. Subacute thyroiditis is associated with very low uptake because of follicular cell damage and TSHsuppression. *Thyrotoxicosis factitia*, caused by self-administration of thyroid hormone, is also associated with low uptake.

Although the use of fine-needle aspiration (FNA) biopsy has diminished the use of thyroid scans in the evaluation of solitary thyroid nodules, the functional features of thyroid nodules have some prognostic significance. So-called cold nodules, which have diminished tracer uptake, are usually benign. However, these nodules are more likely to be malignant (~5 to 10%) than so-called hot nodules, which are almost never malignant.

Thyroid scanning is also used in the follow-up of thyroid cancer. After thyroidectomy and ablation using^{131}I, there is diminished radioiodine uptake in the thyroid bed, allowing the detection of metastatic thyroid cancer deposits that retain the ability to transport iodine. Whole-body scans using 111 to 185 MBq (3 to 5 mCi)^{131}I are typically performed after thyroid hormone withdrawal to raise theTSHlevel or after the administration of recombinant human TSH.

THYROID ULTRASOUND

Ultrasonography is used increasingly to assist in the diagnosis of nodular thyroid disease, a reflection of the limitations of the physical examination and improvements in ultrasound technology. Using 10-MHz instruments, spatial resolution and image quality are excellent, allowing the detection of nodules and cysts>3 mm. In addition to detecting thyroid nodules, ultrasound is useful for monitoring nodule size, for guidingFNAbiopsies, and for the aspiration of cystic lesions. Ultrasound is also used in the evaluation of recurrent thyroid cancer, including possible spread to cervical lymph nodes.

AUTOIMMUNE BASIS OF THYROID DISEASE

PREVALENCE

Thyroid autoimmunity can cause several forms of thyroiditis and may lead to hypothyroidism as well as Graves' disease. Focal thyroiditis is present in 20 to 40% of autopsy cases and is associated with serologic evidence of autoimmunity, particularly the presence ofTPOantibodies. These antibodies are 4 to 10 times more common in otherwise healthy women than men. About 5% of women experience self-limited *postpartum (silent) thyroiditis* in the months after pregnancy, often with transient clinical

symptoms. This condition is associated with the presence of TPO antibodies ante-partum. Up to 20% of women with an episode of postpartum thyroiditis develop permanent hypothyroidism 5 to 10 years after delivery. Autoimmune-mediated hypothyroidism affects about 5 to 10% of middle-aged and elderly women, depending on diagnostic criteria and geographic location. Graves' disease is about one-tenth as common as hypothyroidism and tends to occur in younger individuals. Although seemingly diverse, these disorders have many pathophysiologic features in common, and patients may progress from one state to the other as the autoimmune process changes.

SUSCEPTIBILITY FACTORS

As with most autoimmune disorders, susceptibility is determined by a combination of genetic and environmental factors. The concordance rate for Graves' disease in monozygotic twins is 20 to 30%. The risk of autoimmune thyroid disease is increased among siblings, who may exhibit features of either Graves' disease or autoimmune hypothyroidism. The autoimmune polyglandular syndrome type 2 (Chap. 339) involves the occurrence of autoimmune thyroid dysfunction with other autoimmune diseases (type 1 diabetes mellitus, Addison's disease, pernicious anemia, vitiligo). Shared genetic factors are likely in this group of autoimmune disorders.

HLA-DR3 is the best documented genetic risk factor for Graves' disease and autoimmune hypothyroidism in Caucasians, though different HLA associations exist for other racial groups, such as the Japanese and Chinese. A weak association with polymorphisms in the T cell regulatory gene CTLA-4 has been found in several racial groups. Other loci, including a region on chromosome 18q21, may be linked to Graves' disease as well as to several other autoimmune disorders such as type 1 diabetes mellitus, rheumatoid arthritis, and systemic lupus erythematosus (SLE). The female preponderance of thyroid autoimmunity is most likely due to the influence of sex steroids. Some studies suggest an association between antecedent major life events and Graves' disease, but a causal role for stress in the autoimmune process remains to be clearly established. Smoking is a minor risk factor for Graves' disease but a major risk factor for the development of ophthalmopathy. There is no convincing evidence for a role of infection in susceptibility, except for the congenital rubella syndrome, which is associated with a high frequency of autoimmune hypothyroidism. Viral thyroiditis does not induce subsequent autoimmune thyroid disease.

HUMORAL FACTORS

The thyrotoxicosis of Graves' disease is caused byTSH-R-stimulating immunoglobulins that bind to the receptor and mimic the action ofTSH. TheseTSI can cross the placenta and cause *transient neonatal thyrotoxicosis*, a phenomenon that complicates 1 to 2% of pregnancies in women with active or previous Graves' disease. However, the autoimmune response against the TSH-R can also result in antibodies that block TSH function, causing hypothyroidism. Stimulating and blocking antibodies bind to separate epitopes on the receptor. TSH-R blocking antibodies are found in about 20% of Asian patients with autoimmune hypothyroidism and are associated with thyroid atrophy; blocking antibodies are less common in Caucasians. Patients may have a mixture of TSH-R antibodies, and thyroid function can oscillate between hyperthyroidism and

hypothyroidism as stimulating or blocking antibodies become dominant. Predicting the course of disease in such individuals is difficult, and close monitoring of thyroid function is required. Assays that measure the binding of antibodies to the receptor by competition with radiolabeled TSH [TSH-binding inhibiting immunoglobulins (TBII)] provide no information about functional effects and are used primarily to demonstrate the presence of TSH-R antibodies in atypical patients. Bioassays measure antibody-mediated stimulation of cyclic AMP production in cultured thyroid cells or cells transfected with the TSH-R. The use of these assays does not generally alter clinical management.

Antibodies toTg andTPO, readily measured by immunofluorescence, hemagglutination, enzyme-linked immunosorbent assay, or radioimmunoassay, are clinically useful markers of thyroid autoimmunity, as discussed above. Any pathogenic effect is likely to be restricted to a secondary role in amplifying an ongoing autoimmune response. For instance, T cell- or cytokine-mediated injury to thyroid follicles could expose the enzyme on the apical border of follicles to TPO antibodies, which may then bind to the autoantigen and fix complement. There is evidence for intrathyroidal complement activation in both Graves' disease and autoimmune hypothyroidism. Tg antibodies do not fix complement, but could be involved in antibody-dependent, natural killer cell-mediated cytotoxicity. The NIS is also a target of autoantibody production in up to one-third of patients with autoimmune thyroid disease, but the functional consequences, if any, have not been established.

CELL-MEDIATED FACTORS

Activated circulating T cells are increased in autoimmune thyroid disease, and the gland is infiltrated with CD4+ and CD8+ T cells. The latter are believed to mediate perforin-dependent cytotoxicity, leading ultimately to thyroid cell destruction. In addition, thyroid cells undergo apoptosis through cytokine-mediated upregulation of Fas and possibly Fas ligand. Cytokines produced by the infiltrating immune cells also induce expression of thyroid cell-surface molecules that lead to: (1) engagement by immune cells (e.g., adhesion molecules, HLA class I and II molecules); (2) induction of cytokine secretion by the thyroid cells themselves; (3) production of nitric oxide; and (4) reduction of thyroid hormone production through inhibition ofTSH-R,TPO, andTgsynthesis. Administration of high concentrations of cytokines for therapeutic purposes [especially interferon (IFN)a] is associated with increased autoimmune thyroid disease, presumably via mechanisms similar to those that occur in sporadic autoimmune disease.

Cytokines appear to play a major role in thyroid-associated ophthalmopathy. There is infiltration of the extraocular muscles by activated T cells; the release of cytokines results in fibroblast activation and increased synthesis of glycosaminoglycans that trap water, thereby leading to characteristic muscle swelling. Late in the disease, there is fibrosis and only then do the muscle cells show evidence of injury. Orbital fibroblasts may be uniquely sensitive to cytokines, perhaps explaining the anatomic localization of the immune response. Though the pathogenesis of thyroid-associated ophthalmopathy remains unclear, there is mounting evidence that expression of theTSH-Rmay provide an important orbital autoantigen. In support of this idea, injection of TSH-R into certain strains of mice induces autoimmune hyperthyroidism, as well as features of ophthalmopathy. A variety of autoantibodies against orbital muscle and fibroblast

antigens have been detected in patients with ophthalmopathy, but these antibodies most likely arise as a secondary phenomenon, dependent on T cell-mediated autoimmune responses.

HYPOTHYROIDISM

Iodine deficiency remains the most common cause of hypothyroidism worldwide. In areas of iodine sufficiency, autoimmune disease (Hashimoto's thyroiditis) and iatrogenic causes (treatment of hyperthyroidism) are most common (Table 330-4).

CONGENITAL HYPOTHYROIDISM

Prevalence Hypothyroidism occurs in about 1 in 3000 to 4000 newborns. It may be transient, especially if the mother hasTSH-Rblocking antibodies or has received antithyroid drugs, but permanent hypothyroidism occurs in the majority. Neonatal hypothyroidism is due to thyroid gland dysgenesis in 85%, inborn errors of thyroid hormone synthesis in 10 to 15%, and is TSH-R antibody-mediated in 5% of affected newborns. The developmental abnormalities are twice as common in girls. Mutations that cause congenital hypothyroidism are being increasingly recognized, but the vast majority remain idiopathic (Table 330-1).

Clinical Manifestations The majority of infants appear normal at birth, and<10% are diagnosed based on clinical features, which include prolonged jaundice, feeding problems, hypotonia, enlarged tongue, delayed bone maturation, and umbilical hernia. Importantly, permanent neurologic damage results if treatment is delayed. Typical features of adult hypothyroidism may also be present (Table 330-5).

Diagnosis and Treatment Because of the severe neurologic consequences of untreated congenital hypothyroidism, neonatal screening programs have been established in developed countries (Chap. 68). These are generally based on measurement ofTSH or T_4levels in heel-prick blood specimens. When the diagnosis is confirmed, T_4 is instituted at a dose of 10 to 15 ug/kg per day and the dosage is adjusted by close monitoring of TSH levels. T_4requirements are relatively great during the first year of life, and a high circulating T_4 level is usually needed to normalize TSH. Early treatment with T_4results in normal IQ levels, but subtle neurodevelopmental abnormalities may be detected in those with the most severe hypothyroidism at diagnosis or when treatment is suboptimal.

AUTOIMMUNE HYPOTHYROIDISM

Classification Autoimmune hypothyroidism may be associated with a goiter (Hashimoto's, or *goitrous thyroiditis*) or, at the later stages of the disease, minimal residual thyroid tissue (*atrophic thyroiditis*). Because the autoimmune process gradually reduces thyroid function, there is a phase of compensation during which normal thyroid hormone levels are maintained by a rise inTSH. Though some patients may have minor symptoms, this state is called *subclinical hypothyroidism*. Later, free T_4levels fall and TSH levels rise further; symptoms become more readily apparent at this stage (usually TSH > 10 mU/L), which is referred to as *clinical hypothyroidism* (*overt hypothyroidism*).

Prevalence The mean annual incidence rate of autoimmune hypothyroidism is up to 4 per 1000 women and 1 per 1000 men. It is more common in certain populations, such as the Japanese, probably as a consequence of genetic factors and chronic exposure to a high-iodine diet. The mean age at diagnosis is about 60 years, and the prevalence of overt hypothyroidism increases with age. Subclinical hypothyroidism is found in 6 to 8% of women (10% over the age of 60) and 3% of men. The annual risk of developing clinical hypothyroidism is about 4% when subclinical hypothyroidism is associated with positiveTPOantibodies.

Pathogenesis In Hashimoto's thyroiditis, there is a marked lymphocytic infiltration of the thyroid with germinal center formation, atrophy of the thyroid follicles accompanied by oxyphil metaplasia, absence of colloid, and mild to moderate fibrosis. In atrophic thyroiditis, the fibrosis is much more extensive, lymphocyte infiltration is less pronounced, and thyroid follicles are almost completely absent. Atrophic thyroiditis likely represents the end stage of Hashimoto's thyroiditis rather than a distinct disorder. Autoimmune features are similar in both types of hypothyroidism, thoughTSH-Rblocking antibodies may be more frequent in Asian patients with atrophic thyroiditis. The mechanisms that result in thyroid follicular destruction are predominantly T cell mediated, but antibodies may also contribute to thyroid dysfunction by complement fixation or inhibition of thyroid cell function (see "Autoimmune Basis of Thyroid Disease," above).

Clinical Manifestations The main clinical features of hypothyroidism are summarized inTable 330-5. The onset is usually insidious, and the patient may become aware of symptoms only when euthyroidism is restored. Patients with Hashimoto's thyroiditis may present because of goiter rather than symptoms of hypothyroidism. The goiter may not be large but is usually irregular and firm in consistency. It is often possible to palpate a pyramidal lobe, normally a vestigial remnant of thyroglossal duct. Rarely, uncomplicated Hashimoto's thyroiditis is associated with pain.

Patients with atrophic thyroiditis, or the late stage of Hashimoto's thyroiditis, present with symptoms and signs of hypothyroidism. The skin is dry, and there is decreased sweating, thinning of the epidermis, and hyperkeratosis of the stratum corneum. Increased dermal glycosaminoglycan content traps water, giving rise to skin thickening without pitting (*myxedema*). Typical features include a puffy face with edematous eyelids and nonpitting pretibial edema (Figs. 330-4,330-CD1and330-CD2). There is pallor, often with a yellow tinge due to carotene accumulation. Nail growth is retarded, and hair is dry, brittle, difficult to manage, and falls out easily. In addition to diffuse alopecia, there is thinning of the outer third of the eyebrows.

Other common features include constipation and weight gain (despite a poor appetite). In contrast to popular perception, the weight gain is usually modest and due mainly to fluid retention in the myxedematous tissues. Libido is decreased in both sexes, and there may be oligomenorrhea or amenorrhea in long-standing disease, but menorrhagia is also common. Fertility is reduced and the incidence of miscarriage is increased. Prolactin levels are often modestly increased (Chap. 328) and may contribute to alterations in libido and fertility as well as causing galactorrhea.

Myocardial contractility and pulse rate are reduced, leading to a reduced stroke volume

and bradycardia. Increased peripheral resistance may be accompanied by hypertension, particularly diastolic. Blood flow is diverted from the skin, producing the cool extremities. Pericardial effusions occur in up to 30% of patients but rarely compromise cardiac function. Though alterations in myosin heavy chain isoform expression have been documented, cardiomyopathy is unusual. Fluid may also accumulate in other serous cavities and in the middle ear, giving rise to conductive deafness. Pulmonary function is generally normal, but dyspnea may be due to pleural effusion, impaired respiratory muscle function, diminished ventilatory drive, or sleep apnea.

Carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps, and pain. On examination, there may be slow relaxation of tendon reflexes (Video 330-1) and pseudomyotonia. Memory and concentration are impaired. Rare neurologic problems include reversible cerebellar ataxia, dementia, psychosis, and myxedema coma. *Hashimoto's encephalopathy* is a rare and distinctive syndrome associated with myoclonus and slow-wave activity on electroencephalography, which can progress to confusion, coma, and death. It is steroid-responsive and may occur in the presence of autoimmune thyroiditis, without hypothyroidism. The hoarse voice and occasionally clumsy speech of hypothyroidism are due to fluid accumulation in the vocal cords and tongue.

The features described above are due to a shortage of thyroid hormone. However, autoimmune hypothyroidism may be associated with signs or symptoms of other autoimmune diseases, particularly vitiligo, pernicious anemia, Addison's disease, alopecia areata, and type 1 diabetes mellitus. Less common associations include celiac disease, dermatitis herpetiformis, chronic active hepatitis, rheumatoid arthritis, SLE, and Sjogren's syndrome. Thyroid-associated ophthalmopathy, which usually occurs in Graves' disease (see below), occurs in about 5% of patients with autoimmune hypothyroidism.

Autoimmune hypothyroidism is uncommon in children and usually presents with slow growth and delayed facial maturation. The appearance of permanent teeth is also delayed. Myopathy, with muscle swelling, is more common than in adults. In most cases, puberty is delayed, but precocious puberty sometimes occurs. There may be intellectual impairment if the onset is before 3 years and the hormone deficiency is severe.

Laboratory Evaluation A summary of the investigations used to determine the existence and cause of hypothyroidism is provided in Fig. 330-5. A normal TSH level excludes primary (but not secondary) hypothyroidism. If the TSH is elevated, a free T_4 level is needed to confirm the presence of clinical hypothyroidism, but free T_4 is inferior to TSH when used as a screening test, as it will not detect subclinical or mild hypothyroidism. Circulating free T_3 levels are normal in about 25% of patients, reflecting adaptive responses to hypothyroidism. T_3 measurements are therefore not indicated.

Once clinical or subclinical hypothyroidism is confirmed, the etiology is usually easily established by demonstrating the presence of TPO antibodies, which are present in 90 to 95% of patients with autoimmune hypothyroidism. TBII can be found in 10 to 20% of patients, but these determinations are not needed routinely. If there is any doubt about

the cause of a goiter associated with hypothyroidism,FNAbiopsy can be used to confirm the presence of autoimmune thyroiditis. Other abnormal laboratory findings in hypothyroidism may include increased creatine phosphokinase, elevated cholesterol and triglycerides, and anemia (usually normocytic or macrocytic). Except when accompanied by iron deficiency, the anemia and other abnormalities gradually resolve with thyroxine replacement.

Differential Diagnosis An asymmetric goiter in Hashimoto's thyroiditis may be confused with a multinodular goiter or thyroid carcinoma, even when thyroid antibodies are present. Ultrasound can be used to show the presence of a solitary lesion or a multinodular goiter, rather than the heterogeneous thyroid enlargement typical of Hashimoto's thyroiditis.FNAbiopsy is useful in the investigation of focal nodules. Other causes of hypothyroidism are discussed below but rarely cause diagnostic confusion (Table 330-4).

OTHER CAUSES OF HYPOTHYROIDISM

Iatrogenic hypothyroidism is a common cause of hypothyroidism and can often be detected by screening before symptoms develop. In the first 3 to 4 months after radioiodine treatment, transient hypothyroidism may occur due to reversible radiation damage rather than to cellular destruction. Low-dose thyroxine treatment can be withdrawn if recovery occurs. BecauseTSHlevels are suppressed by hyperthyroidism, free T_4levels are a better measure of thyroid function than TSH in the months following radioiodine treatment. Mild hypothyroidism after subtotal thyroidectomy may also resolve after several months, as the gland remnant is stimulated by increased TSH levels.

Iodine deficiency is responsible for endemic goiter and cretinism but is an uncommon cause of adult hypothyroidism unless the iodine intake is very low or there are complicating factors, such as the consumption of thiocyanates in cassava or selenium deficiency. Though hypothyroidism due to iodine deficiency can be treated with thyroxine, public health measures to improve iodine intake should be advocated to eliminate this problem. Iodized salt or bread or the use of a single bolus of oral or intramuscular iodized oil have all been used successfully.

Paradoxically, chronic iodine excess can also induce goiter and hypothyroidism. The intracellular events that account for this effect are unclear, but individuals with autoimmune thyroiditis are especially susceptible. Iodine excess is responsible for the hypothyroidism that occurs in up to 13% of patients treated with amiodarone (see below). Other drugs, particularly lithium, may also cause hypothyroidism.

Secondary hypothyroidism is usually diagnosed in the context of other anterior pituitary hormone deficiencies; isolatedTSHdeficiency is very rare (Chap. 328). TSH levels may be low, normal, or even slightly increased in secondary hypothyroidism; the latter is due to secretion of immunoactive but bioinactive forms of TSH. The diagnosis is confirmed by detecting a low free T_4level. The goal of treatment is to maintain free T_4levels in the upper half of the reference range, as TSH levels cannot be used to monitor therapy.

TREATMENT

Clinical Hypothyroidism If there is no residual thyroid function, the daily replacement dose of levothyroxine is usually 1.5 ug/kg body weight (typically 100 to 150 ug). In many patients, however, lower doses suffice until residual thyroid tissue is destroyed. In patients who develop hypothyroidism after the treatment of Graves' disease, there is often underlying autonomous function, necessitating lower replacement doses (typically 75 to 125 ug/d).

Adult patients under 60 without evidence of heart disease may be started on 50 to 100ug levothyroxine (T_4) daily. The dose is adjusted on the basis ofTSHlevels, with the goal of treatment being a normal TSH, ideally in the lower half of the reference range. TSH responses are gradual and should be measured about 2 months after instituting treatment or after any subsequent change in levothyroxine dosage. The clinical effects of levothyroxine replacement are often slow to appear. Patients may not experience full relief from symptoms until 3 to 6 months after normal TSH levels are restored. Adjustment of levothyroxine dosage is made in 12.5- or 25-ug increments if the TSH is high; decrements of the same magnitude should be made if the TSH is suppressed. Patients with a suppressed TSH of any cause, including T_4overtreatment, have an increased risk of atrial fibrillation and reduced bone density.

Although dessicated animal thyroid preparations (thyroid extract USP) are available, they are not recommended as potency and composition vary between batches. Interest in using levothyroxine combined with liothyronine (triiodothyronine, T_3) has been revived, based on studies suggesting that patients feel better when taking the T_4/T_3combination compared to T_4alone. However, a long-term benefit from this combination is not established. There is no place for liothyronine alone as long-term replacement, because the short half-life necessitates three or four daily doses and is associated with fluctuating T_3levels.

Once full replacement is achieved andTSHlevels are stable, follow-up measurement of TSH is recommended at annual intervals and may be extended to every 2 to 3 years, if a normal TSH is maintained over several years. It is important to ensure ongoing compliance, however, as patients do not feel any difference after missing a few doses of levothyroxine, sometimes leading to self-discontinuation.

In patients of normal body weight who are taking ^{3}200 ug of levothyroxine per day, an elevatedTSHlevel is often a sign of poor compliance. This is also the likely explanation for fluctuating TSH levels, despite a constant levothyroxine dosage. Such patients often have normal or high free T_4levels, despite an elevated TSH, because they remember to take medication for a few days before testing; this is sufficient to normalize T_4 but not TSH levels. It is important to consider variable compliance, as this pattern of thyroid function tests is otherwise suggestive of disorders associated with inappropriate TSH secretion (Table 330-3). Because T_4 has a long half-life (7 days), patients who miss doses can be advised to take up to three doses of the skipped tablets at once. Other causes of increased levothyroxine requirements must be excluded, particularly malabsorption (e.g., celiac disease, small-bowel surgery) and drugs that interfere with T_4absorption or clearance such as cholestyramine, ferrous sulfate, calcium supplements, lovastatin, aluminum hydroxide, rifampicin, amiodarone, carbamazepine, and phenytoin.

Subclinical Hypothyroidism By definition, subclinical hypothyroidism refers to biochemical evidence of thyroid hormone deficiency in patients who have few or no apparent clinical features of hypothyroidism. There are no generally accepted guidelines for the treatment of subclinical hypothyroidism. As long as excessive treatment is avoided, there is little risk in correcting a slightly increasedTSH, and some patients likely derive modest clinical benefit from treatment. Moreover, there is some risk that patients will progress to overt hypothyroidism, particularly whenTPOantibodies are present. Treatment is administered by starting with a low dose of levothyroxine (25 to 50 ug/d) with the goal of normalizing TSH.

Special Treatment Considerations Rarely, levothyroxine replacement is associated with pseudotumor cerebri in *children*. Presentation appears to be idiosyncratic and occurs months after treatment is begun. Women with a history or high risk of hypothyroidism should ensure that they are euthyroid prior to conception and during early pregnancy as maternal hypothyroidism may adversely affect fetal neural development.TSH and free T_4levels should be measured once pregnancy is confirmed and at the beginning of the second and third trimesters. The dose of levothyroxine may need to be increased by ^{3}50% during pregnancy and returned to previous levels after delivery. In the *elderly*, especially patients with known coronary artery disease, the starting dose of levothyroxine is 12.5 to 25 ug/d with similar increments every 2 to 3 months until TSH is normalized. In some patients it may be impossible to achieve full replacement, despite optimal antianginal treatment. *Emergency surgery* is generally safe in patients with untreated hypothyroidism, although routine surgery in a hypothyroid patient should be deferred until euthyroidism is achieved.

Myxedema coma still has a high mortality rate, despite intensive treatment. Clinical manifestations include reduced level of consciousness, sometimes associated with seizures, as well as the other features of hypothyroidism (Table 330-5). Hypothermia can reach 23°C (74°F). There may be a history of treated hypothyroidism with poor compliance, or the patient may be previously undiagnosed. Myxedema coma almost always occurs in the elderly and is usually precipitated by factors that impair respiration, such as drugs (especially sedatives, anesthetics, antidepressants), pneumonia, congestive heart failure, myocardial infarction, gastrointestinal bleeding, or cerebrovascular accidents. Sepsis should also be suspected. Exposure to cold may also be a risk factor. Hypoventilation, leading to hypoxia and hypercapnia, plays a major role in pathogenesis; hypoglycemia and dilutional hyponatremia also contribute to the development of myxedema coma.

Levothyroxine can initially be administered as a single intravenous bolus of 500 ug, which serves as a loading dose. Although further levothyroxine is not strictly necessary for several days, it is usually continued at a dose of 50 to 100 ug/d. If a suitable intravenous preparation is not available, the same initial dose of levothyroxine can be given by nasogastric tube (though absorption may be impaired in myxedema). An alternative is to give liothyronine (T_3) intravenously or via nasogastric tube, in doses ranging from 10 to 25 ug every 8 to 12 h. This treatment has been advocated because T_4®T_3conversion is impaired in myxedema coma. However, excess liothyroxine has the potential to provoke arrhythmias. Another commonly used option is to combine levothyroxine (200 ug) and liothyronine (25 ug) as a single, initial intravenous bolus

followed by daily treatment with levothyroxine (50 to 100 ug/d) and liothyronine (10 ug every 8 h).

Supportive therapy should be provided to correct any associated metabolic disturbances. External warming is indicated only if the temperature is<30°C, as it can result in cardiovascular collapse (Chap. 17). Space blankets should be used to prevent further heat loss. Parenteral hydrocortisone (50 mg every 6 h) should be administered, as there is impaired adrenal reserve in profound hypothyroidism. Any precipitating factors should be treated, including the early use of broad-spectrum antibiotics, pending the exclusion of infection. Ventilatory support with regular blood gas analysis is usually needed during the first 48 h. Hypertonic saline or intravenous glucose may be needed if there is hyponatremia or hypoglycemia; hypotonic intravenous fluids should be avoided because they may exacerbate water retention secondary to reduced renal perfusion and inappropriate vasopressin secretion. The metabolism of most medications is impaired, and sedatives should be avoided if possible or used in reduced doses. Blood levels should be monitored, when available, to guide medication dosage.

THYROTOXICOSIS

Thyrotoxicosis is defined as the state of thyroid hormone excess and is not synonymous with *hyperthyroidism*, which is the result of excessive thyroid function. However, the major etiologies of thyrotoxicosis are hyperthyroidism caused by Graves' disease, toxic multinodular goiter, and toxic adenomas. Other causes are listed in Table 330-6.

GRAVES' DISEASE

Epidemiology Graves' disease accounts for 60 to 80% of thyrotoxicosis, though the prevalence varies among populations, depending mainly on iodine intake (high iodine intake is associated with an increased prevalence of Graves' disease). Graves' disease occurs in up to 2% of women but is one-tenth as frequent in men. The disorder rarely begins before adolescence and typically occurs between 20 and 50 years of age, though it also occurs in the elderly.

Pathogenesis The hyperthyroidism of Graves' disease is caused byTSI that are directed to theTSH-R(see "Autoimmune Basis of Thyroid Disease," below). Other thyroid autoimmune responses coexist in these patients, and therefore there is no direct correlation between the levels of TSI and thyroid hormones. The extrathyroidal manifestations of Graves' disease -- i.e., ophthalmopathy and dermopathy -- are due to immunologically mediated activation of fibroblasts in the extraocular muscles and skin, with accumulation of glycosaminoglycans, leading to the trapping of water and edema. Later, fibrosis becomes prominent. The fibroblast activation is caused by cytokines (IFN-g, tumor necrosis factor,IL-1) derived from locally infiltrating T cells and macrophages.

Clinical Manifestations Signs and symptoms include features that are common to any cause of thyrotoxicosis (Table 330-7) as well as those specific for Graves' disease. The clinical presentation depends on the severity of thyrotoxicosis, the duration of the disease, individual susceptibility to excess thyroid hormone, and the age of the patient. In the elderly, features of thyrotoxicosis may be subtle or masked, and patients may

present mainly with fatigue and weight loss, leading to *apathetic hyperthyroidism*.

Thyrotoxicosis may cause unexplained weight loss, despite an enhanced appetite, and is due to the increased metabolic rate. Weight gain occurs in 5 to 10% of patients, however, as a result of increased food intake. Other prominent features include hyperactivity, nervousness, and irritability, ultimately leading to a sense of easy fatiguability in some patients. Insomnia and impaired concentration are common; apathetic thyrotoxicosis may be mistaken for depression in the elderly. Fine tremor is a very frequent finding, best elicited by asking patients to stretch out the fingers and feeling the fingertips with the palm. Common neurologic manifestations include hyperreflexia, muscle wasting, and proximal myopathy without fasciculation. Chorea is a rare feature. Thyrotoxicosis is sometimes associated with a form of hypokalemic periodic paralysis; this disorder is particularly common in Asian males with thyrotoxicosis.

The most common cardiovascular manifestation is sinus tachycardia, often associated with palpitations and sometimes due to supraventricular tachycardia. The high cardiac output produces a bounding pulse, widened pulse pressure, and an aortic systolic murmur, and can lead to worsening of angina or heart failure in the elderly or those with preexisting heart disease. Atrial fibrillation is more common in patients>50. Treatment of the thyrotoxic state alone reverts atrial fibrillation to normal sinus rhythm in fewer than half of patients, suggesting the existence of an underlying cardiac problem in the remainder.

The skin is usually warm and moist, and the patient complains of sweating and heat intolerance, particularly during warm weather. Palmar erythema; onycholysis; and, less commonly, pruritus, urticaria, and diffuse hyperpigmentation may be evident. Hair texture may become fine, and a diffuse alopecia occurs in up to 40% of patients, persisting for months after restoration of euthyroidism. Gastrointestinal transit time is decreased, leading to increased stool frequency, often with diarrhea and occasionally mild steatorrhea. Women frequently experience oligomenorrhea or amenorrhea; in men there may be impaired sexual function and, rarely, gynecomastia. The direct effect of thyroid hormones on bone resorption leads to osteopenia in long-standing thyrotoxicosis; mild hypercalcemia occurs in up to 20% of patients, but hypercalcuria is more common. There is a small increase in fracture rate in patients with a previous history of thyrotoxicosis.

In Graves' disease the thyroid is usually diffusely enlarged to two to three times its normal size. The consistency is firm, but less so than in multinodular goiter. There may be a thrill or bruit due to the increased vascularity of the gland and the hyperdynamic circulation.

Lid retraction, causing a staring appearance, can occur in any form of thyrotoxicosis and is the result of sympathetic overactivity. However, Graves' disease is associated with specific eye signs that comprise *Graves' ophthalmopathy* (Fig. 330-6*A* and 330-CD2). This condition is also called *thyroid-associated ophthalmopathy*, as it occurs in the absence of Graves' disease in 10% of patients. Most of these individuals have autoimmune hypothyroidism or thyroid antibodies. The onset of Graves' ophthalmopathy occurs within the year before or after the diagnosis of thyrotoxicosis in 75% of patients

but can sometimes precede or follow thyrotoxicosis by several years, accounting for some cases of euthyroid ophthalmopathy.

Many patients with Graves' disease have little clinical evidence of ophthalmopathy. However, the enlarged extraocular muscles typical of the disease, and other subtle features, can be detected in almost all patients when investigated by ultrasound or computed tomography (CT) imaging of the orbits. Unilateral signs are found in up to 10% of patients. The earliest manifestations of ophthalmopathy are usually a sensation of grittiness, eye discomfort, and excess tearing. About a third of patients have proptosis, best detected by visualization of the sclera between the lower border of the iris and the lower eyelid, with the eyes in the primary position. Proptosis can be measured using an exophthalmometer. In severe cases, proptosis may cause corneal exposure and damage, especially if the lids fail to close during sleep. Periorbital edema, scleral injection, and chemosis are also frequent. In 5 to 10% of patients, the muscle swelling is so severe that diplopia results, typically but not exclusively when the patient looks up and laterally. The most serious manifestation is compression of the optic nerve at the apex of the orbit, leading to papilledema, peripheral field defects, and, if left untreated, permanent loss of vision.

Many scoring systems have been used to gauge the extent and activity of the orbital changes in Graves' disease. The NO SPECS scheme is an acronym derived from the following classes of eye change:

0= No signs or symptoms

1 =Only signs (lid retraction or lag), no symptoms

2 =Soft tissue involvement (periorbital edema)

3 =Proptosis (>22 mm)

4 =Extraocular muscle involvement (diplopia)

5 =Corneal involvement

6= Sight loss

Although useful as a mnemonic, the NO SPECS scheme is inadequate to describe the eye disease fully, and patients do not necessarily progress from one class to another. When Graves' eye disease is active and severe, referral to an ophthalmologist is indicated and objective measurements are needed, such as lid fissure width; corneal staining with fluorescein; and evaluation of extraocular muscle function (e.g., Hess chart), intraocular pressure and visual fields, acuity, and color vision.

Thyroid dermopathy occurs in<5% of patients with Graves' disease (Fig. 330-6*B*), almost always in the presence of moderate or severe ophthalmopathy. Although most frequent over the anterior and lateral aspects of the lower leg (hence the term *pretibial myxedema*), skin changes can occur at other sites, particularly after trauma. The typical lesion is a noninflamed, indurated plaque with a deep pink or purple color and an

"orange-skin" appearance. Nodular involvement can occur, and the condition can rarely extend over the whole lower leg and foot, mimicking elephantiasis. *Thyroid acropachy* refers to a form of clubbing found in<1% of patients with Graves' disease (Fig. 330-6*C*). It is so strongly associated with thyroid dermopathy that an alternative cause of clubbing should be sought in a Graves' patient without coincident skin and orbital involvement.

Laboratory Evaluation Investigations used to determine the existence and cause of thyrotoxicosis are summarized in Fig. 330-7. In Graves' disease, the TSH level is suppressed and free and total thyroid hormone levels are increased. In 2 to 5% of patients (and more in areas of borderline iodine intake), only T_3 is increased (T_3 toxicosis). The converse state of T_4 toxicosis, with elevated total and free T_4 and normal T_3 levels, is occasionally seen when hyperthyroidism is induced by excess iodine, providing surplus substrate for thyroid hormone synthesis. Measurement of TPO antibodies is useful in differential diagnosis, but assays for TSH-R antibodies are not usually needed. Associated abnormalities that may cause diagnostic confusion in thyrotoxicosis include elevation of bilirubin, liver enzymes, and ferritin. Microcytic anemia and thrombocytopenia occur less often.

Differential Diagnosis Diagnosis of Graves' disease is straightforward in a patient with biochemically confirmed thyrotoxicosis, diffuse goiter on palpation, ophthalmopathy, positive TPO antibodies, and often a personal or family history of autoimmune disorders. For patients with thyrotoxicosis who lack these features, the most reliable diagnostic method is a radionuclide (^{99m}Tc, ^{123}I, or ^{131}I) scan of the thyroid, which will distinguish the diffuse, high uptake of Graves' disease from nodular thyroid disease, destructive thyroiditis, ectopic thyroid tissue, and factitious thyrotoxicosis. In secondary hyperthyroidism due to a TSH-secreting pituitary tumor, there is also a diffuse goiter. The presence of a nonsuppressed TSH level, and the finding of a pituitary tumor on CT or magnetic resonance imaging (MRI) scan readily identify such patients.

Clinical features of thyrotoxicosis can mimic certain aspects of other disorders including panic attacks, mania, pheochromocytoma, and the weight loss associated with malignancy. The diagnosis of thyrotoxicosis can be easily excluded if the TSH level is normal. A normal TSH also excludes Graves' disease as a cause of diffuse goiter.

Clinical Course Clinical features generally worsen without treatment; mortality was 10 to 30% before the introduction of satisfactory therapy. Some patients with mild Graves' disease experience spontaneous relapses and remissions. Rarely, there may be fluctuation between hypo- and hyperthyroidism due to changes in the functional activity of TSH-R antibodies. About 15% of patients who enter remission after treatment with antithyroid drugs develop hypothyroidism 10 to 15 years later as a result of the destructive autoimmune process. The clinical course of ophthalmopathy does not follow that of the thyroid disease. Ophthalmopathy typically worsens over the initial 3 to 6 months, followed by a plateau phase over the next 12 to 18 months, with spontaneous improvement, particularly in the soft tissue changes. However, the course is more fulminant in up to 5% of patients, requiring intervention in the acute phase if there is optic nerve compression or corneal ulceration. Diplopia may appear late in the disease due to fibrosis of the extraocular muscles. Some studies suggest that radioiodine treatment for hyperthyroidism worsens the eye disease in a small proportion of patients (especially smokers). Antithyroid drugs or surgery have no adverse effects on the

clinical course of ophthalmopathy. Thyroid dermopathy, when it occurs, usually appears 1 to 2 years after the development of Graves' hyperthyroidism; it may improve spontaneously.

TREATMENT

The *hyperthyroidism* of Graves' disease is treated by reducing thyroid hormone synthesis, using antithyroid drugs, or by reducing the amount of thyroid tissue with radioiodine (^{131}I) treatment or subtotal thyroidectomy. Antithyroid drugs are the predominant therapy in many centers in Europe and Japan, whereas radioiodine is more often the first line of treatment in North America. These differences reflect the fact that no single approach is optimal and that patients may require multiple treatments to achieve remission.

The main *antithyroid drugs* are the thionamides, such as propylthiouracil, carbimazole, and the active metabolite of the latter, methimazole. All inhibit the function ofTPO, reducing oxidation and organification of iodide. These drugs also reduce thyroid antibody levels by mechanisms that remain unclear, and they appear to enhance rates of remission. Propylthiouracil inhibits deiodination of T_4®T_3. However, this effect is of minor benefit, except in the most severe thyrotoxicosis, and is offset by the much shorter half-life of this drug (90 min) compared to methimazole (6 h).

There are many variations of antithyroid drug regimens. The initial dose of carbimazole or methimazole is usually 10 to 20 mg every 8 or 12 h, but once-daily dosing is possible after euthyroidism is restored. Propylthiouracil is given at a dose of 100 to 200 mg every 6 to 8 h, and divided doses are usually given throughout the course. Lower doses of each drug may suffice in areas of low iodine intake. The starting dose of antithyroid drugs can be gradually reduced (titration regimen) as thyrotoxicosis improves. Alternatively, high doses may be given combined with levothyroxine supplementation (block-replace regimen) to avoid drug-induced hypothyroidism. Initial reports suggesting superior remission rates with the block-replace regimen have not been reproduced in several other trials. The titration regimen is often preferred to minimize the dose of antithyroid drug and provide an index of treatment response.

Thyroid function tests and clinical manifestations are reviewed 3 to 4 weeks after starting treatment, and the dose is titrated based on free T_4levels. Most patients do not achieve euthyroidism until 6 to 8 weeks after treatment is initiated.TSHlevels often remain suppressed for several months and therefore do not provide a sensitive index of treatment response. The usual daily maintenance doses of antithyroid drugs in the titration regimen are 2.5 to 10 mg of carbimazole or methimazole and 50 to 100 mg of propylthiouracil. In the block-replace regimen, the initial dose of antithyroid drug is held constant and the dose of levothyroxine is adjusted to maintain normal free T_4levels.

Maximum remission rates (up to 30 to 50% in some populations) are achieved by 18 to 24 months. For unclear reasons, remission rates appear to vary in different geographic regions. Patients with severe hyperthyroidism and large goiters are most likely to relapse when treatment stops, but outcome is difficult to predict. All patients should be followed closely for relapse during the first year after treatment and at least annually thereafter.

The common side effects of antithyroid drugs are rash, urticaria, fever, and arthralgia (1 to 5% of patients). These may resolve spontaneously or after substituting an alternative antithyroid drug. Rare but major side effects include hepatitis, anSLE-like syndrome, and, most importantly, agranulocytosis (<1%). It is essential that antithyroid drugs are stopped and not restarted if a patient develops major side effects. Patients should be given written instructions regarding the symptoms of possible agranulocytosis (e.g., sore throat, fever, mouth ulcers) and the need to stop treatment pending a complete blood count to confirm that agranulocytosis is not present. Management of agranulocytosis is described inChap. 109. Most physicians do not prospectively monitor blood counts, as the onset of agranulocytosis is idiosyncratic and abrupt.

Propranolol (20 to 40 mg every 6 h) or longer acting beta blockers, such as atenolol, may be useful to control adrenergic symptoms, especially in the early stages before antithyroid drugs take effect. Anticoagulation with warfarin should be considered in all patients with atrial fibrillation. If digoxin is used, increased doses are often needed in the thyrotoxic state.

Radioiodine causes progressive destruction of thyroid cells and can be used as initial treatment or for relapses after a trial of antithyroid drugs. There is a small risk of thyrotoxic crisis (see below) after radioiodine, which can be avoided by pretreatment with antithyroid drugs for at least a month before treatment. Antecedent treatment with antithyroid drugs should be considered in all elderly patients, or in those with cardiac problems, to deplete thyroid hormone stores before administration of radioiodine. Antithyroid drugs must be stopped 3 to 5 days before radioiodine administration to achieve optimum iodine uptake.

Efforts to calculate an optimal dose of radioiodine that achieves euthyroidism, without a high incidence of relapse or progression to hypothyroidism, have not been successful. Some patients inevitably relapse after a single dose because the biologic effects of radiation vary between individuals, and hypothyroidism cannot be uniformly avoided even using accurate dosimetry. A practical strategy is to give a fixed dose based on clinical features, such as the severity of thyrotoxicosis, the size of the goiter (increases the dose needed), and the level of radioiodine uptake (decreases the dose needed).^{131}I dosage generally ranges between 185 MBq (5 mCi) to 555 MBq (15 mCi). Incomplete treatment or early relapse is more common in males and in patients<40 years of age. Many authorities favor an approach aimed at thyroid ablation (as opposed to euthyroidism), given that levothyroxine replacement is straightforward and most patients ultimately progress to hypothyroidism over 5 to 10 years anyway, frequently with some delay in the diagnosis of hypothyroidism.

Certain radiation safety precautions are necessary in the first few days after radioiodine treatment, but the exact guidelines vary depending on local protocols. In general, patients need to avoid close, prolonged contact with children and pregnant women for several days because of possible transmission of residual isotope and excessive exposure to radiation emanating from the gland. Rarely there may be mild pain due to radiation thyroiditis 1 to 2 weeks after treatment. Hyperthyroidism can persist for 2 to 3 months before radioiodine takes full effect. For this reason, b-adrenergic blockers or antithyroid drugs can be used to control symptoms during this interval. Persistent

hyperthyroidism can be treated with a second dose of radioiodine, usually 6 months after the first dose. The risk of hypothyroidism after radioiodine depends on the dosage but is at least 10 to 20% in the first year and 5% per year thereafter. Patients should be informed of this possibility before treatment and require close follow-up during the first year and annual thyroid function testing thereafter.

Pregnancy and breast feeding are absolute contraindications to radioiodine treatment, but patients can conceive safely 6 to 12 months after treatment. The presence of severe ophthalmopathy requires caution, and some authorities advocate the use of prednisone, 40 mg/d, at the time of radioiodine treatment, tapered over 2 to 3 months to prevent exacerbation of ophthalmopathy. The overall risk of cancer after radioiodine treatment in adults is not increased, but many physicians avoid radioiodine in children and adolescents because of the theoretical risks of malignancy.

Subtotal thyroidectomy is an option for patients who relapse after antithyroid drugs and prefer this treatment to radioiodine. Some experts recommend surgery in young individuals, particularly when the goiter is very large. Careful control of thyrotoxicosis with antithyroid drugs, followed by potassium iodide (3 drops SSKI orally tid) is needed prior to surgery to avoid thyrotoxic crisis and to reduce the vascularity of the gland. The major complications of surgery -- i.e., bleeding, laryngeal edema, hypoparathyroidism, and damage to the recurrent laryngeal nerves -- are unusual when the procedure is performed by highly experienced surgeons. Recurrence rates in the best series are <2%, but the rate of hypothyroidism is only slightly less than that following radioiodine treatment.

The titration regimen of antithyroid drugs should be used to manage Graves' disease in *pregnancy*, as blocking doses of these drugs produce fetal hypothyroidism. Propylthiouracil is usually used because of relatively low transplacental transfer and its ability to block T_4®T_3conversion. Also, carbimazole and methimazole have been associated with rare cases of fetal *aplasia cutis*. The lowest effective dose of propylthiouracil should be given, and it is often possible to stop treatment in the last trimester sinceTSH-Rantibodies tend to decline in pregnancy. Nonetheless, the transplacental transfer of these antibodies rarely causes *fetal thyrotoxicosis* or *neonatal thyrotoxicosis*. Poor intrauterine growth, a fetal heart rate of>160 beats/min, and high levels of maternal TSH-R antibodies should suggest this complication. Antithyroid drugs given to the mother can be used to treat the fetus and may be needed for 1 to 3 months after delivery, until the maternal antibodies disappear from the baby's circulation. The post-partum period is a time of major risk for relapse of Graves' disease. Breast feeding is safe with low doses of antithyroid drugs. Graves' disease in *children* is best managed with antithyroid drugs, often given as a prolonged course of the titration regimen. Surgery may be indicated for severe disease. Radioiodine can also be used in children, though most experts defer this treatment until adolescence or later.

Thyrotoxic crisis, or *thyroid storm*, is rare and presents as a life-threatening exacerbation of hyperthyroidism, accompanied by fever, delirium, seizures, coma, vomiting, diarrhea, and jaundice. The mortality rate due to cardiac failure, arrhythmia, or hyperthermia is ~30%, even with treatment. Thyrotoxic crisis is usually precipitated by acute illness (e.g., stroke, infection, trauma, diabetic ketoacidosis), surgery (especially on the thyroid), or radioiodine treatment of a patient with partially treated or untreated

hyperthyroidism. Management requires intensive monitoring and supportive care, identification and treatment of the precipitating cause, and measures that reduce thyroid hormone synthesis. Large doses of propylthiouracil (600-mg loading dose and 200 to 300 mg every 6 h) should be given orally or by nasogastric tube or per rectum; the drug's inhibitory action on T_4®T_3conversion makes it the agent of choice. One hour after the first dose of propylthiouracil, stable iodide is given to block thyroid hormone synthesis via the Wolff-Chaikoff effect (the delay allows the antithyroid drug to prevent the excess iodine from being incorporated into new hormone). A saturated solution of potassium iodide (5 drops SSKI every 6 h), or ipodate or iopanoic acid (0.5 mg every 12 h), may be given orally. (Sodium iodide, 0.25 g intravenously every 6 h is an alternative but is not generally available.) Propranolol should also be given to reduce tachycardia and other adrenergic manifestations (40 to 60 mg orally every 4 h; or 2 mg intravenously every 4 h). Although otherb-adrenergic blockers can be used, high doses of propranolol have been documented to decrease T_4®T_3conversion, and the doses can be easily adjusted. Caution is needed to avoid acute negative inotropic effects, but controlling the heart rate is important, as some patients develop a form of high-output heart failure. Additional therapeutic measures include glucocorticoids (e.g., dexamethasone, 2 mg every 6 h), antibiotics if infection is present, cooling, and intravenous fluids.

Ophthalmopathy requires no active treatment when it is mild or moderate, as there is usually spontaneous improvement. General measures include meticulous control of thyroid hormone levels, advice about cessation of smoking, and an explanation of the natural history of ophthalmopathy. Discomfort can be relieved with artificial tears (e.g., 1% methylcellulose) and the use of dark glasses with side frames. Periorbital edema responds to a more upright sleeping position. Corneal exposure during sleep can be avoided by taping the eyelids shut. Minor degrees of diplopia improve with prisms fitted to spectacles. Severe ophthalmopathy, with optic nerve involvement or chemosis resulting in corneal damage, is an emergency requiring joint management with an ophthalmologist. Short-term benefit can be gained in about two-thirds of patients by the use of high-dose glucocorticoids (e.g., prednisone, 40 to 80 mg daily), sometimes combined with cyclosporine. Glucocorticoid doses are tapered by 5 mg every 1 to 2 weeks, but the taper often results in reemergence of congestive symptoms. Pulse therapy with intravenous methylprednisolone (1 g of methylprednisolone in 250 mL of saline infused over 2 h daily for 1 week) followed by an oral regimen is also used. Once the eye disease has stabilized, surgery may be indicated for relief of diplopia and correction of the appearance of the eyes. Orbital decompression can be achieved by removing bone from any wall of the orbit, thereby allowing displacement of fat and swollen extraocular muscles. The transantral route is used most often, as it requires no external incision. Proptosis recedes an average of 5 mm, but there may be residual or even worsened diplopia. Alternatively, retroorbital tissue can be decompressed without removal of bony tissue. External beam radiotherapy of the orbits has been used for many years, but the objective evidence that this therapy is beneficial remains equivocal.

Thyroid dermopathy does not usually require treatment but can cause cosmetic problems or interfere with the fit of shoes. Surgical removal is not indicated. Treatment consists of topical, high-potency glucocorticoid ointment under an occlusive dressing. Octreotide may be beneficial.

OTHER CAUSES OF THYROTOXICOSIS

Destructive thyroiditis (subacute or silent thyroiditis) typically presents with a short thyrotoxic phase due to the release of preformed thyroid hormones and catabolism ofTg (see "Subacute Thyroiditis," below). True hyperthyroidism is absent, as demonstrated by a low radionuclide uptake. Circulating Tg andIL-6 levels are usually increased. Other causes of thyrotoxicosis with low or absent thyroid radionuclide uptake include *thyrotoxicosis factitia*; iodine excess and, rarely, ectopic thyroid tissue, particularly teratomas of the ovary (*struma ovarii*); and functional metastatic follicular carcinoma. Whole-body radionuclide studies can demonstrate ectopic thyroid tissue, and thyrotoxicosis factitia can be distinguished from destructive thyroiditis by the clinical features and low levels of Tg. Amiodarone treatment is associated with thyrotoxicosis in up to 10% of patients, particularly in areas of low iodine intake.

TSH-secreting pituitary adenoma is a rare causes of thyrotoxicosis. It can be identified by the presence of an inappropriately normal or increasedTSHlevel in a patient with hyperthyroidism, diffuse goiter, and elevated free T_4 and T_3levels (Chap. 328). Elevated levels of thea subunit of TSH, released by the TSH-secreting adenoma, support this diagnosis, which can be confirmed by demonstrating the pituitary tumor onCT orMRIscan. A combination of transsphenoidal surgery, sella irradiation, and octreotide may be required to normalize TSH, as many of these tumors are large and locally invasive at the time of diagnosis. Radioiodine or antithyroid drugs can be used to control thyrotoxicosis.

Thyrotoxicosis caused by *toxic multinodular goiter* and *hyperfunctioning solitary nodules* is discussed below.

THYROIDITIS

A clinically useful classification of thyroiditis is based on the onset and duration of disease (Table 330-8).

ACUTE THYROIDITIS

Acute thyroiditis is rare and is due to suppurative infection of the thyroid. In children and young adults, the most common cause is the presence of a piriform sinus, a remnant of the fourth branchial pouch that connects the oropharynx with the thyroid. Such sinuses are predominantly left sided. A long-standing goiter and degeneration in a thyroid malignancy are risk factors in the elderly. The patient presents with thyroid pain, often referred to the throat or ears, and a small, tender goiter that may be asymmetric. Fever, dysphagia, and erythema over the thyroid are common, as are systemic symptoms of a febrile illness and lymphadenopathy.

The differential diagnosis of *thyroid pain* includes subacute or, rarely, chronic thyroiditis, hemorrhage into a cyst, malignancy including lymphoma, and, rarely, amiodarone-induced thyroiditis or amyloidosis. However, the abrupt presentation and clinical features of acute thyroiditis rarely cause confusion. The erythrocyte sedimentation rate (ESR) and white cell count are usually increased, but thyroid function is normal.FNAbiopsy shows infiltration by polymorphonuclear leukocytes; culture of the sample can identify the organism. Caution is needed in immunocompromised patients

as fungal or *Pneumocystis* thyroiditis can occur in this setting. Antibiotic treatment is guided initially by Gram stain and subsequently by cultures of the FNA biopsy. Surgery may be needed to drain an abscess, which can be localized byCT scan or ultrasound. Tracheal obstruction, septicemia, retropharyngeal abscess, mediastinitis, and jugular venous thrombosis may complicate acute thyroiditis but are uncommon with prompt use of antibiotics.

SUBACUTE THYROIDITIS

This is also termed *de Quervain's thyroiditis*, *granulomatous thyroiditis*, or *viral thyroiditis*. Many viruses have been implicated, including mumps, coxsackie, influenza, adenoviruses, and echoviruses, but attempts to identify the virus in an individual patient are often unsuccessful and do not influence management. The diagnosis of subacute thyroiditis is often overlooked because the symptoms can mimic pharyngitis. The peak incidence occurs at 30 to 50 years, and women are affected three times more frequently than men.

Pathophysiology The thyroid shows a characteristic patchy inflammatory infiltrate with disruption of the thyroid follicles and multinucleated giant cells within some follicles. The follicular changes progress to granulomas accompanied by fibrosis. Finally, the thyroid returns to normal, usually several months after onset. During the initial phase of follicular destruction, there is release ofTg and thyroid hormones, leading to increased circulating free T_4 and T_3 and suppression ofTSH(Fig. 330-8). During this destructive phase, radioactive iodine uptake is low or undetectable. After several weeks, the thyroid is depleted of stored thyroid hormone and a phase of hypothyroidism typically occurs, with low free T_4 (and sometimes T_3) and moderately increased TSH levels. Radioactive iodine uptake returns to normal or is even increased as a result of the rise in TSH. Finally, thyroid hormone and TSH levels return to normal as the disease subsides.

Clinical Manifestations The patient usually presents with a painful and enlarged thyroid, sometimes accompanied by fever. There may be features of thyrotoxicosis or hypothyroidism, depending on the phase of the illness. Malaise and symptoms of an upper respiratory tract infection may precede the thyroid-related features by several weeks. In other patients, the onset is acute, severe, and without obvious antecedent. Though the patient typically complains of a sore throat, examination reveals a small goiter that is exquisitely tender, and asymmetry is common. Pain is often referred to the jaw or ear. Complete resolution is the usual outcome, but permanent hypothyroidism can occur, particularly in those with coincidental thyroid autoimmunity. A prolonged course over many months, with one or more relapses, occurs in a small percentage of patients.

Laboratory Evaluation As depicted in Fig. 330-8, thyroid function tests characteristically evolve through three distinct phases over about 6 months: (1) thyrotoxic phase, (2) hypothyroid phase, and (3) recovery phase. In the thyrotoxic phase, T_4 and T_3levels are increased, reflecting their discharge from the damaged thyroid cells, and TSHis suppressed. The T_4/T_3ratio is greater than in Graves' disease or thyroid autonomy, in which T_3 is often disproportionately increased. The diagnosis is confirmed by a highESR and low radioiodine uptake. SerumIL-6 levels increase during the thyrotoxic phase. The white blood cell count may be increased, and thyroid

antibodies are negative. If the diagnosis is in doubt, FNA biopsy may be useful, particularly to distinguish unilateral involvement from bleeding into a cyst or neoplasm.

TREATMENT

Relatively large doses of aspirin (e.g., 600 mg every 4 to 6 h) or nonsteroidal anti-inflammatory drugs are sufficient to control symptoms in most cases. If this treatment is inadequate, or if the patient has marked local or systemic symptoms, glucocorticoids should be given. The usual starting dose is 40 to 60 mg prednisone, depending on severity. The dose is gradually tapered over 6 to 8 weeks, in response to improvement in symptoms and the ESR. If a relapse occurs during glucocorticoid withdrawal, treatment should be started again and withdrawn more gradually. In these patients, it is useful to wait until the radioactive iodine uptake normalizes before stopping treatment. Thyroid function should be monitored every 2 to 4 weeks using TSH and free T_4 levels. Symptoms of thyrotoxicosis improve spontaneously but may be ameliorated by b-adrenergic blockers; antithyroid drugs play no role in treatment of the thyrotoxic phase. Levothyroxine replacement may be needed if the hypothyroid phase is prolonged, but doses should be low enough (50 to 100 ug daily) to allow TSH-mediated recovery.

SILENT THYROIDITIS

Painless thyroiditis, or *"silent" thyroiditis*, occurs in patients with underlying autoimmune thyroid disease. It has a clinical course similar to that of subacute thyroiditis, except that there is little or no thyroid tenderness. The condition occurs most frequently 3 to 6 months after pregnancy and is then termed *post-partum thyroiditis*. Typically, patients have a brief phase of thyrotoxicosis, lasting 2 to 4 weeks, followed by hypothyroidism for 4 to 12 weeks, and then resolution; often, however, only one phase is apparent. As in subacute thyroiditis, the radioactive iodine uptake is initially suppressed. In addition to the painless goiter, silent thyroiditis can be distinguished from subacute thyroiditis by the normal ESR and the presence of TPO antibodies. Glucocorticoid treatment is not indicated for silent thyroiditis. Severe thyrotoxic symptoms can be managed with a brief course of propranolol, 20 to 40 mg three or four times daily. Thyroxine replacement may be needed for the hypothyroid phase but should be withdrawn after 6 to 9 months, as recovery is the rule. Annual follow-up thereafter is recommended, as a proportion of these individuals develop permanent hypothyroidism.

DRUG-INDUCED THYROIDITIS

Patients receiving IFN-a, IL-2, or amiodarone may develop painless thyroiditis. INF-a, which is used to treat chronic hepatitis B or C, causes thyroid dysfunction in up to 5% of treated patients. It has been associated with painless thyroiditis, hypothyroidism, and Graves' disease. IL-2, which has been used to treat various malignancies, has also been associated with thyroiditis and hypothyroidism, though fewer patients have been studied. For discussion of amiodarone, see "Amiodarone Effects on Thyroid Function," below.

CHRONIC THYROIDITIS

The most common cause of chronic thyroiditis is *Hashimoto's thyroiditis*, an autoimmune disorder that often presents as a firm or hard goiter of variable size (see above). *Riedel's thyroiditis* is a rare disorder that typically occurs in middle-aged women. It presents with an insidious, painless goiter with local symptoms due to compression of the esophagus, trachea, neck veins, or recurrent laryngeal nerves. Dense fibrosis disrupts normal gland architecture and can extend outside the thyroid capsule. Despite these extensive histologic changes, thyroid dysfunction is uncommon. The goiter is hard, nontender, often asymmetric and fixed, leading to suspicion of a malignancy. Diagnosis requires open biopsy as FNAbiopsy is usually unhelpful. Treatment is surgical and directed to relief of compressive symptoms. There is an association between Riedel's thyroiditis and idiopathic fibrosis at other sites (retroperitoneum, mediastinum, biliary tree, lung, and orbit).

SICK EUTHYROID SYNDROME

Any acute, severe illness can cause abnormalities of circulatingTSH or thyroid hormone levels in the absence of underlying thyroid disease, making these measurements potentially misleading. The major cause of these hormonal changes is the release of cytokines. Unless a thyroid disorder is strongly suspected, the routine testing of thyroid function should be avoided in acutely ill patients.

The most common hormone pattern in sick euthyroid syndrome (SES) is a decrease in total and free T_3levels (low T_3syndrome) with normal levels of T_4 andTSH. The magnitude of the fall in T_3correlates with the severity of the illness. T_4conversion to T_3 via peripheral deiodination is impaired, leading to increased reverse T_3(rT_3). Despite this effect, decreased clearance rather than increased production is the major basis for increased rT_3. Also, $T_4$is alternately metabolized to the hormonally inactive T_3sulfate. It is generally assumed that this low T_3 state is adaptive, as it can be induced in normal individuals by fasting. Teleologically, the fall in T_3 may provide a mechanism for limiting catabolism in starved or ill patients.

Very sick patients may have a fall in total $T_4$and T_3levels (low T_4syndrome). This state has a poor prognosis. A key factor in the fall in T_4levels is altered binding toTBG. Free T_4assays usually demonstrate a normal free T_4 level in such patients, depending on the assay method used. Fluctuation inTSHlevels also creates challenges in the interpretation of thyroid function in sick patients. TSH levels may range from <0.1 to>20 mU/L; these alterations reverse after recovery, confirming the absence of underlying thyroid disease. A rise in cortisol or administration of glucocorticoids may provide a partial explanation for decreased TSH levels. However, the exact mechanisms underlying the subnormal TSH seen in 10% of sick patients and the increased TSH seen in 5% remain unclear.

Any severe illness can induce changes in thyroid hormone levels, but certain disorders exhibit a distinctive pattern of abnormalities. Acute liver disease is associated with an initial rise in total (but not free) T_3 and T_4levels, due toTBGrelease; these levels become subnormal with progression to liver failure. A transient increase in total and free T_4levels, usually with a normal T_3level, is seen in 5 to 30% of acutely ill psychiatric patients.TSHvalues may be transiently low, normal, or high in these patients. In the early stage of HIV infection, T_3 and T_4levels rise, even if there is weight loss. T_3levels fall

with progression to AIDS, but TSH levels usually remain normal. Renal disease is often accompanied by low T_3 concentrations, but with normal rather than increased rT_3 levels, due to an unknown factor that increases uptake of rT_3 into the liver.

The diagnosis of the SES is challenging. Historic information may be limited, and patients often have multiple metabolic derangements. Useful features to consider include previous history of thyroid disease and thyroid function tests, evaluation of the severity and time course of the patient's acute illness, documentation of medications that may affect thyroid function or thyroid hormone levels, and measurements of rT_3 together with free thyroid hormones and TSH. The diagnosis of SES is frequently presumptive, given the clinical context and pattern of laboratory values; only resolution of the test results with clinical recovery can clearly establish this disorder. Treatment of SES with thyroid hormone (T_4 and/or T_3) is controversial, but most authorities recommend monitoring the patient's thyroid function tests during recovery, without administering thyroid hormone, unless there is historic or clinical evidence suggestive of hypothyroidism. Sufficiently large randomized controlled trials using thyroid hormone are unlikely to resolve this therapeutic controversy in the near future, because clinical presentations and outcomes are highly variable.

AMIODARONE EFFECTS ON THYROID FUNCTION

Amiodarone is a commonly used type III antiarrhythmic agent (Chap. 230). It is structurally related to thyroid hormone and contains 39% iodine by weight. Thus, typical doses of amiodarone (200 mg/d) are associated with very high iodine intake, leading to >40-fold increases in plasma and urinary iodine levels. Moreover, because amiodarone is stored in adipose tissue, high iodine levels persist for >6 months after discontinuation of the drug. Amiodarone inhibits deiodinase activity, and its metabolites function as weak antagonists of thyroid hormone action. Amiodarone has the following multiple effects on thyroid function: (1) acute, transient changes in thyroid function; (2) hypothyroidism in patients susceptible to the inhibitory effects of a high iodine load; and (3) thyrotoxicosis that may be caused by at least three mechanisms -- a Jod-Basedow effect from the iodine load in the setting of multinodular goiter, a thyroiditis-like condition, and possibly induction of autoimmune Graves' disease.

The initiation of amiodarone treatment is associated with a transient decrease of T_4 levels, reflecting the inhibitory effect of iodine on T_4 release. Soon thereafter, most individuals escape from iodide-dependent suppression of the thyroid (Wolff-Chaikoff effect), and the inhibitory effects on deiodinase activity and thyroid hormone receptor action become predominant. These events lead to the following pattern of thyroid function tests: increased T_4, decreased T_3, increased rT_3, and a transient increase of TSH (up to 20 mU/L). TSH levels normalize or are slightly suppressed after about 1 to 3 months.

The incidence of hypothyroidism from amiodarone varies geographically, apparently correlating with iodine intake. Hypothyroidism occurs in up to 13% of amiodarone-treated patients in iodine-replete countries, such as the United States, but is less common (<6% incidence) in areas of lower iodine intake, such as Italy or Spain. The pathogenesis appears to involve an inability of the thyroid to escape from the high iodine load. Consequently, amiodarone-associated hypothyroidism is more common in

women and individuals with positiveTPOantibodies. It is usually unnecessary to discontinue amiodarone for this side effect, as levothyroxine can be used to normalize thyroid function.TSHlevels should be monitored, because T_4levels are often increased for the reasons described above.

The management of amiodarone-induced thyrotoxicosis (AIT) is complicated by the fact that there are several causes of thyrotoxicosis and because the increased thyroid hormone levels exacerbate underlying arrhythmias and coronary artery disease. Amiodarone treatment causes thyrotoxicosis in 10% of patients living in areas of low iodine intake and in 2% of patients in regions of high iodine intake. There are two major forms of AIT. Type 1 AIT is associated with an underlying thyroid abnormality (preclinical Graves' disease or nodular goiter). Thyroid hormone synthesis becomes excessive as a result of increased iodine exposure (Jod-Basedow phenomenon). Type 2 AIT occurs in individuals with no intrinsic thyroid abnormalities and is the result of drug-induced lysosomal activation leading to destructive thyroiditis with histiocyte accumulation in the thyroid. Mild forms of type 2 AIT can resolve spontaneously or can occasionally lead to hypothyroidism. Color-flow doppler thyroid scanning shows increased vascularity in type 1 but decreased vascularity in type 2 AIT;IL-6 levels are markedly raised in type 2 but only slightly increased in type 1 AIT. Thyroid scans are difficult to interpret in this setting, because the high endogenous iodine levels diminish tracer uptake. However, the presence of normal or increased uptake favors type 1 AIT.

In amiodarone-induced thyrotoxicosis the drug should be stopped, if possible, though this is often impractical because of the underlying cardiac disorder. Discontinuation of amiodarone will not have an acute effect because of its storage and prolonged half-life. High doses of antithyroid drugs can be used in type 1AIT but are often ineffective. Potassium perchlorate, 200 mg every 6 h, has been used to reduce thyroidal iodide content. Perchlorate treatment has been associated with agranulocytosis, though the risk appears relatively low with short-term use. Glucocorticoids, administered as for subacute thyroiditis, are beneficial in type 2 AIT. Lithium blocks thyroid hormone release and can provide modest benefit. Near-total thyroidectomy rapidly decreases thyroid hormone levels and may be the most effective long-term solution, if the patient can undergo the procedure safely.

THYROID FUNCTION IN PREGNANCY

Three factors alter thyroid function in pregnancy: (1) the transient increase inhCGduring the first trimester, which stimulates theTSH-R; (2) the estrogen-induced rise inTBGduring the first trimester, which is sustained during pregnancy; and (3) increased urinary iodide excretion, which can cause impaired thyroid hormone production in areas of marginal iodine sufficiency. Women with a precarious iodine intake (<50 ug/d) are most at risk of developing a goiter during pregnancy, and iodine supplementation should be considered to prevent maternal and fetal hypothyroidism and the development of neonatal goiter.

The rise in circulatinghCGlevels during the first trimester is accompanied by a reciprocal fall inTSH that persists into the middle of pregnancy. This appears to reflect weak binding of hCG, which is present at very high levels, to theTSH-R. Rare individuals have been described with variant TSH-R sequences that enhance hCG binding and TSH-R

activation. Occasionally these hCG-induced changes in thyroid function result in transient gestational hyperthyroidism and/or *hyperemesis gravidarum*, a condition characterized by severe nausea and vomiting and risk of volume depletion. Antithyroid drugs are rarely needed, and parenteral fluid replacement usually suffices until the condition resolves.

Maternal hypothyroidism occurs in 2 to 3% of women of child-bearing age and is associated with increased risk of developmental delay in the offspring. Thyroid hormone requirements are increased by 25 to 50 ug/d during pregnancy.

GOITER AND NODULAR THYROID DISEASE

Goiter refers to an enlarged thyroid gland. Biosynthetic defects, iodine deficiency, autoimmune disease, and nodular diseases can each lead to goiter, though by different mechanisms. Biosynthetic defects and iodine deficiency are associated with reduced efficiency of thyroid hormone synthesis, leading to increasedTSH, which stimulates thyroid growth as a compensatory mechanism to overcome the block in hormone synthesis. Graves' disease and Hashimoto's thyroiditis are also associated with goiter. In Graves' disease, the goiter results mainly from theTSH-R-mediated effects ofTSI. The goitrous form of Hashimoto's thyroiditis occurs because of acquired defects in hormone synthesis, leading to elevated levels of TSH and its consequent growth effects. Lymphocytic infiltration and immune system-induced growth factors also contribute to thyroid enlargement in Hashimoto's thyroiditis. Nodular disease is characterized by the disordered growth of thyroid follicles, often combined with the gradual development of fibrosis. The management of goiter differs in patients depending on the etiology, and the detection of thyroid enlargement on physical examination should prompt further evaluation to identify its cause.

Nodular thyroid disease is common, occurring in about 3 to 7% of adults when assessed by physical examination. Using more sensitive techniques, such as ultrasound, it is present in>25% of adults. Thyroid nodules may be solitary or multiple, and they may be functional or nonfunctional.

DIFFUSE NONTOXIC (SIMPLE) GOITER

Etiology and Pathogenesis When diffuse enlargement of the thyroid occurs in the absence of nodules and hyperthyroidism, it is referred to as a *diffuse nontoxic goiter*. This is sometimes called *simple goiter*, because of the absence of nodules, or *colloid goiter*, because of the presence of uniform follicles that are filled with colloid. Worldwide, diffuse goiter is most commonly caused by iodine deficiency and is termed *endemic goiter* when it affects>5% of the population. In nonendemic regions, *sporadic goiter* occurs, and the cause is usually unknown. Thyroid enlargement in teenagers is sometimes referred to as *juvenile goiter*. In general, goiter is more common in women than men, probably because of the greater prevalence of underlying autoimmune disease and the increased iodine demands associated with pregnancy.

In *iodine-deficient areas*, thyroid enlargement reflects a compensatory effort to trap iodide and produce sufficient hormone under conditions in which hormone synthesis is relatively inefficient. Somewhat surprisingly,TSHlevels are usually normal or only slightly

increased, suggesting increased sensitivity to TSH or activation of other pathways that lead to thyroid growth. Iodide appears to have direct actions on thyroid vasculature and may indirectly affect growth through vasoactive substances such as endothelins and nitric oxide. Endemic goiter is also caused by exposure to environmental *goitrogens* such as cassava root, which contains a thiocyanate, vegetables of the Cruciferae family (e.g., brussels sprouts, cabbage, and cauliflower), and milk from regions where goitrogens are present in grass. Though relatively rare, inherited defects in thyroid hormone synthesis also lead to a diffuse nontoxic goiter. These involve abnormalities at each step in hormone synthesis including iodide transport (NIS),Tgsynthesis, organification and coupling (TPO), and the regeneration of iodide (dehalogenase).

Clinical Manifestations and Diagnosis If thyroid function is preserved, most goiters are asymptomatic. Spontaneous hemorrhage into a cyst or nodule may cause the sudden onset of localized pain and swelling. Examination of a diffuse goiter reveals a symmetrically enlarged, nontender, generally soft gland without palpable nodules. Goiter is defined, somewhat arbitrarily, as a lateral lobe with a volume greater than the thumb of the individual being examined. If the thyroid is markedly enlarged, it can cause tracheal or esophageal compression. These features are unusual, however, in the absence of nodular disease and fibrosis. *Substernal goiter* may obstruct the thoracic inlet. *Pemberton's sign* refers to symptoms of faintness with evidence of facial congestion and external jugular venous obstruction when the arms are raised above the head, a maneuver that draws the thyroid into the thoracic inlet. Respiratory flow measurements andCT orMRIshould be used to evaluate substernal goiter in patients with obstructive signs or symptoms.

Thyroid function tests should be performed in all patients with goiter to exclude thyrotoxicosis or hypothyroidism. It is not unusual, particularly in iodine deficiency, to find a low total T_4, with normal T_3 andTSH, reflecting enhanced T_4®T_3conversion. A low TSH, particularly in older patients, suggests the possibility of thyroid autonomy or undiagnosed Graves' disease, causing subclinical thyrotoxicosis.TPOantibodies may be useful to identify patients at increased risk of autoimmune thyroid disease. Low urinary iodine levels (<100 ug/L) support a diagnosis of iodine deficiency. Thyroid scanning is not generally necessary but will reveal increased uptake in iodine deficiency and most cases of dyshormonogenesis. Ultrasound is not generally indicated in the evaluation of diffuse goiter, unless a nodule is palpable on physical examination.

TREATMENT

Iodine or thyroid hormone replacement induces variable regression of goiter in iodine deficiency, depending on how long it has been present and the degree of fibrosis that has developed. For other causes of nontoxic diffuse goiter, levothyroxine can be used in an attempt to reduce goiter size. Because of the possibility of underlying thyroid autonomy, caution should be exercised when instituting suppressive thyroxine therapy, particularly if the baselineTSH is in the low-normal range. In younger patients, the dose can be started at 100 ug/d and adjusted to suppress the TSH into the low-normal but detectable range. Treatment of elderly patients should be initiated at 50 ug/d. The efficacy of suppressive treatment is greater in younger patients and in those with soft goiters. Significant regression is usually seen within 3 to 6 months of treatment; after this time it is unlikely to occur. In older patients, and in those with some degree of

nodular disease or fibrosis, fewer than one-third demonstrate significant shrinkage of the goiter. Surgery is rarely indicated for diffuse goiter. Exceptions include documented evidence of tracheal compression or obstruction of the thoracic inlet, which are more likely to be associated with substernal multinodular goiters (see below). Subtotal or near-total thyroidectomy for these or cosmetic reasons should be performed by an experienced surgeon to minimize complication rates, which occur in up to 10% of cases. Surgery should be followed by mild suppressive treatment with levothyroxine to prevent regrowth of the goiter. Radioiodine reduces goiter size by about 50% in the majority of patients. It is rarely associated with transient acute swelling of the thyroid, which is usually inconsequential unless there is severe tracheal narrowing. If not treated with levothyroxine, patients should be followed after radioiodine treatment for the possible development of hypothyroidism.

NONTOXIC MULTINODULAR GOITER

Etiology and Pathogenesis Depending on the geographic region and the sensitivity of the methods used to detect the disorder, multinodular goiter (MNG) is common, occurring in between 1 and 12% of the population. MNG is more common in women than men and increases in prevalence with age. It is more common in iodine-deficient regions but also occurs in regions of iodine sufficiency, reflecting multiple genetic, autoimmune, and environmental influences on the pathogenesis.

Individual patients exhibit wide variation in nodule size. Histology reveals a spectrum of morphologies ranging from hypercellular regions to cystic areas filled with colloid. Fibrosis is often extensive, and areas of hemorrhage or lymphocytic infiltration may be seen. Using molecular techniques, most nodules within aMNG are polyclonal in origin, suggesting a hyperplastic response to locally produced growth factors and cytokines.TSH, which is usually not elevated, may play a permissive or contributory role. Monoclonal lesions also occur within a MNG, reflecting mutations in genes that confer a selective growth advantage to the progenitor cell.

Clinical Manifestations Most patients with nontoxicMNG are asymptomic and, by definition, euthyroid. MNG typically develops over many years and is detected on routine physical examination or because an individual notices an enlargement in the neck. If the goiter is large enough, it can ultimately lead to compressive symptoms including difficulty swallowing, respiratory distress (tracheal compression), or plethora (venous congestion), but these symptoms are uncommon. Symptomatic MNGs are usually extraordinarily large and/or develop fibrotic areas that cause compression. Sudden pain in a MNG is often caused by hemorrhage into a nodule but should raise the possibility of invasive malignancy. Hoarseness, reflecting laryngeal nerve involvement, also suggests malignancy.

Diagnosis On examination, thyroid architecture is distorted and multiple nodules of varying size can be appreciated. Substernal goiter is suggested by Pemberton's sign. Because many nodules are deeply embedded in thyroid tissue or reside in posterior or substernal locations, it is not possible to palpate all nodules. ATSHlevel should be measured to exclude subclinical hyper- or hypothyroidism, but thyroid function is usually normal. Tracheal deviation is common, but compression must usually exceed 70% of the tracheal diameter before there is significant airway compromise. Pulmonary function

testing can be used to assess the functional effects of compression and to detect tracheomalacia, which characteristically causes inspiratory stridor.CT orMRI can be used to evaluate the anatomy of the goiter and the extent of substernal extension, which is often much greater than is apparent on physical examination. A barium swallow may reveal the extent of esophageal obstruction.MNG does not appear to predispose to thyroid carcinoma or to more aggressive carcinoma. For this reason, and because it is not possible to biopsy all nodular lesions, thyroid biopsies should only be performed if malignancy is suspected because of a dominant or enlarging nodule.

TREATMENT

Most nontoxicMNGs can be managed conservatively. T_4suppression is rarely effective for reducing goiter size and introduces the risk of thyrotoxicosis, if there is underlying autonomy or if it develops during treatment. If levothyroxine is used, it should be started at low doses (50 ug) and advanced gradually while monitoring theTSHlevel to avoid excessive suppression. Contrast agents and other iodine-containing substances should be avoided because of the risk of inducing the *Jod-Basedow effect*, characterized by enhanced thyroid hormone production by autonomous nodules. Radioiodine is being used with increasing frequency because it often decreases goiter size and may selectively ablate regions of autonomy. Dosage of^{131}I depends on the size of the goiter and radioiodine uptake but is usually about 3.7 MBq (0.1 mCi) per gram of tissue, corrected for uptake [typical dose, 370 to 1070 Mbq (10 to 29 mCi)]. Repeat treatment may be needed. It is possible to achieve a 40 to 50% reduction in goiter size in most patients. Earlier concerns about radiation-induced thyroid swelling and tracheal compression have diminished as recent studies have shown this complication to be rare. When acute compression occurs, glucocorticoid treatment or surgery may be needed. Radiation-induced hypothyroidism is less common than occurs after treatment for Graves' disease. However, posttreatment autoimmune thyrotoxicosis may occur in up to 5% of patients treated for nontoxic MNG. Surgery remains highly effective but is not without risk, particularly in older patients with underlying cardiopulmonary disease.

TOXIC MULTINODULAR GOITER

The pathogenesis of toxicMNGappears to be similar to that of nontoxic MNG, the major difference being the presence of functional autonomy in toxic MNG. The molecular basis for autonomy in toxic MNG remains unknown. As in nontoxic goiters, many nodules are polyclonal, while others are monoclonal and vary in their clonal origins. Genetic abnormalities known to confer functional autonomy, such as activatingTSH-R or G_{sa}mutations (see below), are not usually found in the autonomous regions of toxic MNG goiter.

In addition to features of goiter, the clinical presentation of toxicMNGincludes subclinical hyperthyroidism or mild thyrotoxicosis. The patient is usually elderly and may present with atrial fibrillation or palpitations, tachycardia, nervousness, tremor, or weight loss. Recent exposure to iodine, from contrast dyes or other sources, may precipitate or exacerbate thyrotoxicosis. TheTSHlevel is low. The T_4 level may be normal or minimally increased; T_3 is often elevated to a greater degree than T_4. Thyroid scan shows heterogeneous uptake with multiple regions of increased and decreased uptake; 24-h uptake of radioiodine may not be increased.

TREATMENT

The management of toxicMNG is challenging. Antithyroid drugs, often in combination with beta blockers, can normalize thyroid function and address clinical features of thyrotoxicosis. This treatment, however, often stimulates the growth of the goiter, and, unlike in Graves' disease, spontaneous remission does not occur. Radioiodine can be used to treat areas of autonomy, as well as to decrease the mass of the goiter. Usually, however, some degree of autonomy remains, presumably because multiple autonomous regions emerge as soon as others are treated. Nonetheless, a trial of radioiodine should be considered before subjecting patients, many of whom are elderly, to surgery. Surgery provides definitive treatment of underlying thyrotoxicosis as well as goiter. Patients should be rendered euthyroid using antithyroid drugs before operation.

HYPERFUNCTIONING SOLITARY NODULE

A solitary, autonomously functioning thyroid nodule is referred to as *toxic adenoma*. The pathogenesis of this disorder has been unraveled by demonstrating the functional effects of mutations that stimulate theTSH-Rsignaling pathway. Most patients with solitary hyperfunctioning nodules have acquired somatic, activating mutations in the TSH-R (Fig. 330-9). These mutations, located primarily in the receptor transmembrane domain, induce constitutive receptor coupling to G_{sa}, increasing cyclic AMP levels and leading to enhanced thyroid follicular cell proliferation and function. Less commonly, somatic mutations are identified in G_{sa}. These mutations, which are similar to those seen in McCune-Albright syndrome (Chap. 336) or in a subset of somatotrope adenomas (Chap. 328), impair GTP hydrolysis, also causing constitutive activation of the cyclic AMP signaling pathway. In most series, activating mutations in either the TSH-R or the G_{sa}subunit genes are identified in >90% of patients with solitary hyperfunctioning nodules.

Thyrotoxicosis is usually mild. The disorder is suggested by the presence of the thyroid nodule, which is generally large enough to be palpable, and by the absence of clinical features suggestive of Graves' disease or other causes of thyrotoxicosis. A thyroid scan provides a definitive diagnostic test, demonstrating focal uptake in the hyperfunctioning nodule and diminished uptake in the remainder of the gland, as activity of the normal thyroid is suppressed.

TREATMENT

Radioiodine ablation is usually the treatment of choice. Because normal thyroid function is suppressed,^{131}I is concentrated in the hyperfunctioning nodule with minimal uptake and damage to normal thyroid tissue. Relatively large radioiodine doses [e.g., 370 to 1110 MBq (10 to 29.9 mCi)^{131}I] have been shown to correct thyrotoxicosis in about 75% of patients within 3 months. Hypothyroidism occurs in <10% of patients over the next 5 years. Surgical resection is also effective and is usually limited to enucleation of the adenoma or lobectomy, thereby preserving thyroid function and minimizing risk of hypoparathyroidism or damage to the recurrent laryngeal nerves. Medical therapy using antithyroid drugs and beta blockers can normalize thyroid function but is not an optimal long-term treatment. Ethanol injection under ultrasound guidance has been used

successfully in some centers to ablate hyperfunctioning nodules. Repeated injections (often more than 5 sessions) are required but reduce nodule size. Normal thyroid function can be achieved in most patients using this technique.

BENIGN NEOPLASMS

The various types of benign thyroid nodules are listed in Table 330-9. These lesions are common (5 to 10% adults) and often multiple, particularly when assessed by sensitive techniques such as ultrasound. The risk of malignancy is very low for *macrofollicular adenomas* and *normofollicular adenomas*. *Microfollicular, trabecular, and Hurthle cell variants* raise greater concern, partly because the histology is more difficult to interpret. About one-third of palpable nodules are *thyroid cysts*. These may be recognized by their ultrasound appearance or based on aspiration of large amounts of pink or straw-colored fluid (colloid). Many are mixed cystic/solid lesions, in which case it is desirable to aspirate cellular components under ultrasound or harvest cells after cytospin of cyst fluid. Cysts frequently recur, even after repeated aspiration, and may require surgical excision if they are large or if the cytology is suspicious. Sclerosis has been used with variable success but is often painful and may be complicated by infiltration of the sclerosing agent.

The treatment approach for benign nodules is similar to that forMNG.TSHsuppression with levothyroxine decreases the size of about 30% of nodules and may prevent further growth. The TSH level should be suppressed into the low-normal range, assuming there are no contraindications; alternatively, nodule size can be monitored without suppression. If a nodule has not decreased in size after 6 to 12 months of suppressive therapy, treatment should be discontinued as little benefit is likely to accrue from long-term treatment.

THYROID CANCER

Thyroid carcinoma is the most common malignancy of the endocrine system. Malignant tumors derived from the follicular epithelium are classified according to histologic features. Differentiated tumors, such as papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC), are often curable, and the prognosis is good for patients identified with early-stage disease. In contrast, anaplastic thyroid cancer (ATC) is aggressive, responds poorly to treatment, and is associated with a bleak prognosis.

The incidence of thyroid cancer (~9/100,000 per year) increases with age, plateauing after about age 50 (Fig. 330-10). Age is also an important prognostic factor -- thyroid cancer at young age (<20) or in older persons (>65) is associated with a worse prognosis. Thyroid cancer is twice as common in women as men, but male sex is associated with a worse prognosis. Additional important risk factors include a history of childhood head or neck irradiation, large nodule size (³4 cm), evidence for local tumor fixation or invasion into lymph nodes, and the presence of metastases (Table 330-10).

Several unique features of thyroid cancer facilitate its management: (1) thyroid nodules are readily palpable, allowing early detection and biopsy byFNA; (2) iodine radioisotopes can be used to diagnose (^{123}I) and treat (^{131}I) differentiated thyroid cancer, reflecting the unique uptake of this anion by the thyroid gland; and (3) serum markers allow the

detection of residual or recurrent disease, including the use of Tg levels for PTC and FTC and calcitonin for medullary thyroid cancer (MTC).

CLASSIFICATION

Thyroid neoplasms can arise in each of the cell types that populate the gland, including thyroid follicular cells, calcitonin-producing C cells, lymphocytes, and stromal and vascular elements, as well as metastases from other sites (Table 330-9). The American Joint Committee on Cancer (AJCC) has designated a staging system using the TNM classification (Table 330-11). Several other classification and staging systems are also widely used, some of which place greater emphasis on histologic features or risk factors such as age or gender.

PATHOGENESIS AND GENETIC BASIS

Radiation Early studies of the pathogenesis of thyroid cancer focused on the role of external radiation, which predisposes to chromosomal breaks, presumably leading to genetic rearrangements and loss of tumor-suppressor genes. External radiation of the mediastinum, face, head, and neck region was administered in the past to treat an array of conditions including acne and enlargement of the thymus, tonsils, and adenoids. Radiation exposure increases the risk of benign and malignant thyroid nodules, is associated with multicentric cancers, and shifts the incidence of thyroid cancer to an earlier age group. Radiation from nuclear fallout also predisposes to thyroid cancer. Children seem more predisposed to the effects of radiation than adults. Of note, radiation derived from ^{131}I therapy appears to contribute little, if any, increased risk of thyroid cancer.

TSH and Growth Factors Thyroid growth is regulated primarily by TSH but also by a variety of growth factors and cytokines. Many differentiated thyroid cancers express TSH receptors and, therefore, remain responsive to TSH. This observation provides the rationale for T_4 suppression of TSH in patients with thyroid cancer. Residual expression of TSH receptors also allows TSH-stimulated uptake of ^{131}I therapy (see below).

Oncogenes and Tumor-Suppressor Genes Thyroid cancers are monoclonal in origin, consistent with the idea that they originate as a consequence of mutations that confer a growth advantage to a single cell. In addition to increased rates of proliferation, some thyroid cancers exhibit impaired apoptosis and features that enhance invasion, angiogenesis, and metastasis (Chap. 83). By analogy with the model of multistep carcinogenesis proposed for colon cancer (Chap. 81), thyroid neoplasms have been analyzed for a variety of genetic alterations, but without clear evidence of an ordered acquisition of somatic mutations as they progress from the benign to the malignant state. On the other hand, certain mutations are relatively specific for thyroid neoplasia, some of which correlate with histologic classification (Table 330-12). For example, activating mutations of the TSH-R and the G_{sa} subunit are associated with autonomously functioning nodules. Though these mutations induce thyroid cell growth, this type of nodule is almost always benign. A variety of rearrangements involving the *RET* gene on chromosome 10 bring this receptor tyrosine kinase under the control of other promoters, leading to receptor overexpression. *RET* rearrangements occur in 20 to 40% of PTCs in different series and were observed with increased frequency in tumors developing after

the Chernobyl radiation disaster. Rearrangements in PTC have also been observed for another tyrosine kinase gene, *TRK1*, which is located on chromosome 1. To date, the identification of PTC with *RET* or *TRK1* rearrangements has not proven useful for predicting prognosis or treatment responses. *RAS* mutations are found in about 20 to 30% of thyroid neoplasms, including adenomas as well as PTC andFTC, suggesting that these mutations do not strongly affect tumor phenotype. Loss of heterozygosity (LOH), consistent with deletions of tumor-suppressor genes, is particularly common in FTC, often involving chromosomes 3p or 11q. Mutations of the tumor suppressor, p53, appear to play an important role in the development of ATC. Because p53 plays a role in cell cycle surveillance, DNA repair, and apoptosis, its loss may contribute to the rapid acquisition of genetic instability as well as poor treatment responses (Chap. 82). The role of other tumor-suppressor genes in thyroid cancer is under investigation (Table 330-12).

MTC, when associated with multiple endocrine neoplasia (MEN) type 2, harbors an inherited mutation of the *RET* gene. Unlike the rearrangements of *RET* seen inPTC, the mutations in MEN-2 are point mutations that induce constitutive activity of the tyrosine kinase (Chap. 339). MTC is preceded by hyperplasia of the C cells, raising the likelihood that as-yet-unidentified "second hits" lead to cellular transformation. A subset of sporadic MTC contain somatic mutations that activate *RET*.

WELL-DIFFERENTIATED THYROID CANCER

Papillary PTC is the most common type of thyroid cancer, accounting for 70 to 90% of well-differentiated thyroid malignancies. Microscopic PTC is present in as many 25% of thyroid glands at autopsy, but most of these lesions are very small (several millimeters) and are not clinically significant. Characteristic cytologic features of PTC help make the diagnosis byFNA or after surgical resection; these include psammoma bodies, cleaved nuclei with an "orphan-Annie" appearance caused by large nucleoli, and the formation of papillary structures.

PTCtends to be multifocal and to invade locally within the thyroid gland as well as through the thyroid capsule and into adjacent structures in the neck. It has a propensity to spread via the lymphatic system but can metastasize as well, particularly to bone and lung. Because of the relatively slow growth of the tumor, a significant burden of pulmonary metastases may accumulate, sometimes with remarkably few symptoms. The prognostic implication of lymph node spread is debated. Lymph node involvement by thyroid cancer can be remarkably well tolerated but probably increases the risk of recurrence and mortality, particularly in older patients. The staging of PTC by the TNM system is outlined in Table 330-11. Most papillary cancers are identified in the early stages (>80% stages I or II) and have an excellent prognosis, with survival curves similar to expected survival (Fig. 330-11*A*). Mortality is markedly increased in stage IV disease (distant metastases), but this group comprises only about 1% of patients. The treatment of PTC is described below.

Follicular The incidence ofFTCvaries widely in different parts of the world; it is more common in iodine-deficient regions. FTC is difficult to diagnose byFNAbecause the distinction between benign and malignant follicular neoplasms rests largely on evidence of invasion into vessels, nerves, or adjacent structures. FTC tends to spread by

hematogenous routes leading bone, lung, and central nervous system metastases. Mortality rates associated with FTC are less favorable than forPTC, in part because a larger proportion of patients present with stage IV disease (Fig. 330-11*B*). Poor prognostic features include distant metastases, age >50 years, primary tumor size >4 cm, Hurthle cell histology, and the presence of marked vascular invasion.

TREATMENT

Surgery All well-differentiated thyroid cancers should be surgically excised. In addition to removing the primary lesion, surgery allows accurate histologic diagnosis and staging, and multicentric disease is commonly found in the contralateral lobe. Lymph node spread can also be assessed at the time of surgery, and involved nodes can be removed. Recommendations about the extent of surgery vary for stage I disease, as survival rates are similar for lobectomy and near-total thyroidectomy. Lobectomy is associated with a lower incidence of hypoparathyroidism and injury to the recurrent laryngeal nerves. However, it is not possible to monitorTglevels or to perform whole-body^{131}I scans in the presence of the residual lobe. Moreover, if final staging or subsequent follow-up indicates the need for radioiodine scanning or treatment, repeat surgery is necessary to remove the remaining thyroid tissue. The authors favor near-total thyroidectomy in almost all patients; complication rates are acceptably low if the surgeon is highly experienced in the procedure. This approach, in combination with postsurgical radioablation of the remnant thyroid tissue, facilitates the use of radioiodine scanning and Tg determinations to assess disease recurrence.

TSH Suppression Therapy As most tumors are stillTSH-responsive, levothyroxine suppression of TSH is a mainstay of thyroid cancer treatment. Though TSH suppression clearly provides therapeutic benefit, there are no prospective studies that identify the optimal level of TSH suppression. A reasonable goal is to suppress TSH to as low as possible without subjecting the patient to unnecessary side effects from excess thyroid hormone, such as atrial fibrillation, osteopenia, anxiety, and other manifestations of thyrotoxicosis. For patients at low risk of recurrence, TSH should be suppressed into the low but detectable range (0.1 to 0.5 IU/L). For patients at high risk of recurrence, or with known metastatic disease, complete TSH suppression is indicated, if there are no strong contraindications to mild thyrotoxicosis. In this instance, free T_4or free T_3levels must also be monitored to avoid excessive treatment.

Radioiodine Treatment Well-differentiated thyroid cancer still incorporates radioiodine, though less efficiently than normal thyroid follicular cells. Radioiodine uptake is determined primarily by expression of the NIS and is stimulated byTSH, requiring expression of theTSH-R. The retention time for radioactivity is influenced by the extent to which the tumor retains differentiated functions such as iodide trapping and organification. After near-total thyroidectomy, substantial thyroid tissue remains, particularly in the thyroid bed and surrounding the parathyroid glands. Consequently,^{131}I ablation is necessary to eliminate remaining normal thyroid tissue and may treat residual tumor cells.

Indications The use of therapeutic doses of radioiodine remains an area of controversy in thyroid cancer management. Postoperative thyroid ablation and radiodine treatment of known residualPTC orFTCreduce recurrence rates.^{131}I ablation of remaining normal

thyroid tissue also facilitates the detection of recurrent disease, using either whole-body iodine scanning or measurements ofTg. For tumors that take up iodine,^{131}I treatment can reduce or eliminate residual disease with relatively little associated toxicity. However, it is not clear that prophylactic radioiodine treatment reduces mortality for patients at relatively low risk. Most patients with stage 1 PTC with primary tumors <1.5 cm in size can usually be managed safely with thyroxine suppression, without radiation treatment, as the risk of recurrence and mortality is very low. For patients with larger papillary tumors, spread to the adjacent lymph nodes, FTC, or evidence of metastases, thyroid ablation and radioiodine treatment are generally indicated.

^{131}I thyroid ablation and treatment As noted above, the decision to use^{131}I for thyroid ablation should be coordinated with the surgical approach, as radioablation is much more effective when there is minimal remaining normal thyroid tissue. A typical strategy is to treat the patient for several weeks postoperatively with liothyronine (25 ug bid or tid), followed by thyroid hormone withdrawal. Ideally, theTSHlevel should increase to >50 IU/L over about 3 to 4 weeks. The level to which TSH rises is dictated largely by the amount of normal thyroid tissue remaining postoperatively. A scanning dose of^{131}I [usually 148 to 185 MBq (4 to 5 mCi)] will reveal the amount of residual tissue and provides guidance about the dose needed to accomplish ablation. A maximum outpatient dose of 1110 MBq (29.9 mCi)^{131}I can be administered in the United States, though ablation is often more complete using greater doses [1850 to 2775 MBq (50 to 75 mCi)]. In patients with known residual cancer, the larger doses ensure thyroid ablation and may destroy remaining tumor cells. A whole-body scan following the high-dose radioiodine treatment is useful to identify possible metastatic disease.

Follow-up whole-body thyroid scanning and thyroglobulin determinations An initial whole-body scan should be performed about 6 months after surgery and thyroid ablation. The strategy for follow-up management of thyroid cancer has been altered by the availability of recombinant humanTSH(rhTSH) to stimulate^{131}I uptake and by the improved sensitivity ofTgassays to detect residual or recurrent disease. A scheme for using either rhTSH or thyroid hormone withdrawal for thyroid scanning is summarized inFig. 330-12. After thyroid ablation, rhTSH can be used to stimulate^{131}I uptake without subjecting patients to thyroid hormone withdrawal and its associated symptoms of hypothyroidism and the risk of prolonged TSH-stimulated tumor growth. This approach is recommended for patients predicted to be at low risk of disease recurrence, since rhTSH is not currently approved for use in conjunction with therapeutic doses of^{131}I. Alternatively, in patients who are likely to require^{131}I treatment, the traditional approach of thyroid hormone withdrawal can be used to increase TSH. This involves switching patients from levothyroxine (T_4) to the more rapidly cleared hormone, liothyronine (T_3), thereby allowing TSH to increase more quickly. If residual disease is detected on the initial whole-body scan [148 to 185 MBq (4 to 5 mCi)], a larger treatment dose, usually between 2775 and 5550 MBq (75 and 150 mCi), can be administered depending on the degree of residual uptake and assessment of cancer risk. Because TSH stimulates Tg levels, Tg measurements should be obtained after administration of rhTSH or when TSH levels have risen after thyroid hormone withdrawal. If the initial whole-body scan is negative and Tg levels are low, a repeat scan should be performed 1 year later. If still negative, the patient can be managed with suppressive therapy and measurements of Tg every 6 to 12 months. If a second follow-up scan is negative, no further scanning may be necessary if the patient is at low risk and there is no clinical or laboratory

evidence of recurrence. Many authorities advocate radioiodine treatment for scan-negative, Tg-positive (Tg >5 to 10 ng/mL) patients, as many derive therapeutic benefit from a large dose of ^{131}I.

In addition to radioiodine, external beam radiotherapy is also used to treat specific metastatic lesions, particularly when they cause bone pain or threaten neurologic injury (e.g., vertebral metastases).

ANAPLASTIC AND OTHER FORMS OF THYROID CANCER

Anaplastic Thyroid Cancer As noted above,ATC is a poorly differentiated and aggressive cancer. The prognosis is poor, and most patients die within 6 months of diagnosis. Because of the undifferentiated state of these tumors, radioiodine uptake is usually negligible but can be used therapeutically if there is residual uptake. Chemotherapy has been attempted with multiple agents, including anthracyclines and paclitaxel, but is usually futile. External radiation therapy can be attempted and continued if tumors are responsive.

Thyroid Lymphoma Lymphoma in the thyroid gland often arises in the background of Hashimoto's thyroiditis. A rapidly expanding thyroid mass should suggest the possibility of this diagnosis. Diffuse large cell lymphoma is the most common type in the thyroid. Biopsies reveal sheets of lymphoid cells that can be difficult to distinguish from small cell lung cancer orATC. These tumors are often highly sensitive to external radiation. Surgical resection should be avoided as initial therapy because it may spread disease that is otherwise localized to the thyroid. If staging indicates disease outside of the thyroid, treatment should follow guidelines used for other forms of lymphoma (Chap. 112).

MEDULLARY THYROID CARCINOMA

MTCcan be sporadic or familial and accounts for about 5 to 10% of thyroid cancers. There are three familial forms of MTC:MEN-2A, MEN-2B, and familial MTC without other features of MEN (Chap. 339). In general, MTC is more aggressive in MEN-2B than in MEN-2A, and familial MTC is more aggressive than sporadic MTC. Elevated serum calcitonin provides a marker of residual or recurrent disease. It is reasonable to test all patients with MTC for *RET* mutations, as genetic counseling and testing of family members can be offered to those individuals who test positive for mutations.

The management ofMTC is primarily surgical. Unlike tumors derived from thyroid follicular cells, these tumors do not take up radioiodine. External radiation treatment and chemotherapy may provide palliation in patients with advanced disease (Chap. 339).

Approach to the Patient

Palpable thyroid nodules are found in about 5% of adults, though the prevalence varies considerably worldwide. Given this high prevalence rate, it is common for the practitioner to identify and evaluate thyroid nodules. The main goal of this evaluation is to identify, in a cost-effective manner, the small subgroup of individuals with malignant lesions.

As described above, nodules are more common in iodine-deficient areas, in women, and with aging. Most palpable nodules are >1 cm in diameter, but the ability to feel a nodule is influenced by its location within the gland (superficial versus deeply embedded), the anatomy of the patient's neck, and the experience of the examiner. More sensitive methods of detection, such as thyroid ultrasound and pathologic studies, reveal thyroid nodules in>20% of glands. These findings have led to much debate about how to detect nodules and which nodules to investigate further. Most authorities still rely on physical examination to detect thyroid nodules, reserving ultrasound for monitoring nodule size or as an aid in thyroid biopsy.

It is important to distinguish whether a patient presents with a solitary thyroid nodule or a prominent nodule in the context of aMNG, as the incidence of malignancy is greater in solitary nodules. An approach to the evaluation of a solitary nodule is outlined inFig. 330-13. Most patients with thyroid nodules have normal thyroid function tests. Nonetheless, thyroid function should be assessed by measuring aTSHlevel, which may be suppressed by one or more autonomously functioning nodules. If the TSH is suppressed, a radionuclide scan is indicated to determine if the identified nodule is "hot," as lesions with increased uptake are almost never malignant andFNA is unnecessary. Otherwise, FNA biopsy should be the first step in the evaluation of a thyroid nodule. FNA has good sensitivity and specificity when performed by physicians familiar with the procedure and when the results are interpreted by experienced cytopathologists. The technique is particularly accurate for detectingPTC. The distinction of benign and malignant follicular lesions is often not possible using cytology alone.

In several large studies,FNAbiopsies yield the following findings: 70% benign, 10% malignant or suspicious for malignancy, and 20% nondiagnostic or yielding insufficient material for diagnosis. Characteristic features of malignancy mandate surgery. A diagnosis of follicular neoplasm also warrants surgery, as benign and malignant lesions cannot be distinguished based on cytopathology or frozen section. The management of patients with benign lesions is more variable. Many authorities advocateTSHsuppression, whereas others monitor nodule size without suppression. With either approach, thyroid nodule size should be monitored, either by palpation or ultrasound. Repeat FNA is indicated if a nodule enlarges, and most authorities recommend a second biopsy within 2 to 5 years to confirm the benign status of the nodule.

Nondiagnostic biopsies occur for many reasons, including a fibrotic reaction with relatively few cells available for aspiration, a cystic lesion in which cellular components reside along the cyst margin, or a nodule that may be too small for accurate aspiration. For these reasons, ultrasound-guidedFNA is useful when the FNA is repeated. Ultrasound is also increasingly used for initial biopsies in an effort to enhance nodule localization and the accuracy of sampling.

The evaluation of a thyroid nodule is stressful for most patients. They are concerned about the possibility of thyroid cancer, whether verbalized or not. It is constructive, therefore, to review the diagnostic approach and to reassure patients when malignancy is not found. When a suspicious lesion or thyroid cancer is identified, an explanation of

the generally favorable prognosis and available treatment options should be provided.

331. DISORDERS OF THE ADRENAL CORTEX - *Gordon H. Williams*, *Robert G. Dluhy*

BIOCHEMISTRY AND PHYSIOLOGY

The adrenal cortex produces three major classes of steroids: (1) glucocorticoids, (2) mineralocorticoids, and (3) adrenal androgens. Consequently, normal adrenal function is important for modulating intermediary metabolism and immune responses through glucocorticoids; blood pressure, vascular volume, and electrolytes through mineralocorticoids; and secondary sexual characteristics (in females) through androgens. The adrenal axis plays an important role in the stress response by rapidly increasing cortisol levels. Adrenal disorders include hyperfunction (Cushing's syndrome) and hypofunction (adrenal insufficiency) as well as a variety of genetic abnormalities of steroidogenesis.

STEROID NOMENCLATURE

Steroids contain as their basic structure a cyclopentenoperhydrophenanthrane nucleus consisting of three 6-carbon hexane rings and a single 5-carbon pentane ring (Fig. 331-1). The carbon atoms are numbered in a sequence beginning with ring A. Adrenal steroids contain either 19 or 21 carbon atoms. The C_{19}steroids have methyl groups at C-18 and C-19. C_{19}steroids with a ketone group at C-17 are termed *17-ketosteroids*; C_{19}steroids have predominantly androgenic activity. The C_{21}steroids have a 2-carbon side chain (C-20 and C-21) attached at position 17 and methyl groups at C-18 and C-19; C_{21}steroids with a hydroxyl group at position 17 are termed *17-hydroxycorticosteroids*. The C_{21}steroids have either glucocorticoid or mineralcorticoid properties.

BIOSYNTHESIS OF ADRENAL STEROIDS

Cholesterol, derived from the diet and from endogenous synthesis, is the substrate for steroidogenesis. Uptake of cholesterol by the adrenal cortex is mediated by the low-density lipoprotein (LDL) receptor. With long-term stimulation of the adrenal cortex by adrenocorticotropic hormone (ACTH), the number ofLDLreceptors increases. The three major adrenal biosynthetic pathways lead to the production of glucocorticoids (cortisol), mineralocorticoids (aldosterone), and adrenal androgens (dehydroepiandrosterone). Separate zones of the adrenal cortex synthesize specific hormones (Fig. 331-2). This zonation is accompanied by the selective expression of the genes encoding the enzymes unique to the formation of each type of steroid: aldosterone synthase is normally expressed only in the outer (glomerulosa) cell layer, whereas 17-hydroxylase is expressed only in the (inner) faciculata-reticularis cell layers, which are the sites of cortisol and androgen biosynthesis, respectively.

STEROID TRANSPORT

Cortisol occurs in the plasma in three forms: free cortisol, protein-bound cortisol, and cortisol metabolites. *Free cortisol* is physiologically active hormone that is not protein-bound and, can act therefore, directly on tissue sites. Normally,<5% of circulating cortisol is free. Only the unbound cortisol and its metabolites are filterable at

the glomerulus. Increased quantities of free steroid are excreted in the urine in states characterized by hypersecretion of cortisol, because the unbound fraction of plasma cortisol rises. Plasma has two cortisol-binding systems. One is a high-affinity, low-capacitya_2-globulin termed *transcortin* or *cortisol-binding globulin* (CBG), and the other is a low-affinity, high-capacity protein, *albumin*. The binding affinity of CBG for cortisol is reduced in areas of inflammation, thus increasing the local concentration of free cortisol. When the concentration of cortisol exceeds 700 nmol/(25 ug/dL), part of the excess binds to albumin, and a greater proportion than usual circulates unbound. The CBG level is increased in high-estrogen states (e.g., pregnancy, oral contraceptive administration). The rise in CBG is accompanied by a parallel rise in *protein-bound cortisol*, with the result that the plasma cortisol concentration is elevated. However, the free cortisol level probably remains normal, and manifestations of glucocorticoid excess are absent. Most synthetic glucocorticoid analogues bind less efficiently to CBG (~70% binding). This may explain the propensity of some synthetic analogues to produce cushingoid effects at low doses. *Cortisol metabolites* are biologically inactive and bind only weakly to circulating plasma proteins.

Aldosterone is bound to proteins to a smaller extent than cortisol, and an ultrafiltrate of plasma contains as much as 50% of the circulating concentration of aldosterone.

STEROID METABOLISM AND EXCRETION

Glucocorticoids The daily secretion of cortisol ranges between 40 and 80 umol (15 and 30 mg, 8-10 mg/m_2), with a pronounced circadian cycle. The plasma concentration of cortisol is determined by the rate of secretion, the rate of inactivation, and the rate of excretion of free cortisol. The liver is the major organ responsible for steroid inactivation. A major enzyme regulating cortisol metabolism is 11b-hydroxysteroid dehydrogenase (11b-HSD). There are two isoforms: 11b-HSD I is primarily expressed in the liver and acts as a reductase, converting the inactive cortisone to the active glucocorticoid, cortisol; the 11b-HSD II isoform is expressed in a number of tissues and converts cortisol to the inactive metabolite cortisone. The oxidative reaction of 11b-HSD I is increased in hyperthyroidism.

Mineralocorticoids In normal individuals with a normal salt intake, the average daily secretion of aldosterone ranges between 0.1 and 0.7 umol (50 and 250 ug). During a single passage through the liver, >75% of circulating aldosterone is normally inactivated by ring A reduction and conjugation with glucuronic acid because it is only weakly bound to proteins. However, under certain conditions, such as congestive failure, this rate of inactivation is reduced.

Adrenal Androgens The major androgen secreted by the adrenal is dehydroepiandrosterone (DHEA) and its sulfuric acid ester (DHEAS). From 15 to 30 mg of these compounds is secreted daily. Smaller amounts of androstenedione, 11b-hydroxyandrostenedione, and testosterone are secreted.DHEA is the major precursor of the urinary 17-ketosteroids. Two-thirds of the urine 17-ketosteroids in the male are derived from adrenal metabolites, and the remaining one-third comes from testicular androgens. In the female, almost all urine 17-ketosteroids are derived from the adrenal.

Steroids diffuse passively through the cell membrane and bind to intracellular receptors (Chap. 327). Glucocorticoids and mineralocorticoids bind with nearly equal affinity to the mineralocorticoid receptor (MR). However, only glucocorticoids bind to the glucocorticoid receptor (GR). After the steroid binds to the receptor, the steroid-receptor complex is transported to the nucleus, where it binds to specific sites on steroid-regulated genes, altering levels of transcription. Some actions of glucocorticoids (e.g., anti-inflammatory effects) are mediated by GR-mediated inhibition of other transcription factors, such as activating protein-1 (AP-1) or nuclear factor kappa-B (NFKB), which normally stimulate the activity of various cytokine genes. Because cortisol binds to the MR with the same affinity as aldosterone, mineralocorticoid specificity is achieved by local metabolism of cortisol to the inactive compound cortisone by 11b-HSDII. The glucocorticoid effects of other steroids, such as high-dose progesterone, correlate with their relative binding affinities for the GR. Inherited defects in the GR cause glucocorticoid resistance states. Individuals with GR defects have high levels of cortisol but do not have manifestations of hypercortisolism.

In addition to the classic genomic effects, which are mediated by steroids binding to cytosolic receptors, evidence is accumulating that mineralocorticoids also have acute, nongenomic effects, presumably by activating a cell-surface receptor yet to be identified. This effect uses a G-protein signaling pathway; among the actions is modification of the sodium-hydrogen exchanger. This effect has been demonstrated in both epithelial and nonepithelial cells, e.g., myocytes and leukocytes.

ACTHPHYSIOLOGY

ACTH and a number of other peptides (lipotropins, endorphins, and melanocyte-stimulating hormones) are processed from a larger precursor molecule of 31,000 mol wt -- pro-opiomelanocortin (POMC) (Chap. 328). POMC is made in a variety of tissues, including brain, anterior and posterior pituitary, and lymphocytes. The constellation of POMC-derived peptides secreted depends on the tissue. ACTH, a 39-amino acid peptide, is synthesized and stored in basophilic cells of the anterior pituitary. The *N*-terminal 18-amino acid fragment of ACTH has full biologic potency, and shorter *N*-terminal fragments have partial biologic activity. Release of ACTH and related peptides from the anterior pituitary gland is stimulated by corticotropin-releasing hormone (CRH), a 41-amino acid peptide produced in the median eminence of the hypothalamus (Fig. 331-3). Urocortin, a neuropeptide related to CRH, also binds to CRH receptors. Urocortin mimics many of the central effects of CRH (e.g., appetite suppression, anxiety), but its role in ACTH regulation is unclear. Some related peptides such as b-lipotropin (b-LPT) are released in equimolar concentrations with ACTH, suggesting that they are cleaved enzymatically from the parent POMC before or during the secretory process. However, b-endorphin levels may or may not correlate with circulating levels of ACTH, depending on the nature of the stimulus. The functions and regulation of secretion of the related peptides derived from POMC are poorly understood.

The major factors controllingACTHrelease includeCRH, the free cortisol concentration in plasma, stress, and the sleep-wake cycle (Fig. 331-3). The plasma level of ACTH varies during the day as a result of its pulsatile secretion, and it follows a circadian pattern with a peak just prior to waking and a nadir before sleeping. If a new sleep-wake cycle is

adopted, the pattern changes over several days to conform to it. ACTH and cortisol levels also increase in response to eating. Stress (e.g., pyrogens, surgery, hypoglycemia, exercise, and severe emotional trauma) causes the release of CRH and arginine vasopressin (AVP) and activation of the sympathetic nervous system. These changes in turn enhance ACTH release, acting individually or in concert. For example, AVP release acts synergistically with CRH to amplify ACTH secretion; CRH also stimulates the locus coeruleus/sympathetic system. Stress-related secretion of ACTH abolishes the circadian periodicity of ACTH levels but is, in turn, suppressed by prior high-dose glucocorticoid administration. The normal pulsatile, circadian pattern of ACTH release is regulated by CRH; this mechanism is the so-called open feedback loop. CRH secretion, in turn, is influenced by hypothalamic neurotransmitters. For example, serotoninergic and cholinergic systems stimulate the secretion of CRH and ACTH; there is contradictory evidence regarding the inhibitory effects of a-adrenergic agonists andg-aminobutyric acid (GABA) on CRH release. In addition, there may be direct pituitary effects of these neurotransmitters. There is also evidence for peptidergic regulation of ACTH release. For example,b-endorphin and enkephalin inhibit the secretion of ACTH, whereas vasopressin and angiotensin II augment it. The immune system also influences the hypothalamic-pituitary-adrenal axis (Fig. 331-4). For example, inflammatory cytokines [tumor necrosis factor (TNF)-a, interleukin (IL)-1a, IL-1b, and IL-6] produced by monocytes increase ACTH release by stimulating secretion of CRH and/or AVP. Finally, ACTH release is regulated by the level of free cortisol in plasma. Cortisol decreases the responsiveness of pituitary corticotropic cells to CRH; the response of thePOMCmRNA to CRH is also inhibited by glucocorticoids. In addition, glucocorticoids inhibit the locus coeruleus/sympathetic system and CRH release. The latter servomechanism establishes the primacy of cortisol in the control of ACTH secretion. The inhibition of ACTH occurs in two phases: (1) an early fast feedback, mediated via the MR, which lasts <10 min and depends on both the rate of increase of glucocorticoid levels and the specific glucocorticoid administered; and (2) a time-dependent, delayed feedback, likely mediated by the GR, which is probably due to inhibition of synthesis of the precursor protein. The suppression of ACTH secretion that results in adrenal atrophy following *prolonged* glucocorticoid therapy is caused primarily by suppression of hypothalamic CRH release, as exogenous CRH administration in this circumstance produces a rise in plasma ACTH. Cortisol also exerts feedback effects on higher brain centers (hippocampus, reticular system, and septum) and perhaps on the adrenal cortex (Fig. 331-4).

The biologic half-life ofACTH in the circulation is <10 min. The action of ACTH is also rapid; within minutes of its release, the concentration of steroids in the adrenal venous blood increases. ACTH stimulates steroidogenesis via activation of the membrane-bound adenyl cyclase. Adenosine-3¢,5¢-monophosphate (cyclic AMP), in turn, activates protein kinase enzymes, thereby resulting in the phosphorylation of proteins that activate steroid biosynthesis.

RENIN-ANGIOTENSIN PHYSIOLOGY (See also Chap. 246)

Renin is a proteolytic enzyme that is produced and stored in the granules of the juxtaglomerular cells surrounding the afferent arterioles of glomeruli in the kidney. Renin exists in both active and inactive forms. Whether the inactive form is a precursor ("prorenin") or is a product formed after release is uncertain. Renin acts on the basic

substrate angiotensinogen (a circulating α_2-globulin made in the liver) to form the decapeptide angiotensin I (Fig. 331-5). Angiotensin I is then enzymatically transformed by angiotensin-converting enzyme (ACE), which is present in many tissues (particularly the pulmonary vascular endothelium), to the octapeptide angiotensin II by the removal of the two C-terminal amino acids. Angiotensin II is a potent pressor agent and exerts its action by a direct effect on arteriolar smooth muscle. In addition, angiotensin II stimulates production of aldosterone by the zona glomerulosa of the adrenal cortex; the heptapeptide angiotensin III may also stimulate aldosterone production. The two major classes of angiotensin receptors are termed *AT1* and *AT2*; AT1 may exist as two subtypesa and b. Most of the effects of angiotensins II and III are mediated by the AT1 receptor. Angiotensinases rapidly destroy angiotensin II (half-life, approximately 1 min), while the half-life of renin is more prolonged (10 to 20 min). In addition to circulating renin-angiotensin, many tissues have a local renin-angiotensin system and the ability to produce angiotensin II. These tissues include the uterus, placenta, vascular tissue, heart, brain, and, particularly, the adrenal cortex and kidney. Although the role of locally generated angiotensin II is not established, it may be involved in the growth and modulation of function of the adrenal cortex and vascular smooth muscle.

The amount of renin released reflects the combined effects of four interdependent factors. The *juxtaglomerular cells*, which are specialized myoepithelial cells that cuff the afferent arterioles, act as miniature pressure transducers, sensing renal perfusion pressure and corresponding changes in afferent arteriolar perfusion pressures. For example, under conditions of a reduction in circulating blood volume, there is a corresponding reduction in renal perfusion pressure and, therefore, in afferent arteriolar pressure (Fig. 331-5). This change is perceived by the juxtaglomerular cells as a decreased stretch exerted on the afferent arteriolar walls. The juxtaglomerular cells then release more renin into the renal circulation. This results in the formation of angiotensin I, which is converted in the kidney and peripherally to angiotensin II byACE. Angiotensin II influences sodium homeostasis via two major mechanisms: it changes renal blood flow so as to maintain a constant glomerular filtration rate, thereby changing the filtration fraction of sodium, and it stimulates the adrenal cortex to release aldosterone. Increasing plasma levels of aldosterone enhance renal sodium retention and thus result in expansion of the extracellular fluid volume, which, in turn, dampens the stimulus for renin release. In this context, the renin-angiotensin-aldosterone system regulates volume by modifying renal hemodynamics and tubular sodium transport.

A second control mechanism for renin release is centered in the *macula densa* cells, a group of distal convoluted tubular epithelial cells directly apposed to the juxtaglomerular cells. They may function as chemoreceptors, monitoring the sodium (or chloride) load presented to the distal tubule, and such information may be conveyed to the juxtaglomerular cells, where appropriate modifications in renin release take place. Under conditions of increased delivery of filtered sodium to the macula densa, increasing release of renin decreases the glomerular filtration rate, thereby reducing the filtered load of sodium.

The *sympathetic nervous system* regulates the release of renin in response to assumption of the upright posture. The mechanism is either a direct effect on the juxtaglomerular cell to increase adenyl cyclase activity or an indirect effect on either the juxtaglomerular or the macula densa cells via vasoconstriction of the afferent arteriole.

Finally, circulating factors influence renin release. Increased dietary intake of *potassium* decreases, and decreased potassium intake increases, renin release. The significance of these effects is unclear. *Angiotensin II* exerts negative feedback control on renin release that is independent of alterations in renal blood flow, blood pressure, or aldosterone secretion. *Atrial natriuretic peptides* also inhibit renin release. Thus, the control of renin release involves both *intrarenal* (pressor receptor and macula densa) and *extrarenal* (sympathetic nervous system, potassium, angiotensin, etc.) mechanisms. Steady-state renin levels reflect all these factors, with the intrarenal mechanism predominating.

GLUCOCORTICOID PHYSIOLOGY

The division of adrenal steroids into glucocorticoids and mineralocorticoids is arbitrary in that most glucocorticoids have some mineralocorticoid-like properties. The descriptive term *glucocorticoid* is used for adrenal steroids whose predominant action is on intermediary metabolism. Their overall actions are directed at enhancing the production of the high-energy fuel, glucose, and reducing all other metabolic activity not directly involved in that process. Sustained activation, however, results in a pathophysiologic state, e.g., Cushing's syndrome. The principal glucocorticoid is cortisol (hydrocortisone). The effect of glucocorticoids on intermediary metabolism is mediated by theGR. Physiologic effects of glucocorticoids include the regulation of protein, carbohydrate, lipid, and nucleic acid metabolism. Glucocorticoids raise the blood glucose level by acting as an insulin antagonist and by suppressing the secretion of insulin, thereby inhibiting peripheral glucose uptake, which promotes hepatic glucose synthesis (gluconeogenesis) and increases hepatic glycogen content. The actions on protein metabolism are mainly catabolic in effect, resulting in an increase in protein breakdown and nitrogen excretion. In large part, these actions reflect a mobilization of glycogenic amino acid precursors from peripheral supporting structures, such as bone, skin, muscle, and connective tissue, due to protein breakdown and inhibition of protein synthesis and amino acid uptake. Hyperaminoacidemia also facilitates gluconeogenesis by stimulating glucagon secretion. Glucocorticoids act directly on the liver to stimulate the synthesis of certain enzymes, such as tyrosine aminotransferase and tryptophan pyrrolase. Glucocorticoids regulate fatty acid mobilization by enhancing the activation of cellular lipase by lipid-mobilizing hormones (e.g., catecholamines and pituitary peptides).

The actions of cortisol on protein and adipose tissue vary in different parts of the body. For example, pharmacologic doses of cortisol can deplete the protein matrix of the vertebral column (trabecular bone), whereas long bones (which are primarily compact bone) are affected only minimally; similarly, peripheral adipose tissue mass decreases, whereas abdominal and interscapular fat expand.

Glucocorticoids have anti-inflammatory properties, which are probably related to effects on the microvasculature and to suppression of inflammatory cytokines. In this sense, glucocorticoids modulate the immune response via the so-called immune-adrenal axis (Fig. 331-4). This "loop" is one mechanism by which a stress, such as sepsis, increases adrenal hormone secretion, and the elevated cortisol level in turn suppresses the immune response. For example, cortisol maintains vascular responsiveness to

circulating vasoconstrictors and opposes the increase in capillary permeability during acute inflammation. Glucocorticoids cause a leukocytosis due to release from the bone marrow of mature cells as well as to inhibition of their egress through the capillary wall. Glucocorticoids produce a depletion of circulating eosinophils and of lymphoid tissue, specifically T cells, by causing a redistribution from the circulation into other compartments. Thus, cortisol impairs cell-mediated immunity. Glucocorticoids also inhibit the production and action of the mediators of inflammation, such as the lymphokines and prostaglandins. These actions occur via theGR and are blocked by inhibitors of RNA and protein synthesis. Glucocorticoids inhibit the production and action of interferon by T lymphocytes and the production ofIL-1 and IL-6 by macrophages. The antipyretic action of glucocorticoids may be explained by the effect on IL-1, which appears to be an endogenous pyrogen (Chap. 17). Glucocorticoids also inhibit the production of T cell growth factor (IL-2) by T lymphocytes. Glucocorticoids reverse macrophage activation and antagonize the action of migration-inhibiting factor (MIF), leading to reduced adherence of macrophages to vascular endothelium. Glucocorticoids inhibit prostaglandin and leukotriene production by inhibiting the activity of phospholipase A_2, thus blocking release of arachidonic acid from phospholipids. Finally, glucocorticoids inhibit the production and inflammatory effects of bradykinin, platelet-activating factor, and serotonin. It is probably only at pharmacologic dosages that antibody production is reduced and lysosomal membranes are stabilized, the latter effect suppressing the release of acid hydrolases.

Cortisol levels respond within minutes to stress, whether physical (trauma, surgery, exercise), psychological (anxiety, depression), or physiologic (hypoglycemia, fever). The reasons why elevated glucocorticoid levels protect the organism under stress are not understood, but in conditions of glucocorticoid deficiency, such stresses may cause hypotension, shock, and death. Consequently, in individuals with adrenal insufficiency, glucocorticoid administration should be increased during stress.

Cortisol has major effects on body water. It helps regulate the extracellular fluid volume by retarding the migration of water into cells and by promoting renal water excretion, the latter effect mediated by suppression of vasopressin secretion, by an increase in the rate of glomerular filtration, and by a direct action on the renal tubule. The consequence is to prevent water intoxication by increasing solute-free water clearance. Glucocorticoids also have weak mineralocorticoid-like properties, and high doses promote renal tubular sodium reabsorption and increased urine potassium excretion. Glucocorticoids also can influence behavior; emotional disorders may occur with either an excess or a deficit of cortisol. Last, cortisol suppresses the secretion of pituitaryPOMC and its derivative peptides (ACTH,b-endorphin, andb-LPT) and the secretion of hypothalamicCRH and vasopressin.

MINERALOCORTICOID PHYSIOLOGY

Mineralocorticoids are major regulators of extracellular fluid volume and the major determinant of potassium metabolism. These effects are mediated by the binding of aldosterone to theMR in target tissues, primarily the kidney. Volume is regulated through a direct effect on the collecting duct, where aldosterone causes an increase in sodium retention and an increase in potassium excretion. The reabsorption of sodium ions causes a fall in the transmembrane potential, thus enhancing the flow of positive

ions, such as potassium, out of the cell into the lumen. The reabsorbed sodium ions are transported out of the tubular epithelium into the renal interstitial fluid and from there into the renal capillary circulation. Water passively follows the transported sodium.

Because the concentration of hydrogen ion is greater in the lumen than in the cell, hydrogen ion is also actively secreted. Mineralocorticoids also act on the epithelium of the salivary ducts, sweat glands, and gastrointestinal tract to cause reabsorption of sodium in exchange for potassium.

When normal individuals are given aldosterone, an initial period of sodium retention is followed by natriuresis, and sodium balance is reestablished after 3 to 5 days. As a result, edema does not develop. This process is referred to as the *escape phenomenon*, signifying an "escape" by the renal tubules from the sodium-retaining action of aldosterone. While renal hemodynamic factors may play a role in the escape, the level of atrial natriuretic peptide also increases. However, it is important to realize that there is no escape from the potassium-losing effects of mineralocorticoids.

There are additional nonclassic effects of mineralocorticoids, primarily on nonepithelial cells. These effects are likely genomic and therefore mediated through activation of the cytosolic MR, but they do not include a modification of sodium-potassium homeostasis. They are probably mediated by mineralocorticoids modifying the expression of several collagen genes and/or genes controlling tissue growth factors, e.g., transforming growth factor b(TGF-b) and plasminogen activator inhibitor (PAI-1). The resultant effects lead to microangiopathy, necrosis (acutely), and fibrosis in a variety of tissues, e.g., heart, kidney, and vasculature. Increased levels of aldosterone are not necessary to produce this damage; rather, an imbalance between the level of aldosterone and the volume and/or sodium balance state appears to be the critical factor.

Three primary mechanisms control aldosterone release -- the renin-angiotensin system, potassium, and ACTH(Table 331-1). The renin-angiotensin system controls extracellular fluid volume via regulation of aldosterone secretion (Fig. 331-5). In effect, the renin-angiotensin system maintains the circulating blood volume constant by causing aldosterone-induced sodium retention during volume deficiency and by decreasing aldosterone-dependent sodium retention when volume is ample.

Potassium ion directly stimulates aldosterone secretion, independent of the circulating renin-angiotensin system, which it suppresses (Fig. 331-5). In addition to potassium's direct effect, it also modifies aldosterone secretion indirectly by activating the local renin-angiotensin system in the zona glomerulosa. This effect can be blocked by the administration ofACEinhibitors that reduce the local production of angiotensin II and thereby reduce the acute aldosterone response to potassium. An increase in serum potassium of as little as 0.1 mmol/L increases plasma aldosterone levels under certain circumstances. Oral potassium loading therefore increases aldosterone secretion, excretion, and plasma levels.

Physiologic amounts ofACTHstimulate aldosterone secretion acutely, but this action is not sustained unless ACTH is administered in a pulsatile fashion. Most studies relegate ACTH to a minor role in the control of aldosterone. For example, subjects receiving high-dose glucocorticoid therapy, and with presumed complete suppression of ACTH,

have normal aldosterone secretion in response to sodium restriction.

Prior dietary intake of both potassium and sodium can alter the magnitude of the aldosterone response to acute stimulation. This effect results from a change in the expression and activity of aldosterone synthase. Increasing potassium intake or decreasing sodium intake sensitizes the response of the glomerulosa cells to acute stimulation byACTH, angiotensin II, and/or potassium. Thus, regulation of aldosterone secretion occurs both early and late in its synthetic pathway.

Neurotransmitters (dopamine and serotonin) and some peptides, such as atrial natriuretic peptide,g-melanocyte-stimulating hormone (g-MSH), and b-endorphin, also participate in the regulation of aldosterone secretion (Table 331-1). Thus, the control of aldosterone secretion involves both stimulatory and inhibitory factors.

ANDROGEN PHYSIOLOGY

Androgens regulate male secondary sexual characteristics and can cause virilizing symptoms in women (Chap. 53). Adrenal androgens have a minimal effect in males whose sexual characteristics are predominately determined by gonadal steroids (testosterone). In females, however, several androgen-like effects, e.g., sexual hair, are largely mediated by adrenal androgens. The principal adrenal androgens areDHEA, androstenedione, and 11-hydroxyandrostenedione. DHEA and androstenedione are weak androgens and exert their effects via conversion to the potent androgen testosterone in extraglandular tissues. DHEA also has poorly understood effects on the immune and cardiovascular systems. Adrenal androgen formation is regulated byACTH, not by gonadotropins. It follows that adrenal androgens are suppressed by exogenous glucocorticoid administration.

LABORATORY EVALUATION OF ADRENOCORTICAL FUNCTION

A basic assumption is that measurements of the plasma or urinary level of a given steroid reflects the rate of adrenal *secretion* of that steroid. However, urine *excretion* values may not truly reflect the secretion rate because of improper collection or altered metabolism. Plasma levels reflect the level of secretion only at the time of measurement. The plasma level (*PL*) depends on two factors: the secretion rate (*SR*) of the hormone and the rate at which it is metabolized, i.e., its metabolic clearance rate (*MCR*). These three factors can be related as follows:

BLOOD LEVELS

Peptides The plasma levels of ACTHand angiotensin II can be measured by immunoassay techniques. Basal ACTH secretion shows a circadian rhythm, with lower levels in the early evening than in the morning. However, ACTH is secreted in a pulsatile manner, leading to rapid fluctuations superimposed on this circadian rhythm. Angiotensin II levels also vary diurnally and are influenced by dietary sodium and potassium intakes and posture. Both upright posture and sodium restriction elevate angiotensin II levels.

Most clinical determinations of the renin-angiotensin system, however, involve measurements of peripheral *plasma renin activity* (PRA) in which the renin activity is gauged by the generation of angiotensin I during a standardized incubation period. This method depends on the presence of sufficient angiotensinogen in the plasma as substrate. The generated angiotensin I is measured by radioimmunoassay. The PRA depends on the dietary sodium intake and on whether the patient is ambulatory. In normal humans, the PRA shows a diurnal rhythm characterized by peak values in the morning and decreases in activity in the afternoon. An alternative approach is to measure plasma active renin, which is easier and not dependent on endogenous substrate concentration. PRA and active renin correlate very well on low-sodium diets (r = 0.85 to 0.9) but less well on high-sodium diets.

Steroids Cortisol and aldosterone are both secreted episodically, and levels generally vary during the day, with peak values in the morning and low levels in the evening. In addition, the plasma level of aldosterone, but not of cortisol, is increased by dietary potassium loading, by sodium restriction, or by assumption of the upright posture. Measurement of the sulfate conjugate ofDHEA may be a useful index of adrenal androgen secretion, as little DHEA sulfate is formed in the gonads and because the half-life of DHEA sulfate is 7 to 9 h. However, DHEA sulfate levels reflect both DHEA production and sulfatase activity.

URINE LEVELS

For the assessment of glucocorticoid secretion, the urine *17-hydroxycorticosteroid* assay has been replaced by measurement of urinary free cortisol. Elevated levels of urinary free cortisol correlate with states of hypercortisolism, reflecting changes in the levels of unbound, physiologically active circulating cortisol. Normally, the rate of excretion is higher in the daytime (7 A.M. to 7 P.M.) than at night (7 P.M. to 7 A.M.).

Urinary *17-ketosteroids* originate in either the adrenal gland or the gonad. In normal women, 90% of urinary 17-ketosteroids is derived from the adrenal, and in men 60 to 70% is of adrenal origin. Urine 17-ketosteroid values are highest in young adults and decline with age.

A carefully timed urine collection is a prerequisite for all excretory determinations. Urinary creatinine should be measured simultaneously to determine the accuracy and adequacy of the collection procedure.

STIMULATION TESTS

Stimulation tests are useful in the diagnosis of hormone deficiency states.

Tests of Glucocorticoid Reserve Within minutes after administration ofACTH, cortisol levels increase. This responsiveness can be used as an index of the functional reserve of the adrenal gland for production of cortisol. Under maximal ACTH stimulation, cortisol secretion increases tenfold, to 800 umol/d (300 mg/d), but maximal stimulation can be achieved only with prolonged ACTH infusions.

A screening test (the so-called rapidACTHstimulation test) involves the administration of 25 units (0.25 mg) of cosyntropin intravenously or intramuscularly and measurement of plasma cortisol levels before and 30 and 60 min after administration; the test can be performed at any time of the day. The most clear-cut criterion for a normal response is a stimulated cortisol level of >500 nmol/L (>18 ug/dL), and the minimal stimulated normal increment of cortisol is >200 nmol/L (>7 ug/dL) above baseline. Severely ill patients with elevated basal cortisol levels may show no further increases following acute ACTH administration.

Tests of Mineralocorticoid Reserve and Stimulation of the Renin-Angiotensin System Stimulation tests use protocols designed to create a programmed volume depletion, such as sodium restriction, diuretic administration, or upright posture. A simple, potent test consists of severe sodium restriction and upright posture. After 3 to 5 days of a 10-mmol/d sodium intake, rates of aldosterone secretion or excretion should increase two- to threefold over the control values. Supine morning plasma aldosterone levels are usually increased three- to sixfold, and they increase a further two- to fourfold in response to 2 to 3 h of upright posture.

When the dietary sodium intake is normal, stimulation testing requires the administration of a potent diuretic, such as 40 to 80 mg furosemide, followed by 2 to 3 h of upright posture. The normal response is a two- to fourfold rise in plasma aldosterone levels.

SUPPRESSION TESTS

Suppression tests to document hypersecretion of adrenal hormones involve measurement of the target hormone response after standardized suppression of its tropic hormone.

Tests of Pituitary-Adrenal Suppressibility TheACTHrelease mechanism is sensitive to the circulating glucocorticoid level. When blood levels of glucocorticoid are increased in normal individuals, less ACTH is released from the anterior pituitary and less steroid is produced by the adrenal gland. The integrity of this feedback mechanism can be tested clinically by giving a glucocorticoid and judging the suppression of ACTH secretion by analysis of urine steroid levels and/or plasma cortisol and ACTH levels. A potent glucocorticoid such as dexamethasone is used, so that the agent can be given in an amount small enough not to contribute significantly to the pool of steroids to be analyzed.

The best *screening* procedure is the overnight dexamethasone suppression test. This involves the measurement of plasma cortisol levels at 8 A.M. following the oral administration of 1 mg dexamethasone the previous midnight. The 8 A.M. value for plasma cortisol in normal individuals should be<140 nmol/L (5 ug/dL).

The definitive test of adrenal suppressibility consists in administering 0.5 mg dexamethasone every 6 h for two successive days while collecting urine over a 24-h period for determination of creatinine and free cortisol and/or measuring plasma cortisol levels. In a patient with a normal hypothalamic-pituitaryACTHrelease mechanism, a fall in the urine free cortisol to<80 nmol/d (30 ug/d) or of plasma cortisol to<140 nmol/L (5 ug/dL) is seen on the second day of administration.

A normal response to either suppression test implies that the glucocorticoid regulation ofACTH and its control of the adrenal glands is physiologically normal. However, an isolated abnormal result, particularly to the overnight suppression test, does not in itself imply pituitary and/or adrenal disease.

Tests of Mineralocorticoid Suppressibility These tests rely on an expansion of extracellular fluid volume, which should decrease circulating plasma renin activity and decrease the secretion and/or excretion of aldosterone. Various tests differ in the rate at which extracellular fluid volume is expanded. One convenient suppression test involves the intravenous infusion of 500 mL/h of normal saline solution for 4 h, which normally suppresses plasma aldosterone levels to<220 pmol/L (<8 ng/dL) on a sodium-restricted diet or to <140 pmol/L (<5 ng/dL) on a normal sodium intake. Alternatively, a high-sodium diet can be administered for 3 days with 0.2 mg fludrocortisone twice daily. Aldosterone excretion is measured on the third day and should be <28 nmol/d (10 ug/d). These tests should not be performed in potassium-depleted individuals since they carry a risk of precipitating hypokalemia.

TESTS OF PITUITARY-ADRENAL RESPONSIVENESS

Stimuli such as insulin-induced hypoglycemia,AVP, and pyrogens cause the release ofACTHfrom the pituitary by an action on higher neural centers or on the pituitary itself. Insulin-induced hypoglycemia is particularly useful, because it stimulates the release of both growth hormone and ACTH. In this test, regular insulin (0.05 to 0.1 U/kg body weight) is given intravenously as a bolus to reduce the fasting glucose level to at least 50% below basal. The normal cortisol response is a rise to more than 500 nmol/L (18 ug/dL).

One of the best ways to test the integrity of the pituitary-adrenal axis is the metyrapone test. Metyrapone inhibits 11b-hydroxylase in the adrenal. As a result, the conversion of 11-deoxycortisol (compound S) to cortisol is impaired, causing 11-deoxycortisol to accumulate in the blood and the blood level of cortisol to decrease (Fig. 331-2). The hypothalamic-pituitary axis responds to the declining cortisol blood levels by releasing moreACTH. Note that assessment of the response depends on both an intact hypothalamic-pituitary axis and an intact adrenal gland.

Although modifications of the original metyrapone test have been described, we believe the best involves administering 750 mg of the drug by mouth every 4 h over a 24-h period and comparing the control and postmetyrapone plasma levels of 11-deoxycortisol, cortisol, andACTH. In normal individuals, plasma 11-deoxycortisol levels should exceed 210 nmol/L (7 ug/dL) and ACTH levels should exceed 17 pmol/L (75 pg/mL) following metyrapone administration. The metyrapone test does not accurately reflect ACTH reserve if subjects are ingesting exogenous glucocorticoids or drugs that accelerate the metabolism of metyrapone (e.g., phenytoin).

A direct and selective test of the pituitary corticotrophs can be achieved withCRH. The bolus injection of ovine CRH (corticorelin, ovine triflutate; 1 ug/kg body weight) stimulates secretion ofACTH andb-LPTin normal human subjects within 15 to 60 min. In normal individuals, the mean increment in ACTH is 9 pmol/L (40 pg/mL). However, the

magnitude of the ACTH response is less than that produced by the insulin tolerance test, which implies that additional factors (such as vasopressin) augment stress-induced increases in ACTH secretion.

Although the rapidACTHstimulation test is useful for the diagnosis of primary adrenal insufficiency, normal cortisol responsiveness may be seen in some patients with a partial ACTH deficit and absence of adrenal atrophy. These patients have an inadequate pituitary ACTH reserve and fail to increase ACTH secretion in response to a stress such as surgery or hypoglycemia. Because the use of a bolus of exogenous ACTH does not invariably exclude a diagnosis of secondary adrenocortical insufficiency, direct tests of pituitary ACTH reserve (metyrapone test, insulin tolerance testing) may be required in the appropriate clinical setting. Alternatively, ACTH at a physiologic dose (1 ug), the so-called low-dose ACTH test, may be used. Abnormal response is similar to the rapid ACTH test. However, levels need to be measured at 30 min, and the ACTH needs to be injected directly intravenously because it can be absorbed to plastic tubing. On the other hand, the rapid ACTH test can distinguish between primary and secondary adrenal insufficiency, because aldosterone secretion is preserved in secondary adrenal failure by the renin-angiotensin system and potassium. Cosyntropin (25 units) is given intravenously or intramuscularly, and plasma cortisol and aldosterone levels are measured before and 30 and 60 min after administration. The cortisol response is abnormal in both groups, but patients with secondary insufficiency show an increase in aldosterone levels by at least 140 pmol/L (5 ng/dL). No aldosterone response is seen in patients in whom the adrenal cortex is destroyed.

HYPERFUNCTION OF THE ADRENAL CORTEX

Excess cortisol is associated with Cushing's syndrome; excess aldosterone causes aldosteronism; and excess adrenal androgens cause adrenal virilism. These syndromes do not always occur in the "pure" form but may have overlapping features.

CUSHING'S SYNDROME

Etiology Cushing described a syndrome characterized by truncal obesity, hypertension, fatigability and weakness, amenorrhea, hirsutism, purplish abdominal striae, edema, glucosuria, osteoporosis, and a basophilic tumor of the pituitary. As awareness of this syndrome has increased, the diagnosis of Cushing's syndrome has been broadened into the classification shown in Table 331-2. Regardless of etiology, all cases of endogenous Cushing's syndrome are due to increased production of cortisol by the adrenal. In most cases the cause is *bilateral adrenal hyperplasia* due to hypersecretion of pituitaryACTH or ectopic production of ACTH by a nonpituitary source. The incidence of pituitary-dependent adrenal hyperplasia is three times greater in women than in men, and the most frequent age of onset is the third or fourth decade. Most evidence indicates that the primary defect is the de novo development of a pituitary adenoma, as tumors are found in >90% of patients with pituitary-dependent adrenal hyperplasia. Alternatively, the defect may occasionally reside in the hypothalamus or in higher neural centers, leading to release ofCRHinappropriate to the level of circulating cortisol. The consequence would be that a higher level of cortisol is required to reduce ACTH secretion to normal. This primary defect leads to hyperstimulation of the pituitary, resulting in hyperplasia or tumor formation. In surgical series, most individuals with

hypersecretion of pituitary ACTH are found to have a microadenoma (<10 mm in diameter; 50% are£5 mm in diameter), but a pituitary macroadenoma (>10 mm) or diffuse hyperplasia of the corticotropic cells may be found. In some studies, the recurrence rate is>20%. Unfortunately, it may be difficult to distinguish between recurrence and inadequate primary therapy. Traditionally, only an individual who has an ACTH-producing pituitary tumor is defined as having *Cushing's disease*.

Nonpituitary tumors may secrete polypeptides that are biologically, chemically, and immunologically indistinguishable from eitherACTH orCRH and that cause bilateral adrenal hyperplasia (Chap. 100). The ectopic production of CRH results in clinical, biochemical, and radiologic features indistinguishable from those caused by hypersecretion of pituitary ACTH. The typical signs and symptoms of Cushing's syndrome may be absent or minimal with ectopic ACTH production, and hypokalemic alkalosis is a prominent manifestation. Most of these cases are associated with the primitive small cell (oat cell) type of bronchogenic carcinoma or with tumors of the thymus, pancreas, or ovary; medullary carcinoma of the thyroid; or bronchial adenomas. The onset of Cushing's syndrome may be sudden, particularly in patients with carcinoma of the lung, and this feature accounts in part for the failure of these patients to exhibit the classic manifestations. On the other hand, patients with carcinoid tumors or pheochromocytomas have longer clinical courses and usually exhibit the typical cushingoid features. The ectopic secretion of ACTH is also accompanied by the accumulation of ACTH fragments in plasma and by elevated plasma levels of ACTH precursor molecules. Because such tumors may produce large amounts of ACTH, baseline steroid values are usually markedly elevated, and increased skin pigmentation may be present. Indeed, hyperpigmentation in patients with Cushing's syndrome almost always points to an extraadrenal tumor, either in an extracranial location or within the cranium.

Approximately 20 to 25% of patients with Cushing's syndrome have an adrenal neoplasm. These tumors are usually unilateral, and about half are malignant. Occasionally, patients have biochemical features both of pituitaryACTHexcess and of an adrenal adenoma. These individuals usually have *nodular hyperplasia* of both adrenal glands often the result of prolonged ACTH stimulation in the absence of a pituitary adenoma. Two additional entities cause nodular hyperplasia: a familial disorder in children or young adults (so-called pigmented micronodular dysplasia; see below) and an abnormal cortisol response to gastric inhibitory polypeptide or luteinizing hormone, probably secondary to expression of receptors for these hormones in the adrenal cortex.

The most common cause of Cushing's syndrome is *iatrogenic* administration of steroids for a variety of reasons. Although the clinical features bear some resemblance to those seen with adrenal tumors, these patients are usually distinguishable on the basis of history and laboratory studies.

Clinical Signs, Symptoms, and Laboratory Findings Many of the signs and symptoms of Cushing's syndrome follow logically from the known action of glucocorticoids (Table 331-3). Mobilization of peripheral supportive tissue causes muscle weakness and fatigability, osteoporosis, broad violaceous cutaneous striae, and easy bruisability. The latter signs are secondary to weakening and rupture of collagen

fibers in the dermis. Osteoporosis may cause collapse of vertebral bodies and pathologic fractures of other bones. Decreased bone mineralization is particularly pronounced in children. Increased hepatic gluconeogenesis and insulin resistance can cause impaired glucose tolerance. Overt diabetes mellitus occurs in <20% of patients, who probably are individuals with a predisposition to this disorder. Hypercortisolism promotes the deposition of adipose tissue in characteristic sites, notably the upper face (producing the typical "moon" facies), the interscapular area (producing the "buffalo hump"), and the mesenteric bed (producing "truncal" obesity) (Fig. 331-6). Rarely, episternal fatty tumors and mediastinal widening secondary to fat accumulation occur. The reason for this peculiar distribution of adipose tissue is not known, but it is associated with insulin resistance and/or elevated insulin levels. The face appears plethoric, even in the absence of any increase in red blood cell concentration (Fig. 331-CD1). Hypertension is common, and emotional changes may be profound, ranging from irritability and emotional lability to severe depression, confusion, or even frank psychosis. In women, increased levels of adrenal androgens can cause acne, hirsutism, and oligomenorrhea or amenorrhea. Some signs and symptoms in patients with hypercortisolism -- i.e., obesity, hypertension, osteoporosis, and diabetes -- are nonspecific and therefore are less helpful in diagnosing the condition. On the other hand, easy bruising, typical striae, myopathy, and virilizing signs (although less frequent) are, if present, more suggestive of Cushing's syndrome (Table 331-3).

Except in iatrogenic Cushing's syndrome, plasma and urine cortisol levels are variably elevated. Occasionally, hypokalemia, hypochloremia, and metabolic alkalosis are present, particularly with ectopic production ofACTH.

Diagnosis The diagnosis of Cushing's syndrome depends on the demonstration of increased cortisol production and failure to suppress cortisol secretion normally when dexamethasone is administered (Chap. 328). Once the diagnosis is established, further testing is designed to determine the etiology (Fig. 331-7 andTable 331-4).

For initial screening, the overnight dexamethasone suppression test is recommended (see above). In difficult cases (e.g., in obese patients), measurement of a 24-h urine free cortisol also can be used as a screening test. A level>140 nmol/d (50 ug/d) is suggestive of Cushing's syndrome. The definitive diagnosis is then established by failure of urinary cortisol to fall to less than <25 nmol/d (10 ug/d) or of plasma cortisol to fall to <140 nmol/L (5 ug/dL) after a standard low-dose dexamethasone suppression test (0.5 mg every 6 h for 48 h). Owing to circadian variability, plasma cortisol and, to a certain extent,ACTHdeterminations are not meaningful when performed in isolation, but the absence of the normal fall of plasma cortisol at midnight is consistent with Cushing's syndrome.

The task of determining the etiology of Cushing's syndrome is complicated by the fact that all the available tests lack specificity and by the fact that the tumors producing this syndrome are prone to spontaneous and often dramatic changes in hormone secretion (periodic hormonogenesis). No test has a specificity >95%, and it may be necessary to use a combination of tests to arrive at the correct diagnosis. A useful step to distinguish patients with anACTH-secreting pituitary microadenoma or hypothalamic-pituitary dysfunction from those with other forms of Cushing's syndrome is to determine the response of cortisol output to administration of high-dose dexamethasone (2 mg every 6

h for 2 days). An alternative 8-mg, overnight high-dose dexamethasone test has been developed; however, this test has a lower sensitivity and specificity than the standard test. When the diagnosis of Cushing's syndrome is clear-cut on the basis of baseline urinary and plasma assays, the high-dose dexamethasone suppression test may be used without performing the preliminary low-dose suppression test. The high-dose suppression test provides close to 100% specificity if the criterion used is suppression of urinary free cortisol by>90%. Occasionally, in individuals with bilateral nodular hyperplasia and/or ectopicCRHproduction, steroid output is also suppressed. Failure of low- and high-dose dexamethasone administration to suppress cortisol production (Table 331-4) is usual in patients with adrenal hyperplasia secondary to an ACTH-secreting pituitary macroadenoma or an ACTH-producing tumor of nonendocrine origin and in those with adrenal neoplasms.

PlasmaACTHlevels can be useful in distinguishing the various causes of Cushing's syndrome, particularly in separating ACTH-dependent from ACTH-independent causes. In general, measurement of plasma ACTH is useful in the diagnosis of ACTH-independent etiologies of the syndrome, since most adrenal tumors cause low or undetectable ACTH levels [<2 pmol/L (10 pg/mL)]. Furthermore, ACTH-secreting pituitary macroadenomas and ACTH-producing nonendocrine tumors usually result in elevated ACTH levels. In the ectopic ACTH syndrome, ACTH levels may be elevated to >110 pmol/L (500 pg/mL), and in most patients the level is>40 pmol/L (200 pg/mL). In Cushing's syndrome as the result of a microadenoma or pituitary-hypothalamic dysfunction, ACTH levels range from 6 to 30 pmol/L (30 to 150 pg/mL) [normal,<14 pmol/L (<60 pg/mL)], with half of values falling in the normal range. However, the main problem with the use of ACTH levels in the differential diagnosis of Cushing's syndrome is that ACTH levels may be similar in individuals with hypothalamic-pituitary dysfunction, pituitary microadenomas, ectopicCRHproduction, and ectopic ACTH production (especially carcinoid tumors) (Table 331-4).

Because of these difficulties, several additional tests have been advocated, such as the metyrapone andCRHinfusion tests. The rationale underlying these tests is that steroid hypersecretion by an adrenal tumor or the ectopic production ofACTHwill suppress the hypothalamic-pituitary axis so that inhibition of pituitary ACTH release can be demonstrated by either test. Thus, most patients with pituitary-hypothalamic dysfunction and/or a microadenoma have an increase in steroid or ACTH secretion in response to metyrapone or CRH administration, whereas most patients with ectopic ACTH-producing tumors do not. Most pituitary macroadenomas also respond to CRH, but their response to metyrapone is variable. However, false-positive and -negative CRH tests can occur in patients with ectopic ACTH and pituitary tumors.

The main diagnostic dilemma in Cushing's syndrome is to distinguish those instances due to microadenomas of the pituitary and/or pituitary-hypothalamic dysfunction from those due to tumors (e.g., carcinoids or pheochromocytoma) that produceCRHand/orACTHectopically. The clinical manifestations are similar unless the ectopic tumor produces other symptoms, such as diarrhea and flushing from a carcinoid tumor or episodic hypertension from a pheochromocytoma. Sometimes, one can distinguish between ectopic and pituitary ACTH production by using metyrapone or CRH tests, as noted above. In these situations, computed tomography (CT) of the pituitary gland is usually normal. Magnetic resonance imaging (MRI) with the enhancing

agent gadolinium may be better than CT for this purpose but demonstrates pituitary microadenomas in only half of patients with Cushing's disease. In subjects with negative imaging studies, selective petrosal sinus venous sampling for ACTH is employed in some centers. Demonstration of an ACTH gradient between the petrosal sinus and peripheral blood localizes the source of ACTH overproduction to the pituitary gland but does not distinguish pituitary-dependent adrenal hyperplasia from pituitary hyperplasia secondary to a tumor producing CRH. CRH levels should be measured in the peripheral blood prior to petrosal sinus sampling. In centers where petrosal sinus sampling is performed frequently, it has proved useful for distinguishing pituitary and nonpituitary sources of ACTH excess. However, the catheterization procedure is technically difficult, and complications have occurred.

The diagnosis of a *cortisol-producing adrenal adenoma* is suggested by disproportionate elevations in baseline urine free-cortisol levels with only modest changes in urinary 17-ketosteroids or plasmaDHEAsulfate. Adrenal androgen secretion is usually reduced in these patients owing to the cortisol-induced suppression ofACTH and subsequent involution of the androgen-producing zona reticularis.

The diagnosis of *adrenal carcinoma* is suggested by a palpable abdominal mass and by *markedly* elevated baseline values of *both* urine 17-ketosteroids and plasmaDHEAsulfate. Plasma and urine cortisol levels are variably elevated. Adrenal carcinoma is usually resistant to bothACTHstimulation and dexamethasone suppression. Elevated adrenal androgen secretion often leads to virilization in the female. Estrogen-producing adrenocortical carcinoma usually presents with gynecomastia in men and dysfunctional uterine bleeding in women. These adrenal tumors secrete increased amounts of androstenedione, which is converted peripherally to the estrogens estrone and estradiol (Chap. 337). Adrenal carcinomas that produce Cushing's syndrome are often associated with elevated levels of the intermediates of steroid biosynthesis (especially 11-deoxycortisol), suggesting inefficient conversion of the intermediates to the final product. This feature also accounts for the characteristic increase in 17-ketosteroids. Approximately 20% of adrenal carcinomas are not associated with endocrine syndromes and are presumed to be nonfunctioning or to produce biologically inactive steroid precursors. In addition, the excessive production of steroids is not always clinically evident (e.g., androgens in adult men).

Differential Diagnosis

Pseudo-Cushing's Syndrome Problems in diagnosis include patients with obesity, chronic alcoholism, depression, and acute illness of any type. Extreme *obesity* is uncommon in Cushing's syndrome; furthermore, with exogenous obesity, the adiposity is generalized, not truncal. On adrenocortical testing, abnormalities in patients with exogenous obesity are usually modest. Basal urine steroid excretion levels in obese patients are also either normal or slightly elevated. Some patients have elevated conversion of secreted cortisol into excreted metabolites. Urinary and blood cortisol levels are usually normal, and the diurnal pattern in blood and urine levels is normal. Patients with *chronic alcoholism* and those with *depression* share similar abnormalities in steroid output: modestly elevated urine cortisol, blunted circadian rhythm of cortisol levels, and resistance to suppression using the overnight dexamethasone test. In contrast to alcoholic subjects, depressed patients do not have signs and symptoms of

Cushing's syndrome. Following discontinuation of alcohol and/or improvement in the emotional status, results of steroid testing usually return to normal. One or more of three tests have been used to differentiate mild Cushing's syndrome and pseudo-Cushing's syndrome. The serum cortisol level following the standard 2-day low-dose dexamethasone test has very high sensitivity and specificity. While theCRH test alone is less useful, in combination with the low-dose dexamethasone test, there is nearly complete discrimination between these two conditions. Finally, a midnight cortisol level obtained in awake patients may have similar predictive value as the low-dose dexamethasone test if a cut-off of 210 nmol/L (7.5 ug/dL) is used. Patients with *acute illness* often have abnormal results on laboratory tests and fail to exhibit pituitary-adrenal suppression in response to dexamethasone, since major stress (such as pain or fever) interrupts the normal regulation ofACTHsecretion. *Iatrogenic Cushing's syndrome*, induced by the administration of glucocorticoids or other steroids such as megestrol that bind to the glucocorticoid receptor, is indistinguishable by physical findings from endogenous adrenocortical hyperfunction. The distinction can be made, however, by measuring blood or urine cortisol levels in a basal state; in the iatrogenic syndrome these levels are low secondary to suppression of the pituitary-adrenal axis. The severity of iatrogenic Cushing's syndrome is related to the total steroid dose, the biologic half-life of the steroid, and the duration of therapy. Also, individuals taking afternoon and evening doses of glucocorticoids develop Cushing's syndrome more readily and with a smaller total daily dose than do patients taking morning doses only. The enzymatic disposition and binding of administered steroids differ among patients.

Radiologic Evaluation for Cushing's Syndrome The preferred radiologic study for visualizing the adrenals is aCT scan of the abdomen (Fig. 331-8). CT is of value both for localizing adrenal tumors and for diagnosing bilateral hyperplasia. All patients believed to have hypersecretion of pituitaryACTHshould have a pituitaryMRI scan with the contrast agent gadolinium. Even with this technique, small microadenomas may be undetectable; alternatively, false-positive masses due to cysts or nonsecretory lesions of the normal pituitary may be imaged. In patients with ectopic ACTH production, chest CT is a useful first step.

Evaluation of Asymptomatic Adrenal Masses With abdominalCTscanning, many incidental adrenal masses (so-called incidentalomas) are discovered. This is not surprising, since 10 to 20% of subjects at autopsy have adrenocortical adenomas. The first step in evaluating such patients is to determine whether the tumor is functioning by means of appropriate screening tests, e.g., measurement of 24-h urine catecholamines and metabolites and serum potassium and assessment of adrenal cortical function by dexamethasone-suppression testing. However, 90% of incidentalomas are nonfunctioning. If an extraadrenal malignancy is present, there is a 30 to 50% chance that the adrenal tumor is a metastasis. If the primary tumor is being treated and there are no other metastases, it is prudent to obtain a fine-needle aspirate of the adrenal mass to establish the diagnosis. In the absence of a known malignancy the next step is unclear. The probability of adrenal carcinoma is <0.01 percent, the vast majority of adrenal masses being benign adenomas. Features suggestive of malignancy include large size (a size >4 to 6 cm suggests carcinoma); irregular margins; and inhomogeneity, soft tissue calcifications visible on CT (Fig. 331-8), and findings characteristic of malignancy on a chemical-shiftMRIimage. If surgery is not performed, a repeat CT scan should be obtained in 3 to 6 months. Fine needle aspiration is not useful

to distinguish between benign and malignant primary adrenal tumors.

TREATMENT

Adrenal Neoplasm When an adenoma or carcinoma is diagnosed, adrenal exploration is performed with excision of the tumor. Adenomas may be resected using laparoscopic techniques. Because of the possibility of atrophy of the contralateral adrenal, the patient is treated pre- and postoperatively as if for total adrenalectomy, even when a unilateral lesion is suspected, the routine being similar to that for an Addisonian patient undergoing elective surgery (seeTable 331-8).

Despite operative intervention, most patients with adrenal carcinoma die within 3 years of diagnosis. Metastases occur most often to liver and lung. The principal drug for the treatment of adrenocortical carcinoma is mitotane (*o,p*¢-DDD), an isomer of the insecticide DDT. This drug suppresses cortisol production and decreases plasma and urine steroid levels. Although its cytotoxic action is relatively selective for the glucocorticoid-secreting zone of the adrenal cortex, the zona glomerulosa may also be inhibited. Because mitotane also alters the extraadrenal metabolism of cortisol, plasma and urinary cortisol levels must be assessed to titrate the effect. The drug is usually given in divided doses three to four times a day, with the dose increased gradually to tolerability (usually<6 g daily). At higher doses, almost all patients experience side effects, which may be gastrointestinal (anorexia, diarrhea, vomiting) or neuromuscular (lethargy, somnolence, dizziness). All patients treated with mitotane should receive long-term glucocorticoid maintenance therapy, and, in some, mineralocorticoid replacement is appropriate. In approximately one-third of patients, both tumor and metastases regress, but long-term survival is not altered. In many patients, mitotane only inhibits steroidogenesis and does not cause regression of tumor metastases. Osseous metastases are usually refractory to the drug and should be treated with radiation therapy. Mitotane can also be given as adjunctive therapy after surgical resection of an adrenal carcinoma, although there is no evidence that this improves survival. Because of the absence of a long-term benefit with mitotane, alternative chemotherapeutic approaches based on platinum therapy have been used. However, there are no data presently available indicating a prolongation of life.

Bilateral Hyperplasia Patients with hyperplasia have a relative or absolute increase inACTHlevels. Since therapy would logically be directed at reducing ACTH levels, the ideal primary treatment for ACTH- orCRH-producing tumors, whether pituitary or ectopic, is surgical removal. Occasionally (particularly with ectopic ACTH production) surgical excision is not possible because the disease is far advanced. In this situation, "medical" or surgical adrenalectomy may correct the hypercortisolism.

Controversy exists as to the proper treatment for bilateral adrenal hyperplasia when the source of theACTHoverproduction is not apparent. In some centers, these patients (especially those who suppress after the administration of a high-dose dexamethasone test) undergo surgical exploration of the pituitary via a transsphenoidal approach in the expectation that a microadenoma will be found. However, in most circumstances selective petrosal sinus venous sampling is recommended, and the patient is referred to an appropriate center if the procedure is not available locally. If a microadenoma is not found at the time of exploration, total hypophysectomy may be needed. Complications

of transsphenoidal surgery include cerebrospinal fluid rhinorrhea, diabetes insipidus, panhypopituitarism, and optic or cranial nerve injuries.

In other centers, total adrenalectomy is the treatment of choice. The cure rate with this procedure is close to 100%. The adverse effects include the certain need for lifelong mineralocorticoid and glucocorticoid replacement and a 10 to 20% probability of a pituitary tumor developing over the next 10 years (Nelson's syndrome; Chap. 328). Many of these tumors require surgical therapy. It is uncertain whether they arise de novo in these patients or were present prior to adrenalectomy but were too small to be detected. Periodic radiologic evaluation of the pituitary gland byMRI as well as serialACTHmeasurements should be performed in all individuals after bilateral adrenalectomy for Cushing's disease. Such pituitary tumors may become locally invasive and impinge on the optic chiasm or extend into the cavernous or sphenoid sinuses.

Except in children, pituitary irradiation is rarely used as primary treatment, being reserved rather for postoperative tumor recurrences. In some centers, high levels of gamma radiation can be focused on the desired site with less scattering to surrounding tissues by using stereotactic techniques. Side effects of radiation include ocular motor palsy and hypopituitarism. There is a long lag time between treatment and remission, and the remission rate is usually<50%.

Finally, in occasional patients in whom a surgical approach is not feasible, "medical" adrenalectomy may be indicated (Table 331-5). Inhibition of steroidogenesis may also be indicated in severely cushingoid subjects prior to surgical intervention. Chemical adrenalectomy may be accomplished by the administration of the inhibitor of steroidogenesis ketoconazole (600 to 1200 mg/d). In addition, mitotane (2 or 3 g/d) and/or the blockers of steroid synthesis aminoglutethimide (1 g/d) and metyrapone (2 or 3 g/d) may be effective either alone or in combination. Mitotane is slow to take effect (weeks). Mifepristone, a competitive inhibitor of the binding of glucocorticoid to its receptor, may be a treatment option. Adrenal insufficiency is a risk with all these agents, and replacement steroids may be required.

ALDOSTERONISM

Aldosteronism is a syndrome associated with hypersecretion of the mineralocorticoid aldosterone. In *primary* aldosteronism the cause for the excessive aldosterone production resides within the adrenal gland; in *secondary* aldosteronism the stimulus is extraadrenal.

Primary Aldosteronism In the original case of excessive and inappropriate aldosterone production, the disease was the result of an *aldosterone-producing adrenal adenoma* (Conn's syndrome). Most cases involve a unilateral adenoma, which is usually small and may occur on either side. Rarely, primary aldosteronism is due to an adrenal carcinoma. Aldosteronism is twice as common in women as in men, usually occurs between the ages of 30 and 50, and is present in approximately 1% of unselected hypertensive patients. However, the prevalence may be as high as 10%, depending on the criteria and study population. Most of this difference is not secondary to the prevalence of patients with an aldosteronoma but rather because of the inclusion of

those with bilateral hyperplasia. In many patients with clinical and biochemical features of primary aldosteronism, a solitary adenoma is not found at surgery. Instead, these patients have *bilateral cortical nodular hyperplasia*. In the literature, this disease is also termed *idiopathic hyperaldosteronism*, and/or *nodular hyperplasia*. The cause is unknown.

Signs and Symptoms Hypersecretion of aldosterone increases the renal distal tubular exchange of intratubular sodium for secreted potassium and hydrogen ions, with progressive depletion of body potassium and development of hypokalemia. Most patients have diastolic hypertension, which may be very severe, and headaches. The hypertension is probably due to the increased sodium reabsorption and extracellular volume expansion. *Potassium depletion* is responsible for the muscle weakness and fatigue and is due to the effect of potassium depletion on the muscle cell membrane. The polyuria results from impairment of urinary concentrating ability and is often associated with polydipsia.

Electrocardiographic and roentgenographic signs of left ventricular enlargement are, in part, secondary to the hypertension. However, the left ventricular hypertrophy is disproportionate to the level of blood pressure when compared to individuals with essential hypertension, and regression of the hypertrophy occurs even if blood pressure is not reduced after removal of an aldosteronoma. Electrocardiographic signs of potassium depletion include prominent U waves, cardiac arrhythmias, and premature contractions. In the absence of associated congestive heart failure, renal disease, or preexisting abnormalities (such as thrombophlebitis), edema is characteristically absent. However, structural damage to the cerebral circulation, retinal vasculature, and kidney occurs more frequently than would be predicted based on the level and duration of the hypertension. Proteinuria may occur in as many as 50% of patients with primary aldosteronism, and renal failure occurs in up to 15%. Thus, it is probable that excess aldosterone production induces cardiovascular damage independent of its effect on blood pressure.

Laboratory Findings Laboratory findings depend on both the duration and the severity of potassium depletion. An overnight concentration test often reveals impaired ability to concentrate the urine, probably secondary to the hypokalemia. Urine pH is neutral to alkaline because of excessive secretion of ammonium and bicarbonate ions to compensate for the metabolic alkalosis.

Hypokalemia may be severe (<3 mmol/L) and reflects body potassium depletion, usually >300 mmol. In mild forms of primary aldosteronism, potassium levels may be normal. *Hypernatremia* is due to sodium retention, a concomitant water loss from polyuria, and a resetting of the osmostat. Metabolic alkalosis and elevation of serum bicarbonate are a result of hydrogen ion loss into the urine and migration into potassium-depleted cells. The alkalosis is perpetuated by potassium deficiency, which increases the capacity of the proximal convoluted tubule to reabsorb filtered bicarbonate. If hypokalemia is severe, serum magnesium levels are also reduced.

Diagnosis The diagnosis is suggested by persistent hypokalemia in a nonedematous patient with a normal sodium intake who is not receiving potassium-wasting diuretics (furosemide, ethacrynic acid, thiazides). If hypokalemia occurs in a hypertensive patient

taking a potassium-wasting diuretic, the diuretic should be discontinued and the patient should be given potassium supplements. After 1 to 2 weeks, the potassium level should be remeasured, and if hypokalemia persists, the patient should be evaluated for a mineralocorticoid excess syndrome (Fig. 331-9).

The criteria for the diagnosis of primary aldosteronism are (1) diastolic hypertension without edema, (2) hyposecretion of renin (as judged by low plasma renin activity levels) that fails to increase appropriately during volume depletion (upright posture, sodium depletion), and (3) hypersecretion of aldosterone that does not suppress appropriately in response to volume expansion.

Patients with primary aldosteronism characteristically *do not have edema*, since they exhibit an "escape" phenomenon from the sodium-retaining aspects of mineralocorticoids. Rarely, pretibial edema is present in patients with associated nephropathy and azotemia.

The estimation of plasma renin activity is of limited value in separating patients with primary aldosteronism from those with hypertension of other causes. Although failure of plasma renin activity to rise normally during volume-depletion maneuvers is a criterion for a diagnosis of primary aldosteronism, suppressed renin activity also occurs in about 25% of patients with essential hypertension.

Although a renin measurement alone lacks specificity, the ratio of serum aldosterone to plasma renin activity is a very useful screening test. A high ratio (>30), when aldosterone is expressed as ng/dL and plasma renin activity as ng/mL per hour, strongly suggests autonomy of aldosterone secretion. Aldosterone levels need to be>500 pmol/L (>15 ng/dL) and the salt intake not be restricted in making this assessment. Ultimately, it is necessary to demonstrate a lack of aldosterone suppression to diagnose primary aldosteronism (Fig. 331-9). The autonomy exhibited in these patients refers only to the resistance to suppression of secretion during volume expansion; aldosterone can and does respond in a normal or above-normal fashion to the stimulus of potassium loading orACTHinfusion.

Once hyposecretion of renin and failure of aldosterone secretion suppression are demonstrated, aldosterone-producing adenomas should be localized by abdominalCT scan, using a high-resolution scanner as many aldosteronomas are<1 cm in size. If the CT scan is negative, percutaneous transfemoral bilateral adrenal vein catheterization with adrenal vein sampling may demonstrate a two- to threefold increase in plasma aldosterone concentration on the involved side. In cases of hyperaldosteronism secondary to cortical nodular hyperplasia, no lateralization is found. It is important for samples to be obtained simultaneously if possible and for cortisol levels to be measured to ensure that false localization does not reflect dilution or anACTH- or stress-induced rise in aldosterone levels. In a patient with an adenoma, the aldosterone/cortisol ratio lateralizes to the side of the lesion.

Differential Diagnosis Patients with hypertension and hypokalemia may have either primary or secondary hyperaldosteronism (Fig. 331-10). A useful maneuver to distinguish between these conditions is the measurement of plasma renin activity. Secondary hyperaldosteronism in patients with accelerated hypertension is due to

elevated plasma renin levels; in contrast, patients with primary aldosteronism have suppressed plasma renin levels. Indeed, in patients with a serum potassium concentration of <2.5 mmol/L, a high ratio of plasma aldosterone to plasma renin activity in a random sample is usually sufficient to establish the diagnosis of primary aldosteronism without additional testing.

Primary aldosteronism must also be distinguished from other *hypermineralocorticoid states*. Nonaldosterone mineralocorticoid states will have suppressed plasma renin activity but low aldosterone levels. The most common problem is to distinguish between hyperaldosteronism due to an adenoma and that due to idiopathic bilateral nodular hyperplasia. This distinction is of importance because hypertension associated with idiopathic hyperplasia is usually not benefited by bilateral adrenalectomy, whereas hypertension associated with aldosterone-producing tumors is usually improved or cured by removal of the adenoma. Although patients with idiopathic bilateral nodular hyperplasia tend to have less severe hypokalemia, lower aldosterone secretion, and higher plasma renin activity than do patients with primary aldosteronism, differentiation is impossible solely on clinical and/or biochemical grounds. An anomalous postural decrease in plasma aldosterone and elevated plasma 18-hydroxycorticosterone levels are present in most patients with a unilateral lesion. However, these tests are also of limited diagnostic value in the individual patient, because some adenoma patients have an increase in plasma aldosterone with upright posture, so-called renin-responsive aldosteronoma. A definitive diagnosis is best made by radiographic studies, including bilateral adrenal vein catheterization, as noted above.

In a few instances, hypertensive patients with hypokalemic alkalosis have adenomas that secrete deoxycorticosterone (DOC). Such patients have reduced plasma renin activity levels, but aldosterone levels are either normal or reduced, suggesting the diagnosis of mineralocorticoid excess due to a hormone other than aldosterone. Several inherited disorders have clinical features similar to those of primary aldosteronism (see below).

TREATMENT

Primary aldosteronism due to an adenoma is usually treated by surgical excision of the adenoma. Where possible a laparoscopic approach is favored. However, dietary sodium restriction and the administration of an aldosterone antagonist, e.g., spironolactone, are effective in many cases. Hypertension and hypokalemia are usually controlled by doses of 25 to 100 mg spironolactone every 8 h. In some patients medical management has been successful for years, but chronic therapy in men is usually limited by side effects of spironolactone such as gynecomastia, decreased libido, and impotence.

When idiopathic bilateral hyperplasia is suspected, surgery is indicated only when significant, symptomatic hypokalemia cannot be controlled with medical therapy, e.g., by spironolactone, triamterene, or amiloride. Hypertension associated with idiopathic hyperplasia is usually not benefited by bilateral adrenalectomy.

Secondary Aldosteronism *Secondary aldosteronism* refers to an appropriately increased production of aldosterone in response to activation of the renin-angiotensin system (Fig. 331-10). The production rate of aldosterone is often higher in patients with

secondary aldosteronism than in those with primary aldosteronism. Secondary aldosteronism usually occurs in association with the accelerated phase of hypertension or on the basis of an underlying edema disorder. Secondary aldosteronism in pregnancy is a normal physiologic response to estrogen-induced increases in circulating levels of renin substrate and plasma renin activity and to the antialdosterone actions of progestogens.

Secondary aldosteronism in hypertensive states is due either to a primary overproduction of renin (primary reninism) or to an overproduction of renin secondary to a decrease in renal blood flow and/or perfusion pressure (Fig. 331-10). Secondary hypersecretion of renin can be due to a narrowing of one or both of the major renal arteries by atherosclerosis or by fibromuscular hyperplasia. Overproduction of renin from both kidneys also occurs in severe arteriolar nephrosclerosis (malignant hypertension) or with profound renal vasoconstriction (the accelerated phase of hypertension). The secondary aldosteronism is characterized by hypokalemic alkalosis, moderate to severe increases in plasma renin activity, and moderate to marked increases in aldosterone levels (Chap. 246).

Secondary aldosteronism with hypertension can also be caused by rare renin-producing tumors (primary reninism). These patients have the biochemical characteristics of renal vascular hypertension, but the primary defect is renin secretion by a juxtaglomerular cell tumor. The diagnosis can be made by demonstration of normal renal vasculature and/or demonstration of a space-occupying lesion in the kidney by radiographic techniques and documentation of a unilateral increase in renal vein renin activity. Rarely, these tumors arise in tissues such as the ovary.

Secondary aldosteronism is present in many forms of *edema*. The rate of aldosterone secretion is usually increased in patients with edema caused by either cirrhosis or the nephrotic syndrome. In congestive heart failure, elevated aldosterone secretion varies depending on the severity of cardiac failure. The stimulus for aldosterone release in these conditions appears to be *arterial hypovolemia* and/or hypotension. Thiazides and furosemide often exaggerate secondary aldosteronism via volume depletion; hypokalemia and, on occasion, alkalosis can then become prominent features. On occasion secondary hyperaldosteronism occurs without edema or hypertension (Bartter's and Gitelman's syndromes, see below).

SYNDROMES OF ADRENAL ANDROGEN EXCESS

Adrenal androgen excess results from excess production ofDHEA and androstenedione, which are converted to testosterone in extraglandular tissues; elevated testosterone levels account for most of the virilization. Adrenal androgen excess may be associated with the secretion of greater or smaller amounts of other adrenal hormones and may, therefore, present as "pure" syndromes of virilization or as "mixed" syndromes associated with excessive glucocorticoids and Cushing's syndrome.**For further discussion of hirsutism and virilization, see Chap. 53.*

HYPOFUNCTION OF THE ADRENAL CORTEX

Cases of adrenal insufficiency can be divided into two general categories: (1) those

associated with primary inability of the adrenal to elaborate sufficient quantities of hormone, and (2) those associated with a secondary failure due to inadequateACTHformation or release (Table 331-6).

PRIMARY ADRENOCORTICAL DEFICIENCY (ADDISON'S DISEASE)

The original description of Addison's disease -- "general languor and debility, feebleness of the heart's action, irritability of the stomach, and a peculiar change of the color of the skin" -- summarizes the dominant clinical features. Advanced cases are usually easy to diagnose, but recognition of the early phases can be a real challenge.

Incidence Primary insufficiency is relatively rare, may occur at any age, and affects both sexes equally. Because of the common therapeutic use of steroids, secondary adrenal insufficiency is relatively common.

Etiology and Pathogenesis Addison's disease results from progressive destruction of the adrenals, which must involve >90% of the glands before adrenal insufficiency appears. The adrenal is a frequent site for chronic granulomatous diseases, predominantly tuberculosis but also histoplasmosis, coccidioidomycosis, and cryptococcosis. In early series, tuberculosis was responsible for 70 to 90% of cases, but the most frequent cause now is *idiopathic* atrophy, and an autoimmune mechanism is probably responsible. Rarely, other lesions are encountered, such as adrenoleukodystrophy, bilateral hemorrhage, tumor metastases, HIV, cytomegalovirus (CMV), amyloidosis, adrenomyeloneuropathy, familial adrenal insufficiency, or sarcoidosis.

Although half of patients with idiopathic atrophy have circulating adrenal antibodies, autoimmune destruction is probably secondary to cytotoxic T lymphocytes. Specific adrenal antigens to which autoantibodies may be directed include 21-hydroxylase (CYP21A2) and side chain cleavage enzyme but the significance of these antibodies in the pathogenesis of adrenal insufficiency is unknown. Some antibodies cause adrenal insufficiency by blocking the binding ofACTH to its receptors. Some patients also have antibodies to thyroid, parathyroid, and/or gonadal tissue (Chap. 339). There is also an increased incidence of chronic lymphocytic thyroiditis, premature ovarian failure, type 1 diabetes mellitus, and hypo- or hyperthyroidism. The presence of two or more of these autoimmune endocrine disorders in the same person defines the polyglandular autoimmune syndrome type II. Additional features include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis. Within families, multiple generations are affected by one or more of the above diseases. Type II polyglandular syndrome is the result of a mutant gene on chromosome 6 and is associated with the HLA alleles B8 and DR3.

The combination of parathyroid and adrenal insufficiency and chronic mucocutaneous moniliasis constitutes type I polyglandular autoimmune syndrome. Other autoimmune diseases in this disorder include pernicious anemia, chronic active hepatitis, alopecia, primary hypothyroidism, and premature gonadal failure. There is no HLA association; this syndrome is inherited as an autosomal recessive trait. It is caused by mutations in *a*utoimmune *p*oly*e*ndocrinopathy *c*andidiasis *e*ctodermal *d*ystrophy (APECED) located on chromosome 21q22.3. The gene encodes a transcription factor thought to be

involved in lymphocyte function. The type I syndrome usually presents during childhood, whereas the type II syndrome is usually manifested in adulthood.

Clinical suspicion of adrenal insufficiency should be high in patients with AIDS (Chap. 309).CMVregularly involves the adrenal glands (so-called CMV necrotizing adrenalitis), and involvement with *Mycobacterium avium-intracellulare*, *Cryptococcus*, and Kaposi's sarcoma has been reported. Adrenal insufficiency in AIDS patients may not be manifest, but tests of adrenal reserve frequently give abnormal results. When interpreting tests of adrenocortical function, it is important to remember that medications such as rifampin, phenytoin, ketoconazole, megace, and opiates may cause or potentiate adrenal insufficiency. Adrenal hemorrhage and infarction occur in patients on anticoagulants and in those with circulating anticoagulants and hypercoagulable states, such as the antiphospholipid syndrome.

There are several rare genetic causes of adrenal insufficiency that present primarily in infancy and childhood (see below).

Clinical Signs and Symptoms Adrenocortical insufficiency caused by gradual adrenal destruction is characterized by an insidious onset of fatigability, weakness, anorexia, nausea and vomiting, weight loss, cutaneous and mucosal pigmentation, hypotension, and occasionally hypoglycemia (Table 331-7). Depending on the duration and degree of adrenal hypofunction, the manifestations vary from mild chronic fatigue to fulminating shock associated with acute destruction of the glands, as described by Waterhouse and Friderichsen.

Asthenia is the cardinal symptom. Early it may be sporadic, usually most evident at times of stress; as adrenal function becomes more impaired, the patient is continuously fatigued, and bed rest is necessary.

Hyperpigmentation may be striking or absent. It commonly appears as a diffuse brown, tan, or bronze darkening of parts such as the elbows or creases of the hand and of areas that normally are pigmented such as the areolae about the nipples. Bluish-black patches may appear on the mucous membranes. Some patients develop dark freckles, and irregular areas of vitiligo may paradoxically be present. As an early sign, tanning following sun exposure may be persistent.

Arterial hypotension with postural accentuation is frequent, and blood pressure may be in the range of 80/50 or less.

Abnormalities of gastrointestinal function are often the presenting complaint. Symptoms vary from mild anorexia with weight loss to fulminating nausea, vomiting, diarrhea, and ill-defined abdominal pain, which may be so severe as to be confused with an acute abdomen. Patients may have personality changes, usually consisting of excessive irritability and restlessness. Enhancement of the sensory modalities of taste, olfaction, and hearing is reversible with therapy. Axillary and pubic hair may be decreased in women due to loss of adrenal androgens.

Laboratory Findings In the early phase of gradual adrenal destruction, there may be no demonstrable abnormalities in the routine laboratory parameters, but adrenal reserve

is decreased -- that is, while basal steroid output may be normal, a subnormal increase occurs after stress. Adrenal stimulation withACTHuncovers abnormalities in this stage of the disease, eliciting a subnormal increase of cortisol levels or no increase at all. In more advanced stages of adrenal destruction, serum sodium, chloride, and bicarbonate levels are reduced, and the serum potassium level is elevated. The hyponatremia is due both to loss of sodium into the urine (due to aldosterone deficiency) and to movement into the intracellular compartment. This extravascular sodium loss depletes extracellular fluid volume and accentuates hypotension. Elevated plasma vasopressin and angiotensin II levels may contribute to the hyponatremia by impairing free water clearance. Hyperkalemia is due to a combination of aldosterone deficiency, impaired glomerular filtration, and acidosis. Basal levels of cortisol and aldosterone are subnormal and fail to increase following ACTH administration. Mild to moderate hypercalcemia occurs in 10 to 20% of patients for unclear reasons. The electrocardiogram may show nonspecific changes, and the electroencephalogram exhibits a generalized reduction and slowing. There may be a normocytic anemia, a relative lymphocytosis, and a moderate eosinophilia.

Diagnosis The diagnosis of adrenal insufficiency should be made only withACTHstimulation testing to assess adrenal reserve capacity for steroid production (see above for ACTH test protocols). In brief, the best screening test is the cortisol response 60 min after 250 ug of cosyntropin given intramuscularly or intravenously. Cortisol levels should exceed 495 nmol/L (18 ug/dL). If the response is abnormal, then primary and secondary adrenal insufficiency can be distinguished by measuring aldosterone levels from the same blood samples. In secondary, but not primary, adrenal insufficiency the aldosterone increment will be normal [^{3}150 pmol/l (5 ng/dL)]. Furthermore, in primary adrenal insufficiency, plasma ACTH and associated peptides (b-LPT) are elevated because of loss of the usual cortisol-hypothalamic-pituitary feedback relationship, whereas in secondary adrenal insufficiency, plasma ACTH values are low or "inappropriately" normal (Fig. 331-11).

Differential Diagnosis Since weakness and fatigue are common, diagnosis of early adrenocortical insufficiency may be difficult. However, the combination of mild gastrointestinal distress, weight loss, anorexia, and a suggestion of increased pigmentation makes it mandatory to performACTHstimulation testing to rule out adrenal insufficiency, particularly before steroid treatment is begun. Weight loss is useful in evaluating the significance of weakness and malaise. Racial pigmentation may be a problem, but a *recent* and progressive *increase* in pigmentation is usually reported by the patient with gradual adrenal destruction. Hyperpigmentation is usually absent when adrenal destruction is rapid, as in bilateral adrenal hemorrhage. The fact that hyperpigmentation occurs with other diseases may also present a problem, but the appearance and distribution of pigment in adrenal insufficiency are usually characteristic. When doubt exists, measurement of ACTH levels and testing of adrenal reserve with the infusion of ACTH provide clear-cut differentiation.

TREATMENT

All patients with adrenal insufficiency should receive specific hormone replacement. Like diabetics, these patients require careful education about the disease. Replacement therapy should correct both glucocorticoid and mineralocorticoid deficiencies.

Hydrocortisone (cortisol) is the mainstay of treatment. The dose for most adults (depending on size) is 20 to 30 mg/d. Patients are advised to take glucocorticoids with meals or, if that is impractical, with milk or an antacid, because the drugs may increase gastric acidity and exert direct toxic effects on the gastric mucosa. To simulate the normal diurnal adrenal rhythm, two-thirds of the dose is taken in the morning, and the remaining one-third is taken in the late afternoon. Some patients exhibit insomnia, irritability, and mental excitement after initiation of therapy; in these, the dosage should be reduced. Other situations that may necessitate smaller doses are hypertension and diabetes mellitus. Obese individuals and those on anticonvulsive medications may require increased dosages. Measurements of plasmaACTH or cortisol or of urine cortisol levels do not appear to be useful in determining optimal glucocorticoid dosages.

Since the replacement dosage of hydrocortisone does not replace the mineralocorticoid component of the adrenal hormones, mineralocorticoid supplementation is usually needed. This is accomplished by the administration of 0.05 to 0.1 mg fludrocortisone per day by mouth. Patients should also be instructed to maintain an ample intake of sodium (3 to 4 g/d).

The adequacy of mineralocorticoid therapy can be assessed by measurement of blood pressure and serum electrolytes. Blood pressure should be normal and without postural changes; serum sodium, potassium, creatinine, and urea nitrogen levels should also be normal. Measurement of plasma renin levels may also be useful in titrating the dose.

In female patients with adrenal insufficiency, androgen levels are also low. Thus, some physicians believe that daily replacement with 25 to 50 mg ofDHEAorally may improve quality of life and skeletal density.

Complications of glucocorticoid therapy, with the exception of gastritis, are *rare* at the dosages recommended for treatment of adrenal insufficiency. Complications of mineralocorticoid therapy include hypokalemia, hypertension, cardiac enlargement, and even congestive heart failure due to sodium retention. Periodic measurements of body weight, serum potassium level, and blood pressure are useful. All patients with adrenal insufficiency should carry medical identification, should be instructed in the parenteral self-administration of steroids, and should be registered with a medical alerting system.

Special Therapeutic Problems During periods of intercurrent illness, especially in the setting of fever, the dose of hydrocortisone should be doubled. With severe illness it should be increased to 75 to 150 mg/d. When oral administration is not possible, parenteral routes should be employed. Likewise, before surgery or dental extractions, supplemental glucocorticoids should be administered. Patients should also be advised to increase the dose of fludrocortisone and to add salt to their otherwise normal diet during periods of strenuous exercise with sweating, during extremely hot weather, and with gastrointestinal upsets such as diarrhea. A simple strategy is to supplement the diet one to three times daily with salty broth (1 cup of beef or chicken bouillon contains 35 mmol of sodium). For a representative program of steroid therapy for the patient with adrenal insufficiency who is undergoing major surgery, seeTable 331-8. This schedule is designed so that on the day of surgery it will mimic the output of cortisol in normal individuals undergoing prolonged major stress (10 mg/h, 250 to 300 mg/d). Thereafter, if the patient is improving and is afebrile, the dose of hydrocortisone is tapered by 20 to

30% daily. Mineralocorticoid administration is unnecessary at hydrocortisone doses >100 mg/d because of the mineralocorticoid effects of hydrocortisone at such dosages.

SECONDARY ADRENOCORTICAL INSUFFICIENCY

ACTHdeficiency causes *secondary* adrenocortical insufficiency; it may be a selective deficiency, as is seen following prolonged administration of excess glucocorticoids, or it may occur in association with deficiencies of multiple pituitary hormones (panhypopituitarism) (Chap. 328). Patients with secondary adrenocortical hypofunction have many symptoms and signs in common with those having primary disease but are *characteristically not hyperpigmented*, since ACTH and related peptide levels are low. In fact, plasma ACTH levels distinguish between primary and secondary adrenal insufficiency, since they are elevated in the former and decreased to absent in the latter. Patients with total pituitary insufficiency have manifestations of multiple hormone deficiencies. An additional feature distinguishing primary adrenocortical insufficiency is the *near-normal level of aldosterone secretion* seen in pituitary and/or isolated ACTH deficiencies (Fig. 331-11). Patients with pituitary insufficiency may have hyponatremia, which can be dilutional or secondary to a subnormal increase in aldosterone secretion in response to severe sodium restriction. However, severe *dehydration*, *hyponatremia*, and *hyperkalemia* are characteristic of severe mineralocorticoid insufficiency and favor a diagnosis of primary adrenocortical insufficiency.

Patients receiving long-term steroid therapy, despite physical findings of Cushing's syndrome, develop adrenal insufficiency because of prolonged pituitary-hypothalamic suppression and adrenal atrophy secondary to the loss of endogenousACTH. These patients have two deficits, a loss of adrenal responsiveness to ACTH and a failure of pituitary ACTH release. They are characterized by low blood cortisol and ACTH levels, a low baseline rate of steroid excretion, and abnormal ACTH and metyrapone responses. Most patients with steroid-induced adrenal insufficiency eventually recover normal hypothalamic-pituitary-adrenal responsiveness, but recovery time varies from days to months. The rapid ACTH test provides a convenient assessment of recovery of hypothalamic-pituitary-adrenal function. Because the plasma cortisol concentrations after injection of cosyntropin and during insulin-induced hypoglycemia are usually similar, the rapid ACTH test assesses the integrated hypothalamic-pituitary-adrenal function (see "Tests of Pituitary-Adrenal Responsiveness," above). Some investigators suggest using the low-dose (1 ug) ACTH test for suspected secondary ACTH deficiency. Additional tests to assess pituitary ACTH reserve include the standard metyrapone and insulin-induced hypoglycemia tests.

Glucocorticoid therapy in patients with secondary adrenocortical insufficiency does not differ from that for the primary disorder. Mineralocorticoid therapy is usually not necessary, as aldosterone secretion is preserved.

ACUTE ADRENOCORTICAL INSUFFICIENCY

Acute adrenocortical insufficiency may result from several processes. On the one hand, *adrenal crisis* may be a rapid and overwhelming intensification of chronic adrenal insufficiency, usually precipitated by sepsis or surgical stress. Alternatively, acute hemorrhagic destruction of both adrenal glands can occur in previously well subjects. In

children, this event is usually associated with septicemia with *Pseudomonas* or meningococcemia (Waterhouse-Friderichsen syndrome). In adults, anticoagulant therapy or a coagulation disorder may result in bilateral adrenal hemorrhage. Occasionally, bilateral adrenal hemorrhage in the newborn results from birth trauma. Hemorrhage has been observed during pregnancy, following idiopathic adrenal vein thrombosis, and as a complication of venography (e.g., infarction of an adenoma). The third and most frequent cause of acute insufficiency is the rapid withdrawal of steroids from patients with adrenal atrophy owing to chronic steroid administration. Acute adrenocortical insufficiency may also occur in patients with congenital adrenal hyperplasia or those with decreased adrenocortical reserve when they are given drugs capable of inhibiting steroid synthesis (mitotane, ketoconazole) or of increasing steroid metabolism (phenytoin, rifampin).

Adrenal Crisis The long-term survival of patients with adrenocortical insufficiency depends largely on the prevention and treatment of adrenal crisis. Consequently, the occurrence of infection, trauma (including surgery), gastrointestinal upsets, or other stresses necessitates an immediate increase in hormone. In untreated patients, preexisting symptoms are intensified. Nausea, vomiting, and abdominal pain may become intractable. Fever may be severe or absent. Lethargy deepens into somnolence, and hypovolemic vascular collapse ensues. In contrast, patients previously maintained on chronic glucocorticoid therapy may not exhibit dehydration or hypotension until they are in a preterminal state, since mineralocorticoid secretion is usually preserved. In all patients in crisis, a precipitating cause should be sought.

TREATMENT

Treatment is directed primarily toward repletion of circulating glucocorticoids and replacement of the sodium and water deficits. Hence an intravenous infusion of 5% glucose in normal saline solution should be started with a bolus intravenous infusion of 100 mg hydrocortisone followed by a continuous infusion of hydrocortisone at a rate of 10 mg/h. An alternative approach is to administer a 100-mg bolus of hydrocortisone intravenously every 6 h. However, only continuous infusion maintains the plasma cortisol constantly at stress levels [>830 nmol/L (30 ug/dL)]. Effective treatment of hypotension requires glucocorticoid replacement and repletion of sodium and water deficits. If the crisis was preceded by prolonged nausea, vomiting, and dehydration, several liters of saline solution may be required in the first few hours. Vasoconstrictive agents (such as dopamine) may be indicated in extreme conditions as adjuncts to volume replacement. With large doses of steroid, e.g., 100 to 200 mg hydrocortisone, the patient receives a maximal mineralocorticoid effect, and supplementary mineralocorticoid is superfluous. Following improvement, the steroid dosage is tapered over the next few days to maintenance levels, and mineralocorticoid therapy is reinstituted if needed (Table 331-8).

HYPOALDOSTERONISM

Isolated aldosterone deficiency accompanied by normal cortisol production occurs in association with hyporeninism, as an inherited biosynthetic defect, postoperatively following removal of aldosterone-secreting adenomas, during protracted heparin or heparinoid administration, in pretectal disease of the nervous system, and in severe

postural hypotension.

The feature common to all forms hypoaldosteronism is the inability to increase aldosterone secretion appropriately in response to salt restriction. Most patients have unexplained hyperkalemia, which often is exacerbated by restriction of dietary sodium intake. In severe cases, urine sodium wastage occurs at a normal salt intake, whereas in milder forms, excessive loss of urine sodium occurs only with salt restriction.

Most cases of isolated hypoaldosteronism occur in patients with a deficiency in renin production (so-called hyporeninemic hypoaldosteronism), most commonly in adults with diabetes mellitus and mild renal failure and in whom hyperkalemia and metabolic acidosis are out of proportion to the degree of renal impairment. Plasma renin levels fail to rise normally following sodium restriction and postural changes. The pathogenesis is uncertain. Possibilities include renal disease (the most likely), autonomic neuropathy, extracellular fluid volume expansion, and defective conversion of renin precursors to active renin. Aldosterone levels also fail to rise normally after salt restriction and volume contraction; this effect is probably related to the hyporeninism, since biosynthetic defects in aldosterone secretion usually cannot be demonstrated. In these patients, aldosterone secretion increases promptly afterACTHstimulation, but it is uncertain whether the magnitude of the response is normal. On the other hand, the level of aldosterone appears to be subnormal in relationship to the hyperkalemia.

Hypoaldosteronism can also be associated with high renin levels and low or elevated levels of aldosterone (see below). Severely ill patients may also have hyperreninemic hypoaldosteronism; such patients have a high mortality rate (80%). Hyperkalemia is not present. Possible explanations for the hypoaldosteronism include adrenal necrosis (uncommon) or a shift in steroidogenesis from mineralocorticoids to glucocorticoids, possibly related to prolongedACTHstimulation.

Before the diagnosis of isolated hypoaldosteronism is considered for a patient with hyperkalemia, "pseudohyperkalemia" (e.g., hemolysis, thrombocytosis) should be excluded by measuring the *plasma* potassium level. The next step is to demonstrate a normal cortisol response toACTHstimulation. Then, the response of renin and aldosterone levels to stimulation (upright posture, sodium restriction) should be measured. Low renin and aldosterone levels establish the diagnosis of hyporeninemic hypoaldosteronism. A combination of high renin levels and low aldosterone levels is consistent with an aldosterone biosynthetic defect or a selective unresponsiveness to angiotensin II. Finally, there is a condition that clinically and biochemically mimics hypoaldosteronism with elevated renin levels. However, the aldosterone levels are not low but high -- so-called pseudohypoaldosteronism. This inherited condition is caused by a mutation in the epithelial sodium channel (see below).

TREATMENT

The treatment is to replace the mineralocorticoid deficiency. For practical purposes, the oral administration of 0.05 to 0.15 mg fludrocortisone daily should restore electrolyte balance if salt intake is adequate (e.g., 150 to 200 mmol/d). However, patients with hyporeninemic hypoaldosteronism may require higher doses of mineralocorticoid to correct hyperkalemia. This need poses a potential risk in patients with hypertension,

mild renal insufficiency, or congestive heart failure. An alternative approach is to reduce salt intake and to administer furosemide, which can ameliorate acidosis and hyperkalemia. Occasionally, a combination of these two approaches is efficacious.

GENETIC CONSIDERATIONS

Glucocorticoid Diseases

Congenital Adrenal Hyperplasia Congenital adrenal hyperplasia (CAH) is the consequence of recessive mutations that cause one of several distinct enzymatic defects (see below). Because cortisol is the principal adrenal steroid regulatingACTHelaboration and because ACTH stimulates adrenal growth and function, a block in cortisol synthesis may result in the enhanced secretion of adrenal androgens and/or mineralocorticids depending on the site of the enzyme block. In severe congenital virilizing hyperplasia, the adrenal output of cortisol may be so compromised as to cause adrenal deficiency despite adrenal hyperplasia.

CAHis the most common adrenal disorder of infancy and childhood (Chap. 338). Partial enzyme deficiencies can be expressed after adolescence, predominantly in women with hirsutism and oligomenorrhea but minimal virilization. Late-onset adrenal hyperplasia may account for 5 to 25% of cases of hirsutism and oligomenorrhea in women, depending on the population.

ETIOLOGY Enzymatic defects have been described in 21-hydroxylase (CYP21A2), 17a-hydroxylase/17,20-Lyase (CYP17), 11b-hydroxylase (CYP11B1), and in (3b-HSD2) (Fig. 331-2). Although the cDNAs for these enzymes have been cloned, the diagnosis of specific enzyme deficiencies with genetic techniques is not practical for routine use. CYP21A2 deficiency is closely linked to the HLA-B locus of chromosome 6 so that HLA typing and/or DNA polymorphism can be used to detect the heterozygous carriers and to diagnose affected individuals in some families (Chap. 306). The clinical expression in the different disorders is variable, ranging from virilization of the female (CYP2/A2) to feminization of the male (3b-HSD2) (Chap. 338).

Adrenal virilization in the female at birth is associated with ambiguous external genitalia (*female pseudohermaphroditism*). Virilization probably begins after the fifth month of intrauterine development. At birth there may be enlarged genitalia in the male infant and enlargement of the clitoris, partial or complete fusion of the labia, and sometimes a urogenital sinus in the female. If the labial fusion is nearly complete, the female infant has external genitalia resembling a penis with hypospadias. In the *postnatal* period, CAH is associated with virilization in the female and isosexual precocity in the male. The excessive androgen levels result in accelerated growth, so that bone age exceeds chronologic age. Because epiphyseal closure is hastened by excessive androgens, growth stops, but truncal development continues, the characteristic appearance being a short child with a well-developed trunk.

The most common form ofCAH (95% of cases) is a result of impairment of CYP21A2. In addition to cortisol deficiency, aldosterone secretion is decreased in approximately one-third of the patients. Thus, with CYP21A2 deficiency, adrenal virilization occurs with or without a salt-losing tendency due to aldosterone deficiency (Fig. 331-2).

CYP11B1 deficiency causes a "hypertensive" variant ofCAH. Hypertension and hypokalemia occur because of the impaired conversion of 11-deoxycorticosterone to corticosterone, resulting in the accumulation of 11-deoxycorticosterone, a potent mineralocorticoid. The degree of hypertension is variable. Increased shunting again occurs into the androgen pathway.

CYP17 deficiency is characterized by hypogonadism, hypokalemia, and hypertension. This rare disorder causes decreased production of cortisol and shunting of precursors into the mineralocorticoid pathway with hypokalemic alkalosis, hypertension, and suppressed plasma renin activity. Usually, 11-deoxycorticosterone production is elevated. Because CYP17 hydroxylation is required for biosynthesis of both adrenal androgens and gonadal testosterone and estrogen, this defect is associated with sexual immaturity, high urinary gonadotropin levels, and low urinary 17-ketosteroid excretion. Female patients have primary amenorrhea and lack of development of secondary sexual characteristics. Because of deficient androgen production, male patients have either ambiguous external genitalia or a female phenotype (*male pseudohermaphroditism*). Exogenous glucocorticoids can correct the hypertensive syndrome, and treatment with appropriate gonadal steroids results in sexual maturation.

With 3b-HSD2 deficiency, conversion of pregnenolone to progesterone is impaired, so that the synthesis of both cortisol and aldosterone is blocked, with shunting into the adrenal androgen pathway via 17a-hydroxypregnenolone andDHEA. Because DHEA is a weak androgen, and because this enzyme deficiency is also present in the gonad, the genitalia of the male fetus may be incompletely virilized or feminized. Conversely, in the female, overproduction ofDHEA may produce partial virilization.

DIAGNOSIS The diagnosis ofCAHshould be considered in infants having episodes of acute adrenal insufficiency or salt-wasting or with hypertension. The diagnosis is further suggested by the finding of hypertrophy of the clitoris, fused labia, or a urogenital sinus in the female or of isosexual precocity in the male. In infants and children with a CYP21A2 defect, increased urine 17-ketosteroid excretion and increased plasmaDHEAsulfate levels are typically associated with an increase in the blood levels of 17-hydroxyprogesterone and the excretion of its urinary metabolite pregnanetriol. Demonstration of elevated levels of 17-hydroxyprogesterone in amniotic fluid at 14 to 16 weeks of gestation allows prenatal detection of affected female infants.

The diagnosis of a *salt-losing form* ofCAH due to defects in CYP21A2 is suggested by episodes of acute adrenal insufficiency with hyponatremia, hyperkalemia, dehydration, and vomiting. These infants and children often crave salt and have laboratory findings indicating deficits in both cortisol and aldosterone secretion.

With the *hypertensive form* ofCAH due to CYP11B1 deficiency, 11-deoxycorticosterone and 11-deoxycortisol accumulate. The diagnosis is confirmed by demonstrating increased levels of 11-deoxycortisol in the blood or increased amounts of tetrahydro-11-deoxycortisol in the urine. Elevation of 17-hydroxyprogesterone levels does not imply a coexisting CYP21A2 deficiency.

Very high levels of urineDHEAwith low levels of pregnanetriol and of cortisol metabolites

in urine are characteristic of children with 3b-HSD2 deficiency. Marked salt-wasting may also occur.

Adults with *late-onset adrenal hyperplasia* (partial deficiency of CYP21A2, CYP11B1, or 3b-HSD2) are characterized by normal or moderately elevated levels of urinary 17-ketosteroids and plasmaDHEAsulfate. A high basal level of a precursor of cortisol biosynthesis (such as 17-hydroxyprogesterone, 17-hydroxypregnenolone, or 11-deoxycortisol), or elevation of such a precursor afterACTHstimulation, confirms the diagnosis of a partial deficiency. Measurement of steroid precursors 60 min after bolus administration of ACTH is usually sufficient. Adrenal androgen output is easily suppressed by the standard low-dose (2 mg) dexamethasone test.

TREATMENT

Patients with CAHhave a fundamental defect of cortisol deficiency with resultant excessiveACTHsecretion, producing hyperplasia of the adrenal glands and causing additional shunting into the precursor steroid pathways. Therapy in these patients consists of daily administration of glucocorticoids to suppress pituitary ACTH secretion. Because of its cost and intermediate half-life, prednisone is the drug of choice except in infants, in whom hydrocortisone is usually used. In adults with late-onset adrenal hyperplasia, the smallest single bedtime dose of a long- or intermediate-acting glucocorticoid that suppresses pituitary ACTH secretion should be administered. The amount of steroid required by children with CAH is approximately 1 to 1.5 times the normal cortisol production rate of 27 to 35 umol (10 to 13 mg) of cortisol per square meter of body surface per day and is given in divided doses two or three times per day. The dosage schedule is governed by repetitive analysis of the urinary 17-ketosteroids, plasmaDHEAsulfate, and/or precursors of cortisol biosynthesis. Skeletal growth and maturation must also be monitored closely, as overtreatment with glucocorticoid replacement therapy retards linear growth.

Receptor Mutations Much less common thanCAH are three syndromes secondary to mutation(s) in a key receptor involved in adrenal function. *Isolated glucocorticoid deficiency* is a rare autosomal recessive disease secondary to a mutation in theACTHreceptor. Usually mineralocorticoid function is normal. Adrenal insufficiency is manifest within the first 2 years of life usually as hyperpigmentation, convulsions, and/or frequent episodes of hypoglycemia. In some patients the adrenal insufficiency is associated with achalasia and alacrima -- Allgrove's, or triple A, syndrome. However, in some triple A syndrome patients, no mutation in the ACTH receptor has been identified, suggesting that a distinct genetic abnormality causes this syndrome. *Adrenal hypoplasia congenita* is a rare X-linked disorder caused by a mutation in the *DAX1* gene located on the X chromosome. This gene encodes an orphan nuclear receptor that plays an important role in the development of the adrenal cortex and also the hypothalamic-pituitary-gonadal axis. Thus, patients present with signs and symptoms secondary to deficiencies of all three major adrenal steroids -- cortisol, aldosterone, and adrenal androgens -- as well as gonadotropin deficiency. Finally a rare cause of hypercortisolism without cushingoid stigmata is *primary cortisol resistance* due to mutations in the glucocorticoid receptor. The resistance is incomplete because patients do not exhibit signs of adrenal insufficiency. Thus, these three rare inherited disorders have in common an elevated ACTH. However, the clinical manifestations range from no

evidence of adrenal insufficiency to only cortisol deficiency (similar to secondary adrenal insufficiency) to a clinical picture indistinguishable from classic Addison's disease.

Miscellaneous Conditions Adrenoleukodystrophy causes severe demyelination and early death in children, and adrenomyeloneuropathy is associated with a mixed motor and sensory neuropathy with spastic paraplegia in adults; both disorders are associated with elevated circulating levels of very long chain fatty acids and cause adrenal insufficiency. Autosomal recessive mutations in the *st*eroidogenic *a*cute *r*egulatory (STAR) protein gene cause congenital lipoid adrenal hyperplasia (Chap. 338), which is characterized by adrenal insufficiency and defective gonadal steroidogenesis. Because STAR mediates cholesterol transport into the mitochondrion, mutations in the protein cause massive lipid accumulation in steroidogenic cells, ultimately leading to cell toxicity. Thus, these three rare inherited disorders have in common an elevated ACTH. However, the clinical manifestations range from no evidence of adrenal insufficiency to only cortisol deficiency (similar to secondary adrenal insufficiency) to a clinical picture indistinguishable from classic Addison's disease.

MINERALOCORTICOID DISEASES

Some forms ofCAH have a mineralocorticoid component (see above). Others are caused by a mutation in other enzymes or ion channels important in mediating or mimicking aldosterone's action.

Hypermineralocorticoidism

Low Plasma Renin Activity Rarely, hypermineralocorticoidism is due to a defect in cortisol biosynthesis, specifically 11- or 17-hydroxylation.ACTHlevels are increased, with a resultant increase in the production of the mineralocorticoid 11-deoxycorticosterone. Hypertension and hypokalemia can be corrected by glucocorticoid administration. The definitive diagnosis is made by demonstrating an elevation of precursors of cortisol biosynthesis in the blood or urine or by direct demonstration of the genetic defect.

Glucocorticoid administration can also ameliorate hypertension or produce normotension even though a hydroxylase deficiency cannot be identified (Fig. 331-9). These patients have normal to slightly elevated aldosterone levels that do not suppress in response to saline but do suppress in response to 2 days of dexamethasone (2 mg/d). The condition is inherited as an autosomal dominant trait and is termed *glucocorticoid-remediable aldosteronism* (GRA). This entity is secondary to a chimeric gene duplication whereby the 11-bhydroxylase gene promoter (which is under the control ofACTH) is fused to the aldosterone synthase coding sequence. Thus, aldosterone synthase activity is ectopically expressed in the zona fasciculata and is regulated by ACTH, in a fashion similar to the regulation of cortisol secretion. Screening for this defect is best performed by assessing the presence or absence of the chimeric gene. Because the abnormal gene may be present in the absence of hypokalemia, its frequency as a cause of hypertension is unknown. Individuals with suppressed plasma renin levels and juvenile-onset hypertension or a history of early-onset hypertension in first-degree relatives should be screened for this disorder. Early hemorrhagic stroke also occurs in GRA-affected individuals.

Glucocorticoid-remediable hyperaldosteronism documented by genetic analysis may be treated with glucocorticoid administration or antimineralocorticoids, e.g., spironolactone, triamterene, or amiloride. Glucocorticoids should be used only in small doses to avoid inducing iatrogenic Cushing's syndrome. A combination approach is often necessary.

High Plasma Renin Activity Bartter's syndrome is characterized by severe hyperaldosteronism (hypokalemic alkalosis) with moderate to marked increases in renin activity and hypercalciuria, but normal blood pressure and no edema; this disorder usually begins in childhood. Renal biopsy shows juxtaglomerular hyperplasia. The pathogenesis involves a defect in the renal conservation of sodium or chloride. The renal loss of sodium is thought to stimulate renin secretion and aldosterone production. Hyperaldosteronism produces potassium depletion, and hypokalemia further elevates prostaglandin production and plasma renin activity. In some cases, the hypokalemia may be potentiated by a defect in renal conservation of potassium. Increased production of prostaglandins is probably not a primary abnormality, since administration of inhibitors of prostaglandin synthesis reverses the features only temporarily (Chap. 276). Bartter's syndrome is caused by a mutation in the renal Na-K-2Cl co-transporter gene.

Gitelman's syndrome is an autosomal recessive trait characterized by renal salt wasting and as a result, as in Bartter's syndrome, activation of the renin-angiotensin-aldosterone system. As a consequence affected individuals have low blood pressure, low serum potassium, low serum magnesium, and high serum bicarbonate. In contrast to Bartter's syndrome, urinary calcium excretion is reduced. Gitelman's syndrome results from loss-of-function mutations of the renal thiazide-sensitive Na-Cl co-transporter.

Increased Mineralocorticoid Action Liddle's syndrome is a rare autosomal dominant disorder that mimicks hyperaldosteronism. The defect is in the genes encoding theb or g subunits of the epithelial sodium channel. Both renin and aldosterone levels are low, owing to the constitutively activated sodium channel and the resulting excess sodium reabsorption in the renal tubule.

A rare autosomal recessive cause of hypokalemia and hypertension is 11b-HSDII deficiency, in which cortisol cannot be converted to cortisone and hence binds to theMR and acts as a mineralocorticoid. This condition, also termed *apparent mineralocorticoid excess syndrome*, is caused by a defect in the gene encoding the renal isoform of this enzyme, 11b-HSD II. Patients can be identified either by documenting an increased ratio of cortisol to cortisone in the urine or by genetic analysis. Patients with the 11b-HSD deficiency syndrome can be treated with small doses of dexamethasone. Although dexamethasone is a potent glucocorticoid that suppressesACTH and endogenous cortisol production, it binds less well to the mineralocorticoid receptor than does cortisol.

The ingestion of candies or chewing tobacco containing certain forms of licorice produces a syndrome that mimics primary aldosteronism. The component of such agents that causes sodium retention is glycyrrhizinic acid, which inhibits the 11b-HSDII and hence allows cortisol to act as a mineralocorticoid and cause sodium retention, expansion of the extracellular fluid volume, hypertension, depressed plasma renin levels, and suppressed aldosterone levels. The diagnosis is established or excluded by

a careful history.

Decreased Mineralocorticoid Production or Action In patients with these conditions, disorders of aldosterone biosynthesis or action are associated with high renin levels, salt wasting, and hyperkalemia. The aldosterone levels may be low or elevated. In patients with a deficiency in aldosterone biosynthesis, the transformation of corticosterone into aldosterone is impaired, owing to a mutation in the aldosterone synthase (CYP11B2) gene. These patients have low to absent aldosterone secretion, elevated plasma renin levels, and elevated levels of the intermediates of aldosterone biosynthesis (corticosterone and 18-hydroxycorticosterone).

Pseudohypoaldosteronism type I (PHA-I) is an autosomal recessive disorder that is seen in the neonatal period and is characterized by salt wasting, hypotension, hyperkalemia, and high renin and aldosterone levels. In contrast to the gain-of-function mutations in the epithelial sodium channel (ENaC) in Liddle's syndrome, mutations in PHA-I result in loss of ENaC function.

NONSPECIFIC CLINICAL USE OF ADRENAL STEROIDS

The widespread use of glucocorticoids emphasizes the need for a thorough understanding of the metabolic effects of these agents. Before adrenal hormone therapy is instituted, the expected gains should be weighed against undesirable effects.

HOW SERIOUS IS THE DISORDER?

In a patient who has unexplained shock or in whom other measures have failed, the physician need not hesitate to employ high-dose steroid therapy. In contrast, one should exercise restraint in administering steroids to a patient with early rheumatoid arthritis for whom physiotherapy, anti-inflammatory agents, disease-modifying agents, and general medical care have not been tried (Chap. 312).

HOW LONG WILL GLUCOCORTICOID THERAPY BE REQUIRED?

The use of intravenous steroids for 24 to 48 h for a life-threatening situation such as status asthmaticus or pseudotumor cerebri has few or no contraindications, in contrast to the initiation of chronic steroid therapy for asthma, arthritis, or psoriasis. In the latter instances, the almost certain development of some degree of Cushing's syndrome must be weighed against the potential benefit. These side effects should be minimized by a careful choice of steroid preparations, alternate-day or interrupted therapy; the use of topical steroids, e.g., inhaled, intranasal, or dermal, whenever possible; and the judicious use of supplementary adjuvants.

WHICH PREPARATION IS BEST?

Several considerations should be taken into account in deciding which steroid preparation to use.

1. *The biologic half-life.* The rationale behind alternate-day therapy is to decrease the metabolic effects of the steroids for a significant part of each 48 h period while still

producing a pharmacologic effect durable enough to be effective. Too long a half-life would defeat the first purpose, and too short a half-life would defeat the second. In general, the more potent the steroid, the longer its biologic half-life.

2. *The importance of the mineralocorticoid effects of the steroid*. Most synthetic steroids have less mineralocorticoid effect than hydrocortisone (Table 331-9).

3. *The biologically active form of the steroid*. Cortisone and prednisone have to be converted to biologically active metabolites before anti-inflammatory effects can occur. Because of this, in a condition for which steroids are known to be effective and when an adequate dose has been given without response, one should consider substituting hydrocortisone or prednisolone for cortisone or prednisone.

4. *The cost of the medication*. This is a serious consideration if chronic administration is planned. Prednisone is the least expensive of available steroid preparations.

5. *The type of formulation*. Topical steroids have the distinct advantage over oral steroids in reducing the likelihood of systemic side effects. In addition, some inhaled steroids have been designed to minimize side effects by increasing their hepatic inactivation if they are swallowed (Chap. 252). However, all topical steroids can be absorbed into the systemic circulation.

EVALUATION OF PATIENTS PRIOR TO INITIATING STEROID THERAPY (SeeTable 331-10)

Chronic Infection Three issues demand attention: (1) Any active infection, particularly tuberculosis, should be identified. (2) If tuberculosis is present, steroid therapy should be employed only in conjunction with antituberculous chemotherapy. The chest film and tuberculin test provide baseline information for future comparison. Since high-dose steroids may impair the tuberculin reaction, serial chest roentgenograms may be necessary. (3) Infection due to opportunistic pathogens should be constantly considered in patients on steroid therapy, especially when combined with other immunosuppressive agents.

Diabetes Mellitus Prolonged glucocorticoid therapy may unmask or aggravate diabetes mellitus. The presence of diabetes mellitus or the demonstration of impaired glucose tolerance may affect the decision to institute glucocorticoid therapy.

Osteoporosis Patients receiving long-term steroid therapy are at risk for osteoporosis. Indeed, osteoporosis with vertebral fractures or compression is a dreaded complication for patients at high risk (postmenopausal women, elderly men, patients with restricted physical activity, and especially organ transplant patients who are maintained on high doses to prevent rejection). Alternate-day or interrupted steroid therapy does not prevent the risk of this complication (Table 331-11). Adjunctive therapies with antiresorptive agents, such as parenteral or oral bisphosphonates, have been shown to be effective in treating the osteoporosis (Chap. 342). Bone mineral density should be assessed periodically with dual-energy X-ray absorptiometry (DEXA) scans.

Peptic Ulcer, Gastric Hypersecretion, or Esophagitis In conventional doses

(equivalent to£15 mg prednisone per day), glucocorticoids probably do not cause peptic ulceration; whether higher doses cause ulcer disease is not established and probably depends on duration, dose of treatment, and predisposing factors such as hypoalbuminemia or cirrhosis and also whether subjects are concomitantly ingesting nonsteroidal anti-inflammatory agents (NSAIDs). However, even at conventional doses, patients with a history of ulcer may experience aggravation of symptoms while receiving glucocorticoids. Consequently, all individuals with a positive history or with known risk factors should be managed with a vigorous antiulcer program (antacids, H_2receptor antagonists, or ATPase inhibitors) along with glucocorticoids. *The development of anemia in a patient receiving glucocorticoids should suggest gastrointestinal bleeding as a cause*.

Hypertension or Cardiovascular Disease The capacity of many adrenal steroid preparations to promote sodium retention makes it necessary to exercise caution when using them in patients with preexisting hypertension or cardiovascular or renal disease. The use of preparations with minimal sodium-retaining activity, restriction of dietary sodium intake, and the use of diuretic agents and supplementary potassium salts minimize the mineralocorticoid effects of steroids. However, hypertension may be exacerbated by steroid-induced increases in renin substrate and angiotensin II levels and by reduction in vasodilator prostaglandin production. Steroids also accelerate atherogenesis by induction of hypertension, glucose intolerance, and unfavorable lipid profiles. Glucocorticoid-associated lipid abnormalities include hypertriglyceridemia, hypercholesterolemia, and increasedLDLcholesterol levels.

Psychological Difficulties Steroid therapy may cause psychological disturbances. In general, these disturbances correlate better with the patient's personality than with the dose of hormone, although larger doses cause more serious reactions. There is no reliable method of predicting the psychological reaction to steroid therapy; moreover, previous tolerance of steroids does not necessarily ensure the safety of subsequent courses. Likewise, untoward psychological reactions on one occasion do not invariably mean that the patient will respond unfavorably to a second course. However, patients with depressive symptoms during a first course of steroids may benefit from prophylactic treatment prior to a second course.

Sleeplessness is common and can be minimized by using the shorter-acting steroids and by prescribing the total daily amount as a single early-morning dose.

ALTERNATE-DAY STEROID THERAPY

The most effective way to minimize the cushingoid effects of glucocorticoids is to administer the total 48-h dose as a *single* dose of *intermediate-acting steroid* in the morning, *every other day*. If symptoms of the underlying disorder can be controlled by this technique, it offers distinct advantages. Three considerations deserve mention: (1) The alternate-day schedule may be approached through transition schedules that allow the patient to adjust gradually; (2) supplementary nonsteroid medications may be needed on the "off" day to minimize symptoms of the underlying disorder; and (3) many symptoms that occur during the off day (e.g., fatigue, joint pain, muscle stiffness or tenderness, and fever) may represent relative adrenal insufficiency rather than exacerbation of the underlying disease.

The alternate-day approach capitalizes on the fact that cortisol secretion and plasma levels normally are highest in the early morning and lowest in the evening. The normal pattern is mimicked by administering an intermediate-acting steroid in the morning (7 to 8 A.M.) (Table 331-9).

Initially, the steroid program often requires daily or more frequent doses of steroid to achieve the desired anti-inflammatory or immunity-suppressing action. *Only after this desired effect is achieved is an attempt made to switch to an alternate-day program.* A number of schedules can be used for transferring from a daily to an alternate-day program. The key points to be considered are flexibility in arranging a program and the use of supportive measures on the off day. One may attempt a gradual transition to the alternate-day schedule rather than an abrupt changeover. One approach is to keep the steroid dose constant on one day and gradually reduce it on the alternate day. Alternatively, the steroid dose can be increased on one day and reduced on the alternate day. In any case, it is important to anticipate that some increase in pain or discomfort may occur in the 36 to 48 h following the last dose.

WITHDRAWAL OF GLUCOCORTICOIDS FOLLOWING LONG-TERM USE

It is possible to reduce gradually and eventually to discontinue a daily steroid dose, but under most circumstances withdrawal of steroids should be initiated by first implementing an alternate-day schedule. Patients who have been on an alternate-day program for a month or more experience less difficulty during termination regimens. The dosage is gradually reduced and finally discontinued after a replacement dosage has been reached (e.g., 5 to 7.5 mg prednisone). Complications rarely ensue unless undue stress is experienced, and patients should understand that for 1 year or longer after withdrawal from long-term high-dose steroid therapy, supplementary hormone should be given in the event of a serious infection, operation, or injury. A useful strategy in patients with symptoms of adrenal insufficiency on a tapering regimen is to measure plasma cortisol levels prior to the steroid dose. A level<140 nmol/L (5 ug/dL) indicates continuing suppression of the pituitary-adrenal axis and implies that a more cautious tapering of steroids is indicated.

In patients on high-dose daily steroid therapy, it is advised to reduce dosage to approximately 20 mg prednisone daily as a single morning dose before beginning the transition to alternate-day therapy. If a patient cannot tolerate an alternate-day program, consideration should be given to the possibility that the patient has developed primary adrenal insufficiency.

(Bibliography omitted in Palm version)

Back to Table of Contents

332. PHEOCHROMOCYTOMA - *Lewis Landsberg*, *James B. Young*

Pheochromocytomas produce, store, and secrete catecholamines. They are usually derived from the adrenal medulla but may develop from chromaffin cells in or about sympathetic ganglia (extraadrenal pheochromocytomas or paragangliomas). Related tumors that secrete catecholamines and produce similar clinical syndromes include chemodectomas derived from the carotid body and ganglioneuromas derived from the postganglionic sympathetic neurons.

The clinical features are due predominantly to the release of catecholamines and, to a lesser extent, to the secretion of other substances. Hypertension is the most common sign, and hypertensive paroxysms or crises, often spectacular and alarming, occur in over half the cases.

Pheochromocytoma occurs in approximately 0.1% of the hypertensive population but is, nevertheless, an important correctable cause of high blood pressure. Indeed, it is usually curable if properly diagnosed and treated, but it may be fatal if undiagnosed or mistreated. Postmortem series indicate that most pheochromocytomas are unsuspected clinically, even when the tumor is related to the fatal outcome.

PATHOLOGY

Location and Morphology In adults, approximately 80% of pheochromocytomas are unilateral and solitary, 10% are bilateral, and 10% are extraadrenal. In children, a fourth of tumors are bilateral, and an additional fourth are extraadrenal. Solitary lesions inexplicably favor the right side. Although pheochromocytomas may grow to large size (over 3 kg), most weigh less than 100 g and are less than 10 cm in diameter. The tumors are highly vascular.

The tumors are made up of large, polyhedral, pleomorphic chromaffin cells. Less than 10% of these tumors are malignant. As with other endocrine tumors, malignancy cannot be determined from the histologic appearance; tumors that contain large numbers of aneuploid or tetraploid cells, as determined by flow cytometry, are more likely to recur. Local invasion of surrounding tissues or distant metastases indicate malignancy.

Extraadrenal Pheochromocytomas Extraadrenal pheochromocytomas usually weigh 20 to 40 g and are <5 cm in diameter. Most are located within the abdomen in association with the celiac, superior mesenteric, and inferior mesenteric ganglia. Approximately 10% are in the thorax, 1% are within the urinary bladder, and <3% are in the neck, usually in association with the sympathetic ganglia or the extracranial branches of the ninth or tenth cranial nerves.

Catecholamine Synthesis, Storage, and Release Pheochromocytomas synthesize and store catecholamines by processes resembling those of the normal adrenal medulla (Chap. 72). Little is known about the mechanisms of catecholamine release from pheochromocytomas, but changes in blood flow and necrosis within the tumor may be the cause in some instances. These tumors are not innervated, and catecholamine release does not result from neural stimulation. Pheochromocytomas also store and secrete a variety of peptides, including endogenous opioids, adrenomedullin,

endothelin, erythropoietin, parathyroid hormone-related protein, neuropeptide Y, and chromagranin A (Chap. 72). These peptides contribute to the clinical manifestations in selected cases, as noted below.

Epinephrine, Norepinephrine, and Dopamine Most pheochromocytomas contain and secrete both norepinephrine and epinephrine, and the percentage of norepinephrine is usually greater than in the normal adrenal. Most extraadrenal pheochromocytomas secrete norepinephrine exclusively. Rarely, pheochromocytomas produce epinephrine alone, particularly in association with multiple endocrine neoplasia (MEN). Although epinephrine-producing tumors may cause a preponderance of metabolic and beta-receptor effects, in general the major catecholamine secreted cannot be predicted from the clinical presentation. Increased production of dopamine and homovanillic acid (HVA) is uncommon with benign lesions but may occur with malignant pheochromocytoma.

FAMILIAL PHEOCHROMOCYTOMA

In approximately 5% of cases, pheochromocytoma is inherited as an autosomal dominant trait either alone or in combination with other abnormalities such asMEN type 2a (Sipple's syndrome) or type 2b (mucosal neuroma syndrome) (Chap. 339), von Hippel-Lindau's retinal cerebellar hemangioblastomosis, or von Recklinghausen's neurofibromatosis. Bilateral adrenal pheochromocytomas are common in the familial syndromes; within MEN kindreds, over half of pheochromocytomas are bilateral. A familial syndrome should be suspected in any patient with bilateral pheochromocytomas.

GENETIC CONSIDERATIONS

Several molecular genetic abnormalities have been identified in the familial pheochromocytoma syndromes. The MEN2A and B syndromes are associated with abnormalities in the RET protooncogene located in pericentromeric region of chromosome 10 (Chap. 339). These mutations result in the constitutive activation of the receptor tyrosine kinase exposing adrenal medullary chromaffin cells and parafollicular C cells to hyperplasia and rendering them susceptible to malignant transformation. The RET mutations are located in the extracellular domain in MEN 2A and in the intracellular portion of the receptor in families with the MEN 2B syndrome. Interestingly, mutations at specific sites in the RET protooncogene are highly predictive of pheochromocytoma. The different phenotypic manifestations of the syndrome in different families, therefore, reflect differences in the specific mutations.

In the von Hippel-Landau (VHL) syndrome, mutation of one copy of the VHL tumor suppressor gene is associated with the development of tumors characteristic of the syndrome including pheochromocytomas. Loss of function of the VHL tumor suppressor gene promotes tumor formation by mechanisms that are incompletely understood but may involve mRNA transcript elongation. In the VHL syndrome, the frequency of pheochromocytoma varies considerably in different kindreds. As in theMEN 2 syndromes, certain VHL mutations are highly associated with the development of pheochromocytoma. Of further interest is the recent finding that the VHL mutation has been identified in some kindreds with familial pheochromocytoma as the sole

manifestation without other clinical evidence of the VHL syndrome. Missense mutations, as opposed to deletions, insertions, or non-sense mutations, appear to be more commonly associated with pheochromocytoma. There is also a high incidence of germ-line VHL mutations in patients with thoracic extraadrenal pheochromocytomas.

Interestingly, neither the RET protooncogene nor the VHL mutation occurs commonly as a somatic mutation in sporadic pheochromocytomas. Screening apparently sporadic cases, however, may uncover a germ-line mutation and lead to the identification of an involved family that was unsuspected on clinical grounds.

CLINICAL FEATURES

Pheochromocytoma occurs at all ages but is most common in young to midadult life. Some series show a slight female preponderance. Most patients come to medical attention as a result of hypertensive crisis, paroxysmal symptoms suggestive of seizure disorder or anxiety attacks, or hypertension that responds poorly to conventional treatment. Less commonly, unexplained hypotension or shock in association with surgery or trauma will suggest the diagnosis. Most patients have hypertension in association with headaches, excessive sweating, and/or palpitations.

Hypertension Hypertension is the most common manifestation. In approximately 60% of cases the hypertension is sustained, although significant blood pressure lability is usually present, and half of patients with sustained hypertension have distinct crises or paroxysms. The other 40% have blood pressure elevations only during an attack. The hypertension is often severe, occasionally malignant, and may be resistant to treatment with standard antihypertensive drugs.

Paroxysms or Crises The paroxysm or crisis occurs in over half of patients. In an individual patient, the symptoms are often similar with each attack. The paroxysms may be frequent or sporadic, occurring at intervals as long as weeks or months. With time, the paroxysms usually increase in frequency, duration, and severity.

The attack usually has a sudden onset. It may last from a few minutes to several hours or longer. Headache, profuse sweating, palpitations, and apprehension, often with a sense of impending doom, are common. Pain in the chest or abdomen may be associated with nausea and vomiting. Either pallor or flushing may occur during the attack. The blood pressure is elevated, often to alarming levels, and the elevation is usually accompanied by tachycardia.

The paroxysm may be precipitated by any activity that displaces the abdominal contents. In some cases a particular stimulus may induce an attack in a characteristic fashion, but in others no clearly defined precipitating event can be found. Although anxiety may accompany the attacks, mental or psychological stress does not usually provoke a crisis.

Other Distinctive Clinical Features Symptoms and signs of an increased metabolic rate, such as profuse sweating and mild to moderate weight loss, are common. Orthostatic hypotension is a consequence of diminished plasma volume and blunted sympathetic reflexes. Both these factors predispose the patient with unsuspected

pheochromocytoma to hypotension or shock during surgery or trauma. Secretion of the hypotensive peptide adrenomedullin may contribute to the hypotension in some patients.

Cardiac Manifestations Sinus tachycardia, sinus bradycardia, supraventricular arrhythmias, and ventricular premature contractions all have been noted. Angina and acute myocardial infarction may occur even in the absence of coronary artery disease. A catecholamine-induced increase in myocardial oxygen consumption and, perhaps, coronary spasm may play a role in these ischemic events. Electrocardiographic changes, including nonspecific ST-T wave changes, prominent U waves, left ventricular strain patterns, and right and left bundle branch blocks may be present in the absence of demonstrable ischemia or infarction. Cardiomyopathy, either congestive with myocarditis and myocardial fibrosis or hypertrophic with concentric or asymmetric hypertrophy, may be associated with heart failure and cardiac arrhythmias. Multiorgan system failure with noncardiogenic pulmonary edema may be the presenting manifestation. Elevated levels of amylase originating from damaged pulmonary endothelium and abdominal pain may suggest acute pancreatitis, although serum lipase levels are normal.

Carbohydrate Intolerance Over half of patients have impaired carbohydrate tolerance due to suppression of insulin and stimulation of hepatic glucose output. The impaired glucose tolerance rarely requires treatment with insulin and disappears after removal of the tumor.

Hematocrit The elevated hematocrit is secondary to diminished plasma volume. Rarely, production of erythropoietin by the tumor may cause a true erythrocytosis.

Other Manifestations Hypercalcemia has been attributed to the ectopic secretion of parathyroid hormone-related protein. Fever and an elevated erythrocyte sedimentation rate have been reported in association with the production of interleukin 6. Elevated temperature more commonly reflects catecholamine-mediated increases in metabolic rate and diminished heat dissipation secondary to vasoconstriction. Polyuria is an occasional finding, and rhabdomyolysis with myoglobinuric renal failure may result from extreme vasoconstriction with muscle ischemia.

Pheochromocytoma of the Urinary Bladder Pheochromocytoma in the wall of the urinary bladder may result in typical paroxysms in relation to micturition. The location in the bladder wall is responsible for the occurrence of symptoms while the tumors are quite small, and, consequently, catecholamine excretion may be normal or minimally elevated. Hematuria is present in over half of patients, and the tumor can often be visualized at cystoscopy.

Adverse Drug Interactions Severe and occasionally fatal paroxysms have been induced by opiates, histamine, adrenocorticotropin, saralasin, and glucagon. These agents appear to release catecholamines directly from the tumor. Indirect-acting sympathomimetic amines, including methyldopa (when administered intravenously), may cause an increase in blood pressure by releasing catecholamines from the augmented stores within nerve endings. Drugs that block neuronal uptake of catecholamines, such as tricyclic antidepressants or guanethidine, may enhance the

physiologic effects of circulating catecholamines. Indeed, all medications should be considered carefully and administered cautiously in patients with known or suspected pheochromocytoma.

Associated Diseases Pheochromocytoma is associated with medullary carcinoma of the thyroid in theMENsyndrome types 2a and 2b and with hyperparathyroidism in MEN 2a (Chap. 339). Hypercalcemia, resolving after tumor resection, also has been described in the absence of parathyroid disease, as described above. Individuals at risk for MEN 2a and 2b should be screened periodically for pheochromocytoma by assay of a 24-h urine sample for catecholamines, including measurement of epinephrine. Pheochromocytoma should be excluded or removed before thyroid or parathyroid surgery.

The association of pheochromocytoma and neurofibromatosis is not common. Nevertheless, since incomplete forms of neurofibromatosis may be associated with pheochromocytoma, minor manifestations such as cafe au lait spots, vertebral abnormalities, or kyphoscoliosis should increase the suspicion of pheochromocytoma in a patient with hypertension. The incidence of pheochromocytoma in some kindreds with von Hippel-Lindau disease may be as high as 10 to 25%. Many of these are unsuspected clinically and diagnosed on a computed tomography (CT) scan or at postmortem.

The incidence of cholelithiasis is 15 to 20%. Cushing's syndrome is a rare association, usually a consequence of ectopic secretion of adrenocorticotropic hormone by the pheochromocytoma or, less commonly, by a coexistent medullary carcinoma of the thyroid.

Diagnosis The diagnosis is established by the demonstration of increased excretion of catecholamines or catecholamine metabolites. The diagnosis can usually be made by the analysis of a single 24-h urine sample, provided the patient is hypertensive or symptomatic at the time of collection.

Biochemical Tests The assays employed include those for vanillylmandelic acid (VMA), the metanephrines, and unconjugated or "free" catecholamines (Chap. 72). The VMA assay is both less sensitive and less specific than assays of metanephrines or catecholamines. Accuracy of diagnosis is improved when two of three determinations are employed. The following considerations apply to all the urinary tests: (1) Despite claims for the adequacy of determinations made on random urine samples, analysis of a full 24-h urine sample is preferable. Creatinine should also be determined to assess the adequacy of collection. (2) Where possible, the collection should be made when the patient is at rest, on no medication, and without recent exposure to radiographic contrast media. When it is not practical to discontinue all medications, drugs known specifically to interfere with these assays (as noted below) should be avoided. (3) The urine should be acidified and refrigerated during and after collection. (4) With high-quality assays, dietary restrictions are minimal and should be specified by the laboratory performing the analyses. (5) Although most patients with pheochromocytoma excrete increased amounts of catecholamines and catecholamine metabolites at all times, the yield is increased in patients with paroxysmal hypertension if a 24-h urine collection is initiated during a crisis.

Free Catecholamines The upper limit of normal for total urinary catecholamines is between 590 and 885 nmol (100 and 150 ug) per 24 h. In most patients with pheochromocytoma, values in excess of 1480 nmol (250 ug) per day are obtained. Measurement of epinephrine is often of value, since increased epinephrine excretion [over 275 nmol (50 ug) per 24 h] is usually due to an adrenal lesion and may be the only abnormality in cases associated withMEN. False-positive increases in catecholamine excretion result from exogenous catecholamines and related drugs such as methyldopa, levodopa, labetalol, and sympathomimetic amines, which may elevate catecholamine excretion for up to 2 weeks. Endogenous catecholamines from stimulation of the sympathoadrenal system also may increase urinary catecholamine excretion. Relevant clinical situations that cause such increases include hypoglycemia, strenuous exertion, central nervous system disease with increased intracranial pressure, severe hypoxia, and clonidine withdrawal.

Metanephrines and VMA In most laboratories, the upper limit of normal is 7 umol (1.3 mg) of total metanephrines and 35 umol (7.0 mg) ofVMAexcretion per 24 h. In most patients with pheochromocytoma, the increase in these urinary metabolites is considerable, often to more than three times the normal range. Metanephrine excretion is increased by exogenous and endogenous catecholamines and by treatment with monoamine oxidase inhibitors; propranolol may cause a spurious increase in metanephrine excretion, since a propranolol metabolite interferes in the commonly used spectrophotometric assay. VMA is less affected by endogenous and exogenous catecholamines but is spuriously increased by a variety of drugs, including carbidopa. VMA excretion is decreased by monoamine oxidase inhibitors.

Plasma Catecholamines Measurement of plasma catecholamines has a limited application. The care required in obtaining basal levels (Chap. 72) and the satisfactory results with urinary determinations make measurement of plasma catecholamines unnecessary in most cases. Plasma catecholamine levels are affected by the same drugs and physiologic perturbations that increase urinary catecholamine excretion. In addition, a- andb-adrenergic receptor blocking agents may elevate plasma catecholamines by impairing clearance.

When the clinical features suggest pheochromocytoma and the urinary assay results are borderline, measurement of plasma catecholamines may be worthwhile. Markedly elevated basal levels of total catecholamines support the diagnosis, although approximately one-third of patients with pheochromocytoma have normal or slightly elevated basal values. The usefulness of plasma catecholamine determinations may be increased by agents that suppress sympathetic nervous system activity. Clonidine and ganglionic blocking agents (Chap. 72) reduce plasma catecholamine levels in normal subjects and in patients with essential hypertension. These drugs have little effect on catecholamine levels in patients with pheochromocytoma. In patients with elevated or borderline basal catecholamine values, failure to suppress plasma or urinary levels with clonidine supports the diagnosis of pheochromocytoma.

Pharmacologic Tests Reliable methods for the measurement of catecholamines and catecholamine metabolites in urine have rendered obsolete both the provocative and adrenolytic tests, which are nonspecific and entail considerable risk. A modified version

of the adrenolytic test may be of some use, however, as a therapeutic trial in a patient in hypertensive crisis with features suggestive of pheochromocytoma. A positive response to phentolamine (5-mg bolus following a test dose of 0.5 mg) is a reduction in blood pressure of at least 35/25 mmHg that peaks after 2 min and persists for 10 to 15 min. The pharmacologic response is never diagnostic, and biochemical confirmation is essential. Provocative tests in normotensive patients are potentially dangerous and rarely indicated. However, a glucagon provocative test may be of use in patients with paroxysmal hypertension and nondiagnostic basal catecholamine levels. Glucagon has a negligible effect on blood pressure or plasma catecholamine levels in normal or hypertensive subjects. In patients with pheochromocytoma, on the other hand, glucagon may increase both blood pressure and circulating catecholamine levels. The elevation in plasma catecholamine concentration, moreover, may occur without a blood pressure response. It must be emphasized, however, that life-threatening pressor crises have occurred after administration of glucagon to patients with pheochromocytoma, so the test should never be performed casually. Careful continuous monitoring of the blood pressure is required, intravenous access must be adequate, and phentolamine must be at hand to terminate the test if a significant pressor reaction ensues.

Differential Diagnosis Since the manifestations of pheochromocytoma can be protean, the diagnosis must be considered and excluded in many patients with suggestive clinical features. In patients with essential hypertension and "hyperadrenergic" features such as tachycardia, sweating, and increased cardiac output, and in patients with anxiety attacks associated with blood pressure elevations, analysis of a 24-h urine collection is usually decisive in excluding the diagnosis. Repeated determinations on urine collected during attacks may be necessary, however, before the diagnosis can be excluded with certainty. The clonidine suppression and glucagon stimulation tests may be helpful in excluding the diagnosis in difficult cases. Pressor crises associated with clonidine withdrawal and the use of cocaine or monoamine oxidase inhibitors (Chap. 72) may mimic the paroxysms of pheochromocytoma. Factitious crises may be produced by self-administration of sympathomimetic amines in psychiatrically disturbed patients.

Intracranial lesions, particularly posterior fossa tumors or subarachnoid hemorrhage, may cause hypertension and increased excretion of catecholamines or catecholamine metabolites. While this is most common in patients with an obvious neurologic catastrophe, the possibility of subarachnoid or intracranial hemorrhage secondary to pheochromocytoma should be considered. Diencephalic or autonomic epilepsy may be associated with paroxysmal spells, hypertension, and increased plasma catecholamine levels. This rare entity may be difficult to distinguish from pheochromocytoma, but an aura, an abnormal electroencephalogram, and a beneficial response to anticonvulsant medications will often suggest the proper diagnosis.

TREATMENT

Preoperative Management The induction of stable a-adrenergic blockade is the basis of preoperative management and provides the foundation for successful surgical treatment. Once the diagnosis is established, the patient should be placed on phenoxybenzamine to induce a long-lived, noncompetitivea-receptor blockade. The usual initial dose is 10 mg every 12 h with increments of 10 to 20 mg added every few days until the blood pressure is controlled and the paroxysms disappear. Because of the

long duration of action, the therapeutic effects are cumulative, and the optimal dose must be achieved gradually with careful monitoring of supine and upright blood pressures. Most patients require between 40 and 80 mg phenoxybenzamine per day, although 200 mg or more may be necessary. Phenoxybenzamine should be administered for at least 10 to 14 days prior to surgery. Over this time, the combination of a-receptor blockade and a liberal salt intake will restore the contracted plasma volume to normal. Before adequatea-adrenergic blockade with phenoxybenzamine is achieved, paroxysms may be treated with oral prazosin or noncompetitive intravenous phentolamine. Selectivea$_1$antagonists have been employed for preoperative preparation, but their role in preparative management should be limited to the treatment of individual paroxysms. They may be useful as antihypertensive agents in patients with suspected pheochromocytoma while workup is in progress, since they are usually better tolerated than phenoxybenzamine and will prevent serious pressor crises if pheochromocytoma is present. Nitroprusside, calcium channel blocking agents, and possibly angiotensin-converting enzyme inhibitors reduce blood pressure in patients with pheochromocytoma. Nitroprusside may also be useful in the treatment of pressor crises.

b-Adrenergic receptor blocking agents should be given only after alpha blockade has been induced, since administration of such agents by themselves may cause a paradoxic increase in blood pressure by antagonizing beta-mediated vasodilation in skeletal muscle. Beta blockade is usually initiated when tachycardia develops during the induction of a-adrenergic blockade. Low doses often suffice, and a reasonable starting dose is 10 mg propranolol three to four times per day, increased as needed to control the pulse rate. Beta blockade is effective for catecholamine-induced arrhythmias, particularly those potentiated by anesthetic agents.

Preoperative Localization of the Tumor Surgical removal of pheochromocytoma is facilitated if the location of the tumor or tumors can be established preoperatively. Once pheochromocytoma is diagnosed, localization should be undertaken while the patient is being prepared for surgery.CT or magnetic resonance imaging (MRI) of the adrenals is usually successful in identifying intraadrenal lesions. Extraadrenal tumors within the chest can frequently be identified by conventional chest films or CT. MRI is useful in identifying extraadrenal tumors in the abdomen. If these studies are negative, abdominal aortography (once a-adrenergic blockade is complete) may identify extraadrenal pheochromocytomas in the abdomen, since these lesions are often supplied by a large aberrant artery. If aortography, CT, and MRI fail to localize the lesion, venous sampling at different levels of the inferior and superior vena cava may reveal catecholamine gradients in the region drained by the tumor; this area may then be restudied by selective angiography or scanning by CT or MRI. An additional localization technique involves a radionuclide scintiscan after administration of the radiopharmaceutical [^{131}I]metaiodobenzylguanidine (MIBG). This agent is concentrated by the amine uptake process and produces an external scintigraphic image at the site of the tumor. This type of scanning may be useful in characterizing lesions discovered by CT when biochemical confirmation is indeterminate, as well as in localizing extraadrenal pheochromocytomas. Percutaneous fine-needle aspiration of chromaffin tumors is contraindicated; indeed, pheochromocytoma should be considered before any adrenal lesions are aspirated.

Surgery Surgical treatment of pheochromocytoma is best performed in centers with experience in the preoperative, anesthetic, and intraoperative management of pheochromocytoma. In experienced hands, surgical mortality is<2 or 3%.

Monitoring during the surgical procedure should include continuous recording of arterial pressure and central venous pressure as well as electrocardiography; in the presence of cardiac disease or if congestive failure has been present, pulmonary capillary wedge pressure should be monitored. Adequate fluid replacement is crucial. Intraoperative hypotension responds better to volume replacement than to vasoconstrictors. Hypertension and cardiac arrhythmias are most likely during induction of anesthesia, intubation, and manipulation of the tumor. Intravenous phentolamine is usually sufficient to control the blood pressure, but nitroprusside may be required. Propranolol may be given in the treatment of tachycardia or ventricular ectopy.

Pheochromocytoma in Pregnancy Spontaneous labor and vaginal delivery in unprepared patients are usually disastrous for mother and fetus. In early pregnancy, the patient should be prepared with phenoxybenzamine, and the tumor should be removed as soon as the diagnosis is confirmed. The pregnancy need not be terminated, but the operative procedure itself may result in spontaneous abortion. In the third trimester, treatment with adrenergic blocking agents should be undertaken; when the fetus is of sufficient size, cesarean section may be followed by extirpation of the tumor. Although the safety of adrenergic blocking drugs in pregnancy is not established, these agents have been administered in several cases without obvious adverse effect. Antepartum diagnosis and treatment lowers the maternal death rate to that approaching nonpregnant pheochromocytoma patients; fetal death rate, however, remains elevated.

Unresectable and Malignant Tumors In cases of metastatic or locally invasive tumor in patients with intercurrent illness that precludes surgery, long-term medical management is required. When the manifestations cannot be adequately controlled by adrenergic blocking agents, the concomitant administration of metyrosine may be required. This agent inhibits tyrosine hydroxylase, diminishes catecholamine production by the tumor, and often simplifies chronic management. Malignant pheochromocytoma frequently recurs in the retroperitoneum, and it metastasizes most commonly to bone and lung. Although these malignant tumors are resistant to radiotherapy, combination chemotherapy has had limited success in controlling them. Use of ^{131}I-MIBG has had limited success in the treatment of malignant pheochromocytoma, due to poor uptake of the radioligand.

PROGNOSIS AND FOLLOW-UP

The 5-year survival rate after surgery is usually over 95%, the recurrence rate is<10%. After successful surgery, catecholamine excretion returns to normal in about 2 weeks and should be measured to ensure complete tumor removal. Catecholamine excretion should be assessed at the reappearance of suggestive symptoms or yearly if the patient remains asymptomatic. For malignant pheochromocytoma, the 5-year survival rate is<50%.

Complete removal cures the hypertension in approximately three-fourths of patients. In the remainder, hypertension recurs but is usually well controlled by standard

antihypertensive agents. In this group, either underlying essential hypertension or irreversible vascular damage induced by catecholamines may cause the persistence of the hypertension.

333. DIABETES MELLITUS - *Alvin C. Powers*

Diabetes mellitus (DM) comprises a group of common metabolic disorders that share the phenotype of hyperglycemia. Several distinct types of DM exist and are caused by a complex interaction of genetics, environmental factors, and life-style choices. Depending on the etiology of the DM, factors contributing to hyperglycemia may include reduced insulin secretion, decreased glucose usage, and increased glucose production. The metabolic dysregulation associated with DM causes secondary pathophysiologic changes in multiple organ systems that impose a tremendous burden on the individual with diabetes and on the health care system. In the United States, DM is the leading cause of end-stage renal disease, nontraumatic lower extremity amputations, and adult blindness. With an increasing incidence worldwide, DM will likely continue to be a leading cause of morbidity and mortality for the foreseeable future.

CLASSIFICATION

Recent advances in the understanding of the etiology and pathogenesis of diabetes have led to a revised classification (Table 333-1). Although all forms ofDM are characterized by hyperglycemia, the pathogenic mechanisms by which hyperglycemia arises differ widely. Some forms of DM are characterized by an absolute insulin deficiency or a genetic defect leading to defective insulin secretion, whereas other forms share insulin resistance as their underlying etiology. Recent changes in classification reflect an effort to classify DM on the basis of the pathogenic process that leads to hyperglycemia, as opposed to criteria such as age of onset or type of therapy (Fig. 333-1).

The two broad categories ofDM are designated type 1 and type 2. Type 1A DM results from autoimmune beta cell destruction, which usually leads to insulin deficiency. Type 1B DM is also characterized by insulin deficiency as well as a tendency to develop ketosis. However, individuals with type 1B DM lack immunologic markers indicative of an autoimmune destructive process of the beta cells. The mechanisms leading to beta cell destruction in these patients are unknown. Relatively few patients with type 1 DM fall into the type 1B idiopathic category; many of these individuals are either African-American or Asian in heritage.

Type 2DM is a heterogeneous group of disorders usually characterized by variable degrees of insulin resistance, impaired insulin secretion, and increased glucose production. Distinct genetic and metabolic defects in insulin action and/or secretion give rise to the common phenotype of hyperglycemia in type 2 DM (see below). The identification of distinct pathogenic processes in type 2 DM has important potential therapeutic implications, as pharmacologic agents that target specific metabolic derangements become available.

Two features of the current classification ofDMdiverge from previous classifications. First, the terms *insulin-dependent diabetes mellitus* (IDDM) and *noninsulin-dependent diabetes mellitus* (NIDDM) are obsolete. These previous designations reflected the observation that most individuals with type 1 DM (previously IDDM) have an absolute requirement for insulin treatment, whereas many individuals with type 2 DM (previously NIDDM) do not require insulin therapy to prevent ketoacidosis. However, because many

individuals with type 2 DM eventually require insulin treatment for control of glycemia, the use of the latter term generated considerable confusion.

A second difference is that age is no longer used as a criterion in the new classification system. Although type 1DM most commonly develops before the age of 30, an autoimmune beta cell destructive process can develop at any age. In fact, it is estimated that between 5 and 10% of individuals who develop DM after age 30 have type 1A DM. Likewise, although type 2 DM more typically develops with increasing age, it also occurs in children, particularly in obese adolescents.

OTHER TYPES OF DM

Other etiologies forDMinclude specific genetic defects in insulin secretion or action, metabolic abnormalities that impair insulin secretion, and a host of conditions that impair glucose tolerance (Table 333-1). *Maturity onset diabetes of the young* (MODY) is a subtype of DM characterized by autosomal dominant inheritance, early onset of hyperglycemia, and impairment in insulin secretion (discussed below). Mutations in the insulin receptor cause a group of rare disorders characterized by severe insulin resistance.

DMcan result from pancreatic exocrine disease when the majority of pancreatic islets (>80%) are destroyed. Several endocrinopathies can lead to DM as a result of excessive secretion of hormones that antagonize the action of insulin. Notable within this group are acromegaly and Cushing's disease, both of which may present with DM. Viral infections have been implicated in pancreatic islet destruction, but are an extremely rare cause of DM. Congenital rubella greatly increases the risk for DM; however, most of these individuals also have immunologic markers indicative of autoimmune beta cell destruction.

GESTATIONAL DIABETES MELLITUS (GDM)

Glucose intolerance may develop and first become recognized during pregnancy. Insulin resistance related to the metabolic changes of late pregnancy increases insulin requirements and may lead to hyperglycemia or impaired glucose tolerance. GDM is seen in approximately 4% of pregnancies in the United States; most women revert to normal glucose tolerance post-partum but have a substantial risk (30 to 60%) of developingDM later in life.

EPIDEMIOLOGY

The worldwide prevalence ofDM has risen dramatically over the past two decades. It is projected that the number of individuals with DM will continue to increase in the near future. Between 1976 and 1994, for example, the prevalence of DM among adults in the United States increased from 8.9% to 12.3%. These findings, based on national epidemiologic data, include individuals with a diagnosis of DM and those with undiagnosed DM (based on identical diagnostic criteria). Likewise, prevalence rates of impaired fasting glucose (IFG) increased from 6.5% to 9.7% over the same period. Although the prevalence of both type 1 and type 2 DM is increasing worldwide, the prevalence of type 2 DM is expected to rise more rapidly in the future because of

increasing obesity and reduced activity levels.

There is considerable geographic variation in the incidence of both type 1 and type 2DM. For example, Scandinavia has the highest rate of type 1 DM (in Finland, incidence is 35/100,000 per year). The Pacific Rim has a much lower rate (in Japan and China, incidence is 1 to 3/100,000 per year) of type 1 DM; Northern Europe and the United States share an intermediate rate (8 to 17/100,000 per year). Much of the increased risk of type 1 DM is believed to reflect the frequency of high-risk HLA alleles among ethnic groups in different geographic locations.

The prevalence of type 2DM and its harbinger, impaired glucose tolerance (IGT), is highest in certain Pacific islands, intermediate in countries such as India and the United States, and relatively low in Russia and China. This variability is likely due to both genetic and environmental factors. There is also considerable variation in DM prevalence among different ethnic populations within a given country.

In 1998, approximately 16 million individuals in the United States met the diagnostic criteria forDM. This represents ~6% of the population. About 800,000 individuals in the United States develop DM each year. The vast majority of these (>90%) have type 2 DM. The number of people with DM increases with the age of the population, ranging from an incidence of ~1.5% in individuals from 20 to 39 years to ~20% of individuals>75 years. The incidence of DM is similar in men and women throughout most age ranges but is slightly greater in men>60 years. The prevalence of DM is approximately twofold greater in African Americans, Hispanic Americans, and Native Americans than in non-Hispanic whites, and the onset of type 2 DM occurs, on average, at an earlier age in the former groups than in the non-Hispanic white population. The incidence of type 2 DM in these ethnic groups is rapidly increasing. The reasons for these differences are not yet clear.

DIAGNOSIS

Revised criteria for diagnosingDM have been issued by consensus panels of experts from the National Diabetes Data Group and the World Health Organization (Table 333-2). The revised criteria reflect new epidemiologic and metabolic evidence and are based on the following premises: (1) the spectrum of fasting plasma glucose (FPG) and the response to an oral glucose load varies in normal individuals, and (2) DM defined as the level of glycemia at which diabetes-specific complications are noted and not on the level of glucose tolerance from a population-based viewpoint. For example, the prevalence of retinopathy in Native Americans (Pima Indian population) begins to increase at a FPG > 6.4 mmol/L (116 mg/dL) (Fig. 333-2).

Glucose tolerance is classified into three categories based on theFPG: (1) FPG < 6.1 mmol/L (110 mg/dL) is considered normal; (2) FPG ³ 6.1 mmol/L (110 mg/dL) but< 7.0 mmol/L (126 mg/dL) is defined asIFG; and (3) FPG ³ 7.0 mmol/L (126 mg/dL) warrants the diagnosis ofDM. IFG is a new diagnostic category defined by the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. It is analogous toIGT, which is defined as plasma glucose levels between 7.8 and 11.1 mmol/L (140 and 200 mg/dL) 2 h after a 75-g oral glucose load (Table 333-2). Individuals with IFG or IGT are at substantial risk for developing type 2 DM and cardiovascular disease in the future,

though they may not meet the criteria for DM.

The revised criteria for the diagnosis ofDMemphasize theFPG as the most reliable and convenient test for diagnosing DM in asymptomatic individuals. A random plasma glucose concentration³11.1 mmol/L (200 mg/dL) accompanied by classic symptoms of DM (polyuria, polydipsia, weight loss) is sufficient for the diagnosis of DM (Table 333-2). Oral glucose tolerance testing, although still a valid mechanism for diagnosing DM, is not recommended as part of routine screening.

Some investigators have advocated the hemoglobin A1c (HbA1c) as a diagnostic test forDM. Though there is a strong correlation between elevations in the plasma glucose and the HbA1c (discussed below), the relationship between theFPG and the HbA1c in individuals with normal glucose tolerance or mild glucose intolerance is less clear, and the test is not universally standardized or available.

The diagnosis ofDM has profound implications for an individual from both a medical and financial standpoint. Thus, the health care provider must be certain that these criteria are completely satisfied before assigning the diagnosis of DM to an individual. The revised criteria also allow for the diagnosis of DM to be withdrawn in situations where theFPG no longer exceeds these criteria. Abnormalities on screening tests for diabetes should be repeated before making a definitive diagnosis of DM, unless acute metabolic derangements or a markedly elevated plasma glucose are present (Table 333-2).

SCREENING

Widespread use of theFPG as a screening test for type 2DM is strongly encouraged because: (1) a large number of individuals who meet the current criteria for DM are unaware that they have the disorder, (2) epidemiologic studies suggest that type 2 DM may be present for up to a decade before diagnosis, and (3) as many as 50% of individuals with type 2 DM have one or more diabetes-specific complications at the time of their diagnosis. The Expert Committee suggests screening all individuals>45 years every 3 years and screening asymptomatic individuals with additional risk factors (Table 333-3) at an earlier age. In contrast to type 2 DM, it is rare for an individual to have a long asymptomatic period of hyperglycemia prior to the diagnosis of type 1 DM. A number of immunologic markers for type 1 DM are becoming available (discussed below), but their use is currently discouraged pending the identification of clinically beneficial interventions for individuals at high risk for developing type 1 DM.

INSULIN BIOSYNTHESIS, SECRETION, AND ACTION

BIOSYNTHESIS

Insulin is produced in the beta cells of the pancreatic islets. It is initially synthesized as a single-chain 86-amino-acid precursor polypeptide, preproinsulin. Subsequent proteolytic processing removes the aminoterminal signal peptide, giving rise to proinsulin. Proinsulin is structurally related to insulin-like growth factors I and II, which bind weakly to the insulin receptor (Chap. 327). Cleavage of an internal 31-residue fragment from proinsulin generates the C peptide and the A (21 amino acids) and B (30 amino acids) chains of insulin, which are connected by disulfide bonds. The mature insulin molecule

and C peptide are stored together and cosecreted from secretory granules in the beta cells. Because the C peptide is less susceptible than insulin to hepatic degradation, it is a useful a marker of insulin secretion and allows discrimination of endogenous and exogenous sources of insulin in the evaluation of hypoglycemia (Chap. 334). Human insulin is now produced by recombinant DNA technology; structural alterations at one or more residues are useful for modifying its physical and pharmacologic characteristics (see below).

SECRETION

Glucose is the key regulator of insulin secretion by the pancreatic beta cell, although amino acids, ketones, various nutrients, gastrointestinal peptides, and neurotransmitters also influence insulin secretion. Glucose levels>3.9 mmol/L (70 mg/dL) stimulate insulin synthesis, primarily by enhancing protein translation and processing, as well as inducing insulin secretion. Glucose stimulates insulin secretion through a series of regulatory steps that begin with transport into the beta cell by the GLUT2 glucose transporter (Fig. 333-3). Glucose phosphorylation by glucokinase is the rate-limiting step that controls glucose-regulated insulin secretion.

Further metabolism of glucose-6-phosphate via glycolysis generates ATP, which inhibits the activity of an ATP-sensitive K_+channel. This channel is a complex of two separate proteins, one of which is the receptor for certain oral hypoglycemics (e.g., sulfonylureas, meglitinides); the other subunit is an inwardly rectifying K_+ channel protein. Inhibition of this K_+channel induces beta cell membrane depolarization, opening of voltage-dependent calcium channels (leading to an influx of calcium), and stimulation of insulin secretion. Careful studies of insulin secretory profiles reveal pulsatile pattern of hormone release, with small secretory bursts occurring about every 10 min, superimposed upon greater amplitude oscillations of about 80 to 150 min. Meals or other major stimuli of insulin secretion induce large (four- to fivefold increase versus baseline) bursts of insulin secretion that usually last for 2 to 3 h before returning to baseline. Derangements in these normal secretory patterns are one of the earliest signs of beta cell dysfunction inDM (see below).

ACTION

Once insulin is secreted into the portal vein, ~50% is removed and degraded by the liver. Unextracted insulin enters the systemic circulation and binds to its receptor in target sites. The insulin receptor belongs to the tyrosine kinase class of membrane-bound receptors (Chap. 327). Insulin binding to the receptor stimulates intrinsic tyrosine kinase activity, leading to receptor autophosphorylation and the recruitment of intracellular signaling molecules, such as insulin receptor substrates (IRS) 1 and 2 (Fig. 333-4). These and other adaptor proteins initiate a complex cascade of phosphorylation and dephosphorylation reactions, ultimately resulting in the widespread metabolic and mitogenic effects of insulin. As an example, activation of the phosphatidylinositol-3¢-kinase (PI-3 kinase) pathway stimulates translocation of glucose transporters (e.g., GLUT4) to the cell surface, an event that is crucial for glucose uptake by skeletal muscle and fat. Activation of other insulin receptor signaling pathways induces glycogen synthesis, protein synthesis, lipogenesis, and regulation of various genes in insulin-responsive cells.

Glucose homeostasis reflects a precise balance between hepatic glucose production and peripheral glucose uptake and utilization. Insulin is the most important regulator of this metabolic equilibrium, but the effects of other pathways including neural input, metabolic signals, and hormones (e.g., glucagon) result in integrated control of glucose supply and utilization (Chap. 334;Fig. 334-1). In the fasting state, low insulin levels promote hepatic gluconeogenesis and glycogenolysis to prevent hypoglycemia. Low insulin levels decrease glycogen synthesis, reduce glucose uptake in insulin-sensitive tissues, and promote mobilization of stored precursors. Reduced insulin levels are also permissive in allowing glucagon to stimulate glycogenolysis and gluconeogenesis by the liver and renal medulla. These processes are of critical importance to ensure an adequate glucose supply for the brain. Postprandially, a large glucose load elicits a rise in insulin and fall in glucagon, leading to a reversal of these processes. The major portion of postprandial glucose is utilized by skeletal muscle. Other tissues, most notably the brain, utilize glucose in an insulin-independent fashion.

PATHOGENESIS

TYPE 1 DM

Type 1ADMdevelops as a result of the synergistic effects of genetic, environmental, and immunologic factors that ultimately destroy the pancreatic beta cells. The temporal development of type 1A DM is shown schematically as a function of beta cell mass in Fig. 333-5. Individuals with a genetic susceptibility have normal beta cell mass at birth but begin to lose beta cells secondary to autoimmune destruction that occurs over months to years. This autoimmune process is thought to be triggered by an infectious or environmental stimulus and to be sustained by a beta cell-specific molecule. In the majority of individuals, immunologic markers appear after the triggering event but before diabetes becomes clinically overt. Beta cell mass then begins to decline, and insulin secretion becomes progressively impaired, although normal glucose tolerance is maintained. The rate of decline in beta cell mass varies widely among individuals, with some patients progressing rapidly to clinical diabetes and others evolving more slowly. Features of diabetes do not become evident until a majority of beta cells are destroyed (~80%). At this point, residual functional beta cells still exist but are insufficient in number to maintain glucose tolerance. The events that trigger the transition from glucose intolerance to frank diabetes are often associated with increased insulin requirements, as might occur during infections or puberty. Following the initial clinical presentation of type 1A DM, a "honeymoon" phase may ensue during which time glycemic control is achieved with modest doses of insulin or, rarely, insulin is not needed. However, this fleeting phase of endogenous insulin production from residual beta cells disappears as the autoimmune process destroys the remaining beta cells, and the individual becomes completely insulin deficient.

GENETIC CONSIDERATIONS

The genetic contributions to type 1ADMinvolve multiple genes. The development of the disease appears to require inheritance of a sufficient complement of genes to confer susceptibility to the disorder. The concordance of type 1A DM in identical twins ranges between 30 and 70%, indicating that additional modifying factors must be involved in

determining whether diabetes develops. The major susceptibility gene for type 1A DM is located in the HLA region on chromosome 6. Polymorphisms in the HLA complex appear to account for 40 to 50% of the genetic risk of developing type 1A DM. This region contains genes that encode the class II MHC molecules, which present antigen to helper T cells and thus are involved in initiating the immune response (Chaps. 305,306,307). The ability of class II MHC molecules to present antigen is dependent on the amino acid composition of their antigen-binding sites. Amino acid substitutions may influence the specificity of the immune response by altering the binding affinity of different antigens for the class II molecules.

Most individuals with type 1ADM have the HLA DR3 and/or DR4 haplotype. Refinements in genotyping of HLA loci have shown that the haplotypes DQA1*0301, DQB1*0302 and DQA1*501, DQB1*0201 have the strongest association with type 1A DM. These haplotypes are present in 40% of children with type 1A DM as compared to 2% of the normal U.S. population.

In addition to MHC class II associations, at least 17 different genetic loci may contribute susceptibility to type 1ADM. For example, polymorphisms in the promoter region of the insulin gene appear to account for ~10% of the predisposition to type 1A DM. Genes that confer protection against the development of the disease also exist. For example, the haplotype DQA1*0102, DQB1*0602 is present in 20% of the U.S. population but is extremely rare in individuals with type 1A DM (<1%).

Although type 1ADM is clearly associated with certain predisposing genotypes, most individuals with these haplotypes do not develop diabetes. In addition, most individuals with type 1A DM do not have a first-degree relative with this disorder. Nevertheless, the risk of developing type 1A DM for relatives of individuals with the disease is considerably higher compared to the risk for the general population.

Autoimmune Factors Although other islet cell types [alpha cells (glucagon-producing), delta cells (somatostatin-producing) or PP cells (pancreatic polypeptide-producing)] are functionally and embryologically similar to beta cells and express most of the same proteins as beta cells, they are inexplicably spared from the autoimmune process. Pathologically, the pancreatic islets are infiltrated with lymphocytes (in a process termed *insulitis*). After all beta cells are destroyed, the inflammatory process abates, the islets become atrophic, and immunologic markers disappear. Studies of the insulitis and autoimmune process in humans and animal models of type 1ADM (NOD mouse and BB rat) have identified the following abnormalities in both the humoral and cellular arms of the immune system: (1) islet cell autoantibodies; (2) activated lymphocytes in the islets, peripancreatic lymph nodes, and systemic circulation; (3) T lymphocytes that proliferate when stimulated with islet proteins; and (4) release of cytokines within the insulitis. Beta cells seem to be particularly susceptible to the toxic effect of some cytokines (tumor necrosis factor a, interferong, and interleukin 1). The precise mechanisms of beta cell death are not known but may involve formation of nitric oxide metabolites, apoptosis, and direct CD8+ T cell cytotoxicity. Islet autoantibodies are not thought to be involved in the destructive process, as these antibodies do not generally react with the cell surface of islet cells and are not capable of transferring diabetes mellitus to animals.

Pancreatic islet molecules targeted by the autoimmune process include insulin, glutamic

acid decarboxylase (GAD; the biosynthetic enzyme for the neurotransmitter GABA), ICA-512/IA-2 (homology with tyrosine phosphatases), and phogrin (insulin secretory granule protein). Other less clearly defined autoantigens include an islet ganglioside and carboxypeptidase H. With the exception of insulin, none of the autoantigens are beta cell specific, which raises the question of how the beta cells are selectively destroyed. Current theories favor initiation of an autoimmune process directed at one beta cell molecule, which then spreads to other islet molecules as the immune process destroys beta cells and creates a series of secondary autoantigens. The beta cells of individuals who develop type 1ADM do not differ from beta cells of normal individuals, since transplanted islets are destroyed by a recurrence of the autoimmune process of type 1A DM.

Immunologic Markers Islet cell autoantibodies (ICAs) are a composite of several different antibodies directed at pancreatic islet molecules such asGAD, insulin, IA-2/ICA512, and an islet ganglioside and serve as a marker of the autoimmune process of type 1ADM. Testing for ICAs can be useful in classifying the type of DM as type IA and in identifying nondiabetic individuals at risk for developing type 1A DM. ICAs are present in the majority of individuals (>75%) diagnosed with new-onset type 1A DM, in a significant minority of individuals with newly diagnosed type 2 DM, and occasionally in individuals withGDM(<5%). ICAs are present in 3 to 4% of first-degree relatives of individuals with type 1A DM. In conjunction with impaired insulin secretion on intravenous glucose tolerance testing, they predict a>50% risk of developing type 1A DM within 5 years. Without this impairment in insulin secretion, the presence of ICAs predicts a 5-year risk of <25%. Based on these data, the risk of a first-degree relative developing type 1A DM is relatively low, and even ICA-positive individuals are not destined to develop diabetes. At present, the ICAs are used predominantly as a research tool and not in clinical practice, in part because of the technically demanding nature of the assay but also because no treatments have been proven to prevent the occurrence or progression of type 1A DM.

Environmental Factors Numerous environmental events have been proposed to trigger the autoimmune process in genetically susceptible individuals; however, none have been conclusively linked to diabetes. Identification of an environmental trigger has been difficult because the event may precede the onset ofDM by several years (Fig. 333-5). Putative environmental triggers include viruses (coxsackie and rubella most prominently), early exposure to bovine milk proteins, and nitrosourea compounds. Epidemiologic studies have noted an association between bovine milk intake and type 1A DM; studies are ongoing to investigate a possible relationship between exposure to bovine milk and the autoimmune process of type 1A DM.

Prevention of Type 1A DM A number of interventions have successfully delayed or prevented diabetes in animal models. Some interventions have targeted the immune system directly (immunosuppression, selective T cell subset deletion, induction of immunologic tolerance to islet proteins), whereas others have prevented islet cell death by blocking cytotoxic cytokines or increasing islet resistance to the destructive process. Though results in animal models are promising, most of these interventions have not been successful in preventing type 1ADM in humans. Clinical trials of several interventions are underway in the United States and Europe. The Diabetes Prevention Trial -- type 1 is being conducted to determine whether administering insulin to

individuals at high risk for developing type 1A DM can induce immune tolerance and alter the autoimmune process of type 1A DM.

TYPE 2 DM

Type 2DM is a heterogeneous disorder with a complex etiology that develops in response to genetic and environmental influences. Central to the development of type 2 DM are insulin resistance and abnormal insulin secretion. Although controversy remains regarding the primary defect, most studies support the view that insulin resistance precedes insulin secretory defects.

GENETIC CONSIDERATIONS

Type 2DM has a strong genetic component. Although the major genes that predispose to this disorder have yet to be identified, it is clear that the disease is polygenic and multifactorial. Various genetic loci contribute to susceptibility, and environmental factors (such as nutrition and physical activity) further modulate phenotypic expression of the disease. The concordance of type 2 DM in identical twins is between 70 and 90%. Individuals with a parent with type 2 DM have an increased risk of diabetes; if both parents have type 2 DM, the risk in offspring may reach 40%. Insulin resistance, as demonstrated by reduced glucose utilization in skeletal muscle, is present in many nondiabetic, first-degree relatives of individuals with type 2 DM. However, definition of the genetic abnormalities of type 2 DM remains a challenge because the genetic defect in insulin secretion or action may not manifest itself unless an environmental event or another genetic defect, such as obesity, is superimposed.

The identification of individuals with mutations in various molecules involved in insulin action (e.g., the insulin receptor and enzymes involved in glucose homeostasis) has been useful for characterizing key steps in insulin action. However, mutations in these molecules account for a very small fraction of type 2DM.Likewise, genetic defects in proteins involved in insulin secretion have not been found in most individuals with type 2 DM. Genome-wide scanning for mutations or polymorphisms associated with type 2 DM is being used in an effort to identify genes associated with type 2 DM.

Pathophysiology Type 2DM is characterized by three pathophysiologic abnormalities: impaired insulin secretion, peripheral insulin resistance, and excessive hepatic glucose production. Obesity, particularly visceral or central, is very common in type 2 DM. Insulin resistance associated with obesity augments the genetically determined insulin resistance of type 2 DM. Adipocytes secrete a number of biologic products (leptin, tumor necrosis factor a, free fatty acids) that modulate processes such as insulin secretion, insulin action, and body weight and may contribute to the insulin resistance. In the early stages of the disorder, glucose tolerance remains normal, despite insulin resistance, because the pancreatic beta cells compensate by increasing insulin output. As insulin resistance and compensatory hyperinsulinemia progress, the pancreatic islets become unable to sustain the hyperinsulinemic state.IGT, marked by elevations in postprandial glucose, then develops. A further decline in insulin secretion and an increase in hepatic glucose production lead to overt diabetes with fasting hyperglycemia. Ultimately, beta cell failure may ensue.

Metabolic Abnormalities

Insulin Resistance This is caused by the decreased ability of insulin to act effectively on peripheral target tissues (especially muscle and liver) and is a prominent feature of type 2DM. This resistance is relative, since supernormal levels of circulating insulin will normalize the plasma glucose. Insulin dose-response curves exhibit a rightward shift, indicating reduced sensitivity, and a reduced maximal response, indicating an overall decrease in maximum glucose utilization (30 to 60% lower than normal individuals). Resistance to the action of insulin impairs glucose utilization by insulin-sensitive tissues and increases hepatic glucose output -- both effects contributing to the hyperglycemia of diabetes. Increased hepatic glucose output predominantly accounts for increasedFPGlevels, whereas decreased peripheral glucose usage results in postprandial hyperglycemia. In skeletal muscle, there is a greater impairment in nonoxidative glucose usage (glycogen formation) than in oxidative glucose metabolism through glycolysis. Glucose usage in insulin-independent tissues is not decreased in type 2 DM.

The precise molecular mechanism of insulin resistance in type 2DM has yet to be elucidated. Insulin receptor levels and tyrosine kinase activity in skeletal muscle are reduced, but these alterations are most likely secondary to hyperinsulinemia and are not a primary defect. Therefore, postreceptor defects are believed to play the predominant role in insulin resistance (Fig. 333-4). Polymorphisms inIRS-1 may be associated with glucose intolerance, raising the possibility that polymorphisms in various postreceptor molecules may combine to create an insulin-resistant state.

A current focus for the pathogenesis of insulin resistance focuses on a PI-3 kinase signaling defect, which causes reduced translocation of GLUT4 to the plasma membrane, among other abnormalities. Of note, not all insulin signal transduction pathways are resistant to the effects of insulin (e.g., those controlling cell growth and differentiation). Consequently, hyperinsulinemia may actually increase the insulin action through these pathways.

Another emerging theory proposes that elevated levels of free fatty acids, a common feature of obesity, may contribute to the pathogenesis of type 2DM in several different ways. Free fatty acids can impair glucose utilization in skeletal muscle, promote glucose production by the liver, and impair beta cell function.

Impaired Insulin Secretion Insulin secretion and sensitivity are interrelated (Fig. 333-6). In type 2DM, insulin secretion initially increases in response to insulin resistance in order to maintain normal glucose tolerance. Initially, the insulin secretory defect is mild and selectively involves glucose-stimulated insulin secretion. The response to other nonglucose secretagogues, such as arginine, is preserved. Eventually, the insulin secretory defect progresses to a state of grossly inadequate insulin secretion. Some endogenous insulin production continues, but the amount secreted is less than the amount secreted by normal individuals at the same plasma glucose concentration.

The reason(s) for the decline in insulin secretory capacity in type 2DM is unclear. Despite the assumption that a second genetic defect -- superimposed upon insulin resistance -- leads to beta cell failure, intense genetic investigation has so far excluded

mutations in islet candidate genes. Islet amyloid polypeptide or amylin is cosecreted by the beta cell and likely forms the amyloid fibrillar deposit found in the islets of individuals with longstanding type 2 DM. Whether such islet amyloid deposits are a primary or secondary event is not known. The metabolic environment may also impact islet function negatively. For example, chronic hyperglycemia paradoxically impairs islet function ("glucose toxicity") and leads to a worsening of hyperglycemia. Improvement in glycemic control is often associated with improved islet function. In addition, elevation of free fatty acid levels ("lipotoxicity") also worsens islet function.

Increased Hepatic Glucose Production The liver maintains plasma glucose during periods of fasting through glycogenolysis and gluconeogenesis using substrates derived from skeletal muscle and fat (alanine, lactate, glycerol, and fatty acids). Insulin promotes the storage of glucose as hepatic glycogen and suppresses gluconeogenesis. In type 2DM, insulin resistance in the liver arises from the failure of hyperinsulinemia to suppress gluconeogenesis, which results in fasting hyperglycemia and decreased glucose storage by the liver in the postprandial state. Increased hepatic glucose production occurs early in the course of diabetes, though likely after the onset of insulin secretory abnormalities and insulin resistance in skeletal muscle.

Insulin Resistance Syndromes It is likely that the insulin resistance condition comprises a spectrum of disorders, with hyperglycemia representing one of the most readily diagnosed features. *Syndrome X* is a term used to describe a constellation of metabolic derangements that includes insulin resistance, hypertension, dyslipidemia, central or visceral obesity, endothelial dysfunction, and accelerated cardiovascular disease. Epidemiologic evidence supports hyperinsulinemia as a marker for coronary artery disease risk, though an etiologic role has not been demonstrated.

A number of forms of severe insulin resistance may be associated with a phenotype similar to that in type 2DM orIGT(Table 333-1). *Acanthosis nigricans* and signs of hyperandrogenism (hirsutism, acne, and oligomenorrhea) are common physical features. In addition to rare genetic syndromes seen in early childhood, two distinct syndromes of severe insulin resistance have been described in adults: (1) type A, which affects young women and is characterized by severe hyperinsulinemia, obesity, and features of hyperandrogenism; and (2) type B, which affects middle-aged women and is characterized by severe hyperinsulinemia, features of hyperandrogenism, and autoimmune disorders. Individuals with the type A insulin resistance syndrome have an undefined defect in the insulin signaling pathway; individuals with the type B insulin resistance syndrome have autoantibodies directed at the insulin receptor. These receptor autoantibodies may block insulin binding or may stimulate the insulin receptor, leading to intermittent hypoglycemia.

Polycystic ovary syndrome (PCOS) is a common disorder that affects premenopausal women and is characterized by chronic anovulation and hyperandrogenism. Insulin resistance is seen in a significant subset of women with PCOS, and the disorder substantially increases the risk for type 2DM, independent of the effects of obesity. Both metformin and thiazolidinediones may attenuate hyperinsulinemia, ameliorate hyperandrogenism, and induce ovulation, but are not approved for this indication.

Prevention Because type 2DM is preceded by a period ofIGT, a number of life-style

modifications and pharmacologic agents have been suggested to prevent or delay its onset. Individuals with a strong family history or those at high risk for developing DM should be strongly encouraged to maintain a normal body mass index and to engage in regular physical activity. Beyond this general advice, however, there are no specific interventions proven to prevent type 2 DM. Clinical trials of various interventions in individuals with IGT or early DM are underway in the United States and worldwide.

MODY: GENETICALLY DEFINED, MONOGENIC FORMS OF DIABETES MELLITUS

Several monogenic forms ofDM have recently been identified.MODYcomprises a phenotypically and genetically heterogeneous subtype of DM. Onset of the disease typically occurs between the ages of 10 and 25. Five different variants of MODY, due to mutations in genes encoding islet cell transcription factors or glucokinase (Fig. 333-3), have been identified so far, and all are transmitted as autosomal dominant disorders (Table 333-1). MODY 2, the most common variant, is caused by mutations in the glucokinase gene. Glucokinase catalyzes the formation of glucose-6-phosphate from glucose, a reaction that is important for glucose sensing by the beta cells and for glucose utilization by the liver. As a result of glucokinase mutations, higher glucose levels are required to elicit insulin secretory responses, thus altering the set point for insulin secretion. MODY 1, MODY 3, and MODY 5 are caused by mutations in the hepatocyte nuclear transcription factors HNF-4a, HNF-1a, and HNF-1b, respectively. As their names imply, these transcription factors are expressed in the liver but also in other tissues, including the pancreatic islets. The mechanisms by which such mutations lead to DM is not well understood, but it is likely that these factors affect islet development or the transcription of genes that are important in stimulating insulin secretion. MODY 4 is a rare variant caused by mutations in the insulin promoter factor (IPF-1), which is a transcription factor that regulates both pancreatic development and insulin gene transcription. Homozygous inactivating mutations lead to pancreatic agenesis, whereas heterozygous mutations result in early-onset DM. Studies of populations with type 2 DM suggest that mutations in the glucokinase gene and various islet cell transcription factors do not account for ordinary type 2 DM. Nevertheless, elucidation of the molecular genetics underlying these rare forms of DM has been important in identifying critical steps in the control of pancreatic beta cell function.

COMPLICATIONS OF DM

ACUTE COMPLICATIONS

Diabetic ketoacidosis (DKA) and nonketotic hyperosmolar state (NKHS) are acute complications of diabetes. DKA is seen primarily in individuals with type 1DM, and NKHS is seen in individuals with type 2 DM. Both disorders are associated with absolute or relative insulin deficiency, volume depletion, and altered mental status. DKA and NKHS exist along a continuum of hyperglycemia, with or without ketosis. The metabolic similarities and differences in DKA and NKHS are highlighted in Table 333-4. Both disorders are associated with potentially serious complications if not promptly diagnosed and treated.

DIABETIC KETOACIDOSIS

Clinical Features The symptoms and physical signs ofDKA are listed in Table 333-5. DKA may be the initial symptom complex that leads to a diagnosis of type 1DM, but more frequently it occurs in individuals with established diabetes. Nausea and vomiting are often prominent, and their presence in an individual with diabetes warrants laboratory evaluation for DKA. Abdominal pain may be severe and sometimes suggests acute pancreatitis or ruptured viscous. Hyperglycemia leads to glucosuria, volume depletion, tachycardia, and possibly hypotension. Kussmaul respirations and an acetone odor on the patient's breath (both secondary to metabolic acidosis) are classic signs of the disorder. Lethargy and central nervous system depression may evolve into coma with severe DKA. Cerebral edema, an extremely serious complication of DKA, is seen most frequently in children. Signs of infection, which may precipitate DKA, should be sought on physical examination, even in the absence of fever.

Pathophysiology DKAresults from insulin deficiency combined with counterregulatory hormone excess (glucagon, catecholamines, cortisol, and growth hormone). Both insulin deficiency and glucagon excess, in particular, are necessary for DKA to develop. The hyperglycemia of DKA results from increased hepatic glucose production (gluconeogenesis and glycogenolysis) and impaired peripheral glucose utilization. The decreased ratio of insulin to glucagon promotes gluconeogenesis, glycogenolysis, and ketone body formation in the liver, as well as increasing substrate delivery from fat and muscle (free fatty acids, amino acids) to the liver.

The combination of insulin deficiency and hyperglycemia reduces the hepatic level of fructose-2,6-phosphate, which alters the activity of phosphofructokinase and fructose-1,6-bisphosphatase. Glucagon excess decreases the activity of pyruvate kinase, whereas insulin deficiency increases the activity of phosphoenolpyruvate carboxykinase. These hepatic changes shift the handling of pyruvate toward glucose synthesis and away from glycolysis. Glycogenolysis is promoted by the increased levels of glucagon and catecholamines in the face of low insulin levels. Insulin deficiency also reduces levels of the GLUT4 glucose transporter, which impairs glucose uptake into skeletal muscle and fat and reduces intracellular glucose metabolism (Fig. 333-4).

Ketosis results from a marked increase in free fatty acid release from adipocytes, with a resulting shift toward ketone body synthesis in the liver. Reduced insulin levels, in combination with elevations in catecholamines and growth hormone, lead to an increase in lipolysis and release of free fatty acids. Normally, these free fatty acids are converted to triglycerides or very low density lipoproteins (VLDL) in the liver, but inDKA, hyperglucagonemia alters hepatic metabolism to favor ketone body formation, through activation of the enzyme carnitine palmitoyltransferase I. This enzyme is crucial for regulating fatty acid transport into the mitochondria, where beta oxidation and conversion to ketone bodies occurs. At physiologic pH, ketone bodies exist as ketoacids, which are neutralized by bicarbonate. As bicarbonate stores are depleted, metabolic acidosis ensues. Increased lactic acid production also contributes to the acidosis. The increased free fatty acids result in increased triglyceride production and increased hepatic production of VLDL. VLDL clearance is also reduced because the activity of insulin-sensitive lipoprotein lipase is decreased. Hypertriglyceridemia may be severe enough to cause pancreatitis.

DKAcan be precipitated by inadequate levels of plasma insulin for a variety of reasons

(Table 333-5). Most commonly, DKA is precipitated when relatively insufficient insulin is available when insulin requirements increase, as might occur during a concurrent illness. Failure to augment insulin therapy appropriately by the patient or health care team compounds the problem. Occasionally, complete omission of insulin by the patient or health care team (in a hospitalized patient with type 1DM) precipitates DKA. Patients using insulin infusion devices with short-acting insulin have a greater potential for DKA, since even a brief interruption in insulin delivery (e.g., mechanical malfunction) quickly leads to insulin deficiency.

Laboratory Abnormalities and Diagnosis The timely diagnosis ofDKA is crucial and allows for prompt initiation of therapy. DKA is characterized by hyperglycemia, ketosis, and metabolic acidosis (increased anion gap) along with a number of secondary metabolic derangements (Table 333-4)). Serum bicarbonate is frequently<10 mmol/L, and arterial pH ranges between 6.8 and 7.3, depending on the severity of the acidosis. Despite a total-body potassium deficit, the serum potassium at presentation is typically at the high end of the normal range or mildly elevated, secondary to the acidosis. Total-body stores of sodium, chloride, phosphorous, and magnesium are also reduced in DKA, but are not accurately reflected by their levels in the serum. Elevated blood urea nitrogen (BUN) and serum creatinine levels reflect intravascular volume depletion. Interference from acetoacetate may falsely elevate the serum creatinine measurement. Leukocytosis, hypertriglyceridemia, and hyperlipoproteinemia are commonly found as well. Hyperamylasemia may suggest a diagnosis of pancreatitis, especially when accompanied by abdominal pain. However, in DKA the amylase is usually of salivary origin and thus is not diagnostic of pancreatitis.

The measured serum sodium is reduced as a consequence of the hyperglycemia [1.6 meq (1.6 mmol/L) reduction in serum sodium for each 100 mg/dL (5.6 mmol/L) rise in the serum glucose]. A normal serum sodium in the setting ofDKAindicates a more profound water deficit. In "conventional" units, the calculated serum osmolality [2 ´ (serum sodium+ serum potassium) + plasma glucose (mg/dL)/18 +BUN/2.8] is mildly to moderately elevated, though to a lesser degree than that found inNKHShyperosmolar state (see below).

InDKA, the ketone body, b-hydroxybutyrate, is synthesized at a threefold greater rate than acetoacetate; however, the latter ketone body is preferentially detected by a commonly used ketosis detection reagent (nitroprusside). Serum ketones are present at significant levels (usually positive at serum dilution of 1:8 or greater). The nitroprusside tablet, or stick, is often used to detect urine ketones; certain medications such as captopril or penicillamine may cause false-positive reactions. Serum or plasma assays for b-hydroxybutyrate more accurately reflect the true ketone body level.

The metabolic derangements ofDKAexist along a spectrum, beginning with mild acidosis with moderate hyperglycemia evolving into more severe findings. The degree of acidosis and hyperglycemia do not necessarily correlate closely, as a variety of factors determine the level of hyperglycemia (oral intake, urinary glucose loss). Ketonemia is a consistent finding in DKA and distinguishes it from simple hyperglycemia.

TREATMENT

The management ofDKA is outlined in Table 333-6. After initiating intravenous fluid replacement and insulin therapy, the agent or event that precipitated the episode of DKA should be sought and aggressively treated. If the patient is vomiting or has altered mental status, a nasogastric tube should be inserted to prevent aspiration of gastric contents. Central to successful treatment of DKA is careful patient monitoring and frequent reassessment to ensure that the patient and the metabolic derangements are improving. A comprehensive flow sheet should record chronologic changes in vital signs, fluid intake and output, and laboratory values as a function of insulin administered.

After the initial bolus of normal saline, replacement of the sodium and free water deficit is carried out over the next 24 h (fluid deficit is often 3 to 5 L). When hemodynamic stability and adequate urine output are achieved, intravenous fluids should be switched to 0.45% saline at a rate of 200 to 300 mL/h, depending on the calculated volume deficit. The change to 0.45% saline helps reduce the trend toward hyperchloremia later in the course ofDKA. Alternatively, initial use of lactated Ringer's intravenous solution may reduce the hyperchloremia that commonly occurs with normal saline.

A bolus of intravenous or intramuscular insulin (10 to 20 units) should be administered immediately (Table 333-6)), and subsequent treatment should provide continuous and adequate levels of circulating insulin. Intravenous administration is preferred, because it assures rapid distribution and allows adjustment of the infusion rate as the patient responds to therapy. Intravenous insulin should be continued until the acidosis resolves and the patient is metabolically stable. As the acidosis and insulin resistance associated withDKAresolve, the insulin infusion rate can be decreased (to 1 to 4 units/h). Intermediate or long-acting insulin, in combination with subcutaneous regular insulin, should be administered as soon as the patient resumes eating, as this facilitates transition to an outpatient insulin regimen and reduces length of hospital stay. It is crucial to continue the insulin infusion until adequate insulin levels are achieved by the subcutaneous route. Even relatively brief periods of inadequate insulin administration in this transition phase may allow for DKA relapse.

Hyperglycemia usually improves at a rate of 4.2 to 5.6 mmol/L (75 to 100 mg/dL per hour) as a result of insulin-mediated glucose disposal, reduced hepatic glucose release, and rehydration. The latter reduces catecholamines, increases urinary glucose loss, and expands the intravascular volume. The decline in the plasma glucose within the first 1 to 2 h may be more rapid and is mostly related to volume expansion. When the plasma glucose reaches 13.9 mmol/L (250 mg/dL), glucose should be added to the 0.45% saline infusion to maintain the plasma glucose in the 11.1 to 13.9 mmol/L (200 to 250 mg/dL) range, and the insulin infusion should be continued. Ketoacidosis begins to resolve as insulin reduces lipolysis, increases peripheral ketone body use, suppresses hepatic ketone body formation, and promotes bicarbonate regeneration. However, the acidosis and ketosis resolve at a slower rate than does the hyperglycemia. As ketoacidosis improves,b-hydroxybutyrate is converted to acetoacetate. Ketone body levels may appear to increase if measured by laboratory assays that use the nitroprusside reaction, which only detects acetoacetate and acetone levels. The improvement in acidosis and anion gap, a result of bicarbonate regeneration and decline in ketone bodies, is reflected by a rise in the serum bicarbonate level and the

arterial pH. Depending on the rise of serum chloride, the anion gap (but not bicarbonate) will normalize. A hyperchloremic acidosis [serum bicarbonate of 15 to 18 mmol/L (15 to 18 meq/L)] often follows successful treatment and is minimized by the use of hypotonic intravenous solutions. This gradually resolves as the kidney regenerates bicarbonate and excretes chloride.

Potassium stores are depleted inDKA[estimated deficit 3 to 5 mmol/kg (3 to 5 meq/kg)], but the serum potassium may be normal or even elevated at the time of presentation. During treatment with insulin and fluids, various factors contribute to the development of hypokalemia. These include insulin-mediated potassium transport into cells, resolution of the acidosis (which also promotes potassium entry into cells), and urinary loss of potassium salts of organic acids. Thus, potassium repletion should commence as soon as adequate urine output and a normal serum potassium are documented. If the initial serum potassium level is elevated, then potassium repletion should be delayed until the potassium falls into the normal range. Inclusion of 20 to 40 meq of potassium in each liter of intravenous fluid is reasonable, but additional potassium supplements may also be required. To reduce the amount of chloride administered, potassium phosphate or acetate can be substituted for the chloride salt. The goal is to maintain the serum potassium>3.5 mmol/L (3.5 meq/L).

Despite a bicarbonate deficit, bicarbonate replacement is not usually necessary or advisable. In fact, theoretical arguments suggest that bicarbonate administration and rapid reversal of acidosis may impair cardiac function, impair tissue oxygenation, and promote hypokalemia. The results of most clinical trials do not support the routine use of bicarbonate replacement. In the presence of severe acidosis (arterial pH< 7.0 or hypotension unresponsive to fluid resuscitation), some physicians administer bicarbonate [50 to 150 mmol/L (meq/L) of sodium bicarbonate in 250 mL of 0.45% saline over 1 to 2 h until the serum bicarbonate rises to approximately 10 mmol/L (meq/L)]. Hypophosphatemia may result from increased glucose usage, but randomized clinical trials have not demonstrated that phosphate replacement is beneficial inDKA. If the serum phosphate is < 0.32 mmol/L (1.0 mg/dl), then phosphate supplement should be considered and the serum calcium monitored. Hypomagnesemia may develop during DKA therapy and may also require supplementation.

With appropriate therapy, the mortality ofDKA is low (<5%) and is related more to the underlying or precipitating event, such as infection or myocardial infarction. The major nonmetabolic complication of DKA therapy is cerebral edema, which most often develops in children as DKA is resolving. The etiology and optimal therapy for cerebral edema are not well established, but overreplacement of free water should be avoided. Venous thrombosis and adult respiratory distress syndrome occasionally complicate DKA.

Following successful treatment ofDKA, the physician and patient should review the sequence of events that led to DKA to prevent future recurrences. Foremost is patient education about the symptoms of DKA, its precipitating factors, and the management of diabetes during a concurrent illness. During illness or when oral intake is compromised, patients should: (1) frequently measure the capillary blood glucose; (2) measure urinary ketones when the serum glucose >16.5 mmol/L (300 mg/dL); (3) drink fluids to maintain hydration; (4) continue or increase insulin; and (5) seek medical attention if dehydration,

persistent vomiting, or uncontrolled hyperglycemia develop. In this way, early DKA can be detected and treated appropriately on an outpatient basis.

NONKETOTIC HYPEROSMOLAR STATE

Clinical Features NKHS is most commonly seen in elderly individuals with type 2DM. Its most prominent features include polyuria; orthostatic hypotension; and a variety of neurologic symptoms that include altered mental status, lethargy, obtundation, seizure, and possibly coma. The prototypical patient is a mildly diabetic, elderly individual with a several week history of polyuria, weight loss, and diminished oral intake that culminates in mental confusion, lethargy, or coma. The physical examination reflects profound dehydration and hyperosmolality and reveals hypotension, tachycardia, and altered mental status. Notably absent are symptoms of nausea, vomiting, and abdominal pain and the Kussmaul respirations characteristic ofDKA. NKHS is often precipitated by a serious, concurrent illness such as myocardial infarction or stroke. Sepsis, pneumonia, and other serious infections are frequent precipitants and should be sought thoroughly. In addition, a debilitating condition (prior stroke or dementia) or social situation that compromises water intake may contribute to the development of the disorder. Finally, the development of NKHS can be associated with the use of certain medications (thiazide diuretics, glucocorticoids, phenytoin).

Pathophysiology Insulin deficiency and inadequate fluid intake are the underlying causes ofNKHS. Insulin deficiency increases hepatic glucose production (through glycogenolysis and gluconeogenesis) and impairs glucose utilization in skeletal muscle (see above discussion underDKA). Hyperglycemia induces an osmotic diuresis that leads to profound intravascular volume depletion, which is exacerbated by inadequate fluid replacement. The absence of ketosis in NKHS is not completely understood. Presumably, the insulin deficiency is only relative and less severe than in DKA. Lower levels of counterregulatory hormones and free fatty acids have been found in NKHS than in DKA in some studies. It is also possible that the liver is less capable of ketone body synthesis or that the insulin/glucagon ratio does not favor ketogenesis.

Laboratory Abnormalities and Diagnosis The laboratory features inNKHS are summarized in Table 333-4. Most notable are the marked hyperglycemia [plasma glucose may be >55.5 mmol/L (1000 mg/dL)], hyperosmolality (>350 mosmol/L), and prerenal azotemia. The measured serum sodium may be normal or slightly low despite the marked hyperglycemia. The corrected serum sodium is usually increased [add 1.6 meq to measured sodium for each 5.6 mmol/L (100 mg/dL) rise in the serum glucose]. In contrast toDKA, acidosis and ketonemia are absent or mild. A small anion gap metabolic acidosis may be present secondary to increased lactic acid. Moderate ketonuria, if present, is secondary to starvation.

TREATMENT

Volume depletion and hyperglycemia are prominent features of bothNKHS andDKA. Consequently, therapy of these disorders involves several shared elements (Table 333-6). In both disorders, careful monitoring of the patient's fluid status, laboratory values, and insulin infusion rate is crucial. Underlying or precipitating problems should be aggressively sought and treated. In NKHS, the volume depletion, free water deficit,

and hyperosmolality are greater than in DKA. The patient with NKHS is usually older, more likely to have mental status changes, and thus more likely to have a life-threatening precipitating event with accompanying comorbidities. Even with proper treatment, NKHS has a substantially higher mortality than DKA (up to 50% in some clinical series).

Fluid replacement should initially stabilize the hemodynamic status of the patient (1 to 3 L of 0.9% normal saline over the first 2 to 3 h). Because the fluid deficit inNKHS is accumulated over a period of days to weeks, the rapidity of reversal of the hyperosmolar state must balance the need for free water repletion and the observation that too rapid a reversal may worsen neurologic function. If the serum sodium is >150mmol/L (150 meq/L), 0.45% saline should be used. After hemodynamic stability is achieved, the intravenous fluid administration is directed at reversing the free water deficit using hypotonic fluids (0.45% saline initially then 5% dextrose in water, D_5W). The calculated free water deficit (which averages 9 to 10 L) should be reversed over the next 1 to 2 days (infusion rates of 200 to 300 mL/h of hypotonic solution). Potassium repletion is usually necessary and should be dictated by repeated measurements of the serum potassium. In patients taking diuretics, the potassium deficit can be quite large and may be accompanied by magnesium deficiency. Hypophosphatemia may occur during therapy and can be improved by using KPO_4 and beginning nutrition.

As inDKA, rehydration and volume expansion lower the plasma glucose initially, but insulin is eventually required. InNKHS, patients tend to be more sensitive to insulin than in DKA and dose requirements are not usually as large. A reasonable regimen for NKHS begins with an intravenous insulin bolus of 5 to 10 units followed by intravenous insulin at a constant infusion rate (3 to 7 units/h). As in DKA, glucose should be added to intravenous fluid when the plasma glucose falls to 13.9 mmol/L (250 mg/dL), and the insulin infusion rate should be decreased to 1 to 2 units/h. The insulin infusion should be continued until the patient has resumed eating and can be transferred to a subcutaneous insulin regimen. The patient should be discharged from the hospital on insulin, though some patients can later undergo a trial of oral glucose-lowering agents.

CHRONIC COMPLICATIONS

The chronic complications ofDMaffect many organ systems and are responsible for the majority of morbidity and mortality associated with the disease. Chronic complications can be divided into vascular and nonvascular complications (Table 333-7). The vascular complications of DM are further subdivided into microvascular (retinopathy, neuropathy, nephropathy) and macrovascular complications (coronary artery disease, peripheral vascular disease, cerebrovascular disease). Nonvascular complications include problems such as gastroparesis, sexual dysfunction, and skin changes. This division is rather arbitrary since it is likely that multiple pathogenic processes are involved in all forms of complications.

The risk of chronic complications increases as a function of the duration of hyperglycemia; they usually become apparent in the second decade of hyperglycemia. Since type 2DM may have a long asymptomatic period of hyperglycemia, many individuals with type 2 DM have complications at the time of diagnosis.

The microvascular complications of both type 1 and type 2DMresult from chronic hyperglycemia. Randomized, prospective clinical trials involving large numbers of individuals with type 1 or type 2 DM have conclusively demonstrated that a reduction in chronic hyperglycemia prevents or reduces retinopathy, neuropathy, and nephropathy. Other incompletely defined factors also modulate the development of complications. For example, despite longstanding DM, some individuals never develop nephropathy or retinopathy. Many of these patients have glycemic control that is indistinguishable from those who develop microvascular complications. Because of these observations, it is suspected that a genetic susceptibility for developing particular complications exists. However, the genetic loci responsible for these susceptibilities have not yet been identified.

Evidence implicating a causative role for chronic hyperglycemia in the development of macrovascular complications is less conclusive, but some results suggest a role for chronic hyperglycemia in the development of macrovascular disease. For example, coronary heart disease events and mortality are two to four times greater in patients with type 2DM. These events correlate with fasting and postprandial plasma glucose levels as well as with the HbA1c. Other factors (dyslipidemia and hypertension) also play important roles in macrovascular complications.

MECHANISMS OF COMPLICATIONS

Although chronic hyperglycemia is an important etiologic factor leading to complications ofDM, the mechanism(s) by which it leads to such diverse cellular and organ dysfunction is unknown. Three major theories, which are not mutually exclusive, have been proposed to explain how hyperglycemia might lead to the chronic complications of DM (Fig. 333-7).

One hypothesis is that increased intracellular glucose leads to the formation of advanced glycosylation end products (AGEs) via the nonenzymatic glycosylaton of cellular proteins. Nonenzymatic glycosylation results from the interaction of glucose with amino groups on proteins. AGEs have been shown to cross-link proteins (e.g., collagen, extracellular matrix proteins), accelerate atherosclerosis, promote glomerular dysfunction, reduce nitric oxide synthesis, induce endothelial dysfunction, and alter extracellular matrix composition and structure. The serum level of AGEs correlates with the level of glycemia, and these products accumulate as glomerular filtration rate declines.

A second hypothesis proposed to explain how chronic hyperglycemia leads to complications ofDM is based on the observation that hyperglycemia increases glucose metabolism via the sorbitol pathway. Intracellular glucose is predominantly metabolized by phosphorylation and subsequent glycolysis, but when intracellular glucose is increased, some glucose is converted to sorbitol by the enzyme aldose reductase. Increased sorbitol concentrations affect several aspects of cellular physiology (decreased myoinositol, altered redox potential) and may lead to cellular dysfunction. However, testing of this theory in humans, using aldose reductase inhibitors, has not demonstrated beneficial effects on clinical endpoints of retinopathy, neuropathy, or nephropathy.

A third hypothesis proposes that hyperglycemia increases the formation of diacylglycerol leading to activation of certain isoforms of protein kinase C (PKC), which, in turn, affect a variety of cellular events that lead toDM-related complications. For example, PKC activation by glucose alters the transcription of genes for fibronectin, type IV collagen, contractile proteins, and extracellular matrix proteins in endothelial cells and neurons in vitro. Growth factors appear to play an important role in DM-related complications. Vascular endothelial growth factor (VEGF) is increased locally in diabetic proliferative retinopathy and decreases after laser photocoagulation. Transforming growth factor b (TGF-b) is increased in diabetic nephropathy and appears to stimulate basement membrane production of collagen and fibronectin by mesangial cells. Other growth factors, such as platelet-derived growth factor, epidermal growth factor, insulin-like growth factor I, growth hormone, basic fibroblast growth factor, and even insulin, have been suggested to play a role in DM-related complications.

Although hyperglycemia serves as the initial trigger for complications of diabetes, it is still unknown whether the same pathophysiologic processes are operative in all complications or whether certain processes predominate in certain organs. Finally, oxidative stress and free radical generation, as a consequence of the hyperglycemia, may also promote the development of complications.

GLYCEMIC CONTROL AND COMPLICATIONS

The Diabetes Control and Complications Trial (DCCT) provided definitive proof that reduction in chronic hyperglycemia can prevent many of the early complications of type 1DM. This large multicenter clinical trial randomized over 1400 individuals with type 1 DM to either intensive or conventional diabetes management, and then evaluated the development of retinopathy, nephropathy, and neuropathy. Individuals in the intensive diabetes management group received multiple administrations of insulin each day along with intense educational, psychological, and medical support. Individuals in the conventional diabetes management group received twice daily insulin injections and quarterly nutritional, educational, and clinical evaluation. The goal in the former group was normoglycemia; the goal in the latter group was prevention of symptoms of diabetes. Individuals in the intensive diabetes management group achieved a substantially lower HbA1c (7.2%) than individuals in the conventional diabetes management group (HbA1c of 9.0%).

Results from theDCCTdemonstrated that improvement of glycemic control reduced nonproliferative and proliferative retinopathy (47% reduction), microalbuminuria (39% reduction), clinical nephropathy (54% reduction), and neuropathy (60% reduction). Improved glycemic control also slowed the progression of early diabetic complications. There was a nonsignificant trend in reduction of macrovascular events. The results of the DCCT predicted that individuals in the intensive diabetes management group would gain 7.7 additional years of sight, 5.8 additional years free from end-stage renal disease (ESRD), and 5.6 years free from lower extremity amputations. If all complications ofDM were combined, individuals in the intensive diabetes management group would experience 15.3 more years of life without significant microvascular or neurologic complications of DM as compared to individuals who received standard therapy. This translates into an additional 5.1 years of life expectancy for individuals in the intensive diabetes management group. The benefit of the improved glycemic control during the

DCCT persisted even after the study concluded and glycemic control worsened.

The benefits of an improvement in glycemic control occurred over the entire range of HbA1c values (Fig. 333-8), suggesting that at any HbA1c level, an improvement in glycemic control is beneficial. Therefore, there is no threshold beneath which the HbA1c can be reduced and the complications ofDMprevented. The clinical implication of this finding is that the goal of therapy is to achieve an HbA1c level as close to normal as possible, without subjecting the patient to excessive risk of hypoglycemia.

Considerable debate has emerged as to whether theDCCTfindings are applicable to individuals with type 2DM, in whom insulin resistance, hyperinsulinemia, and obesity predominate. Concerns have been raised that therapies associated with weight gain and additional insulin therapy may worsen underlying insulin resistance and hyperinsulinemia. Despite these concerns, most available data support extrapolation of the results of the DCCT to individuals with type 2 DM.

The United Kingdom Prospective Diabetes Study (UKPDS) studied the course of>5000 individuals with type 2DM for>10 years. This complex and important study utilized multiple treatment regimens and monitored the effect of intensive glycemic control and risk factor treatment on the development of diabetic complications. Newly diagnosed individuals with type 2 DM were randomized to (1) intensive management using various combinations of insulin, a sulfonylurea, or metformin; or (2) conventional therapy using dietary modification and pharmacotherapy with the goal of symptom prevention. In addition, individuals were randomly assigned to different antihypertensive regimens. Individuals in the intensive treatment arm achieved an HbA1c of 7.0%, compared to a 7.9% HbA1c in the standard treatment group. The UKPDS demonstrated that each percentage point reduction in HbA1c was associated with a 35% reduction in microvascular complications, a 25% reduction in DM-related deaths, and a 7% reduction in all-cause mortality. As in theDCCT, there was a continuous relationship between glycemic control and development of complications. Although there was no statistically significant effect of glycemic control on cardiovascular complications, there was a 16% reduction in fatal and nonfatal myocardial infarctions.

One of the major findings of theUKPDSwas the observation that strict blood pressure control significantly reduced both macro- and microvascular complications. In fact, the beneficial effects of blood pressure control were greater than the beneficial effects of glycemic control. Lowering blood pressure to moderate goals (144/82 mmHg) reduced the risk ofDM-related death, stroke, microvascular end points, retinopathy, and heart failure (risk reductions between 32 and 56%). Improved glycemic control did not conclusively reduce (nor worsen) cardiovascular mortality but was associated with improvement with lipoprotein risk profiles, such as reduced triglycerides and increased high-density lipoprotein (HDL).

Similar reductions in the risks of retinopathy and nephropathy were also seen in a small trial of lean Japanese individuals with type 2DMrandomized to either intensive glycemic control or standard therapy with insulin (Kumamoto study). These results demonstrate the effectiveness of improved glycemic control in individuals of different ethnicity with a presumably different etiology of DM (i.e., phenotypically different from those in theDCCT andUKPDS).

The findings of theDCCT,UKPDS, and Kumamoto study support the idea that chronic hyperglycemia plays a causative role in the pathogenesis of diabetic microvascular complications. These landmark studies prove the value of metabolic control and emphasize the importance of (1) intensive glycemic control in all forms ofDM, and (2) early diagnosis and strict blood pressure control in type 2 DM.

OPHTHALMOLOGIC COMPLICATIONS OF DIABETES MELLITUS

DMis the leading cause of blindness between the ages of 20 and 74 in the United States. The gravity of this problem is highlighted by the finding that individuals with DM are 25 times more likely to become legally blind than individuals without DM. Blindness is primarily the result of progressive diabetic retinopathy and clinically significant macular edema. Diabetic retinopathy is classified into two stages: nonproliferative and proliferative. *Nonproliferative diabetic retinopathy* usually appears late in the first decade or early in the second decade of the disease and is marked by retinal vascular microaneurysms, blot hemorrhages, and cotton wool spots (seePlate IV-15). Mild nonproliferative retinopathy progresses to more extensive disease, characterized by changes in venous vessel caliber, intraretinal microvascular abnormalities, and more numerous microaneurysms and hemorrhages. The pathophysiologic mechanisms invoked in nonproliferative retinopathy include loss of retinal pericytes, increased retinal vascular permeability, alterations in retinal blood flow, and abnormal retinal microvasculature, all of which lead to retinal ischemia.

The appearance of neovascularization in response to retinal hypoxia is the hallmark of *proliferative diabetic retinopathy*. These newly formed vessels may appear at the optic nerve and/or macula and rupture easily, leading to vitreous hemorrhage, fibrosis, and ultimately retinal detachment. Not all individuals with nonproliferative retinopathy develop proliferative retinopathy, but the more severe the nonproliferative disease, the greater the chance of evolution to proliferative retinopathy within 5 years. This creates a clear opportunity for early detection and treatment of diabetic retinopathy (discussed below). In contrast, *clinically significant macular edema* may appear when only nonproliferative retinopathy is present. Fluorescein angiography is often useful to detect macular edema, which is associated with a 25% chance of moderate visual loss over the next 3 years.

Duration ofDM and degree of glycemic control are the best predictors of the development of retinopathy. Nonproliferative retinopathy is found in almost all individuals who have had DM for >20 years (25% incidence with 5 years, and 80% incidence with 15 years of type 1 DM). Although there is genetic susceptibility for retinopathy, it confers less influence on the development of retinopathy than either the duration of DM or the degree of glycemic control.

TREATMENT

The most effective therapy for diabetic retinopathy is prevention. Intensive glycemic control will greatly delay the development or slow the progression of retinopathy in individuals with either type 1 or type 2DM. Paradoxically, during the first 6 to 12 months of improved glycemic control, established diabetic retinopathy may transiently worsen.

Fortunately, this progression is temporary, and in the long term, improved glycemic control is associated with less diabetic retinopathy. Individuals with known retinopathy should be considered candidates for prophylactic photocoagulation when initiating intensive therapy. Once advanced retinopathy is present, improved glycemic control imparts less benefit, though adequate ophthalmologic care can prevent most blindness.

Equally as important as glycemic control are regular, comprehensive eye examinations for all individuals with DM. Most diabetic eye disease can be successfully treated if detected early. Routine, nondilated eye examinations by the primary care provider or diabetes specialist are *inadequate* to detect diabetic eye disease properly. The treatment of diabetic eye disease requires an ophthalmologist experienced in these disorders. Laser photocoagulation is very successful in preserving vision. Proliferative retinopathy is usually treated with panretinal laser photocoagulation, whereas macular edema is treated with focal laser photocoagulation. Although exercise has not been conclusively shown to worsen proliferative diabetic retinopathy, most ophthalmologists advise individuals with advanced diabetic eye disease to limit physical activities associated with repeated Valsalva maneuvers. Aspirin therapy (650 mg/d) does not appear to influence the natural history of diabetic retinopathy, but studies of other antiplatelet agents are under way.

RENAL COMPLICATIONS OF DIABETES MELLITUS

Diabetic nephropathy is the leading cause ofESRD in the United States and a leading cause ofDM-related morbidity and mortality. Proteinuria in individuals with DM is associated with markedly reduced survival and increased risk of cardiovascular disease. Individuals with diabetic nephropathy almost always have diabetic retinopathy also.

Like other microvascular complications, the pathogenesis of diabetic nephropathy is related to chronic hyperglycemia (Fig. 334-7). The mechanisms by which chronic hyperglycemia leads toESRD, though incompletely defined, involve the following: interaction of soluble factors (growth factors, angiotensin II, endothelin,AGEs), hemodynamic alterations in the renal microcirculation (glomerular hyperfiltration, increased glomerular capillary pressure), and structural changes in the glomerulus (increased extracellular matrix, basement membrane thickening, mesangial expansion, fibrosis). Some of these effects may be mediated through angiotensin receptors. Smoking accelerates the decline in renal function.

The natural history of diabetic nephropathy is shown schematically inFig. 333-9 and is characterized by a fairly predictable pattern of events. Although this sequence of events was defined for individuals with type 1DM, a similar pattern is also likely in type 2 DM. Glomerular hyperfusion and renal hypertrophy occur in the first years after the onset of DM and are reflected by an increased glomerular filtration rate (GFR). During the first 5 years of DM, thickening of the glomerular basement membrane, glomerular hypertrophy, and mesangial volume expansion occur as the GFR returns to normal. After 5 to 10 years of type 1 DM, ~40% of individuals begin to excrete small amounts of albumin in the urine (microalbuminuria). *Microalbuminuria* is defined as 30 to 300 mg/d in a 24-h collection or 30 to 300 ug/mg creatinine in a spot collection. The appearance of microalbuminuria (incipient nephropathy) in type 1 DM is a very important predictor of progression to overt proteinuria (>300 mg/d). Blood pressure may rise slightly at this

point but usually remains in the normal range. Once overt proteinuria is present, there is a steady decline in GFR, and ~50% of individuals reachESRD in 7 to 10 years. The early pathologic changes and albumin excretion abnormalities are reversible with normalization of plasma glucose. However, once nephropathy becomes overt, the pathologic changes are likely irreversible.

The nephropathy that develops in type 2DMdiffers from that of type 1 DM in the following respects: (1) microalbuminuria or overt nephropathy may be present when type 2 DM is diagnosed, reflecting its long asymptomatic period; (2) hypertension more commonly accompanies microalbuminuria or overt nephropathy in type 2 DM; and (3) microalbuminuria may be less predictive of progression to overt nephropathy in type 2 DM. Finally, it should be noted that albuminuria in type 2 DM may be secondary to factors unrelated to DM, such as hypertension, congestive heart failure, prostate disease, or infection.

Other renal problems may also occur in individuals withDM. Type IV renal tubular acidosis (hyporeninemic hypoaldosteronism) occurs in many individuals with DM. These individuals develop a propensity to hyperkalemia, which may be exacerbated by medications [especially angiotensin-converting enzyme (ACE) inhibitors]. Patients with DM are predisposed to radiocontrast-induced nephrotoxicity. Individuals with DM undergoing radiographic procedures with contrast dye should be well hydrated before and after dye exposure, and the serum creatinine should be monitored for several days following the procedure.

TREATMENT

The optimal therapy for diabetic nephropathy is prevention. As part of comprehensive diabetes care, microalbuminuria should be detected at an early stage when effective therapies can be instituted. The recommended strategy for detecting microalbuminuria is outlined in Fig. 333-10. Interventions effective in slowing progression from microalbuminuria to overt nephropathy include: (1) near normalization of glycemia, (2) strict blood pressure control, and (3) administration ofACEinhibitors.

Improved glycemic control reduces the rate at which microalbuminuria appears and progresses in both type 1 and type 2DM. However, once overt nephropathy exists, it is unclear whether improved glycemic control will slow progression of renal disease. During the phase of declining renal function, insulin requirements may fall as the kidney is a site of insulin degradation. Furthermore, glucose-lowering medications (sulfonylureas and metformin) may accumulate and are contraindicated in renal insufficiency.

Many individuals with type 1 or type 2DMdevelop hypertension. Numerous studies in both type 1 and type 2 DM demonstrate the effectiveness of strict blood pressure control in reducing albumin excretion and slowing the decline in renal function. Blood pressure should be maintained at <130/85 mmHg in diabetic individuals without proteinuria. A slightly lower blood pressure (120/80) should be targeted for individuals with microalbuminuria or overt nephropathy. Treatment of hypertension is discussed below.

ACEinhibitors reduce the progression of overt nephropathy in individuals with type 1 or

type 2DM and should be prescribed in individuals with type 1 or type 2 DM and microalbuminuria. After 2 to 3 months of therapy, measurement of proteinuria should be repeated and the drug dose increased until either the albuminuria disappears or the maximum dose is reached. If an ACE inhibitor has an unacceptable side-effect profile (hyperkalemia, cough, and renal insufficiency), angiotensin II receptor blockers and calcium channel blockers (phenylalkylamine class) are alternatives. However, their efficacy in slowing the fall in glomerular filtration rate is not proven. Blood pressure control with any agent is extremely important, but a drug-specific benefit in diabetic nephropathy, independent of blood pressure control, has been shown only for ACE inhibitors.

A consensus panel of the American Diabetes Association (ADA) suggests modest restriction of protein intake in diabetic individuals with microalbuminuria (0.8 g/kg per day, which is the adult Recommended Daily Allowance, and about 10% of the daily caloric intake). Protein intake should be restricted further in individuals with overt diabetic nephropathy (0.6 g/kg per day), though conclusive proof of the efficacy of protein restriction is lacking.

Nephrology consultation should be considered after the diagnosis of early nephropathy. Once overt nephropathy ensues, the likelihood ofESRD is very high. As compared to nondiabetic individuals, hemodialysis in patients withDM is associated with more frequent complications, such as hypotension (autonomic neuropathy, loss of reflex tachycardia), more difficult vascular access, and accelerated progression of retinopathy. Survival after the onset of ESRD is shorter in the diabetic population compared to nondiabetics with similar clinical features. Atherosclerosis is the leading cause of death in diabetic individuals on dialysis, and hyperlipidemia should be aggressively treated. Renal transplantation from a living-related donor is the preferred therapy but requires chronic immunosuppression. Combined pancreas-kidney transplant offers the promise of normoglycemia but requires substantial expertise.

NEUROPATHY AND DIABETES MELLITUS

Diabetic neuropathy occurs in approximately 50% of individuals with long-standing type 1 and type 2DM. It may manifest as polyneuropathy, mononeuropathy, and/or autonomic neuropathy. As with other complications of DM, the development of neuropathy correlates with the duration of diabetes and glycemic control. Because the clinical features of diabetic neuropathy are similar to those of other neuropathies, the diagnosis of *diabetic* neuropathy should be made only after other possible etiologies are excluded (Chap. 378).

Polyneuropathy/Mononeuropathy The most common form of diabetic neuropathy is distal symmetric *polyneuropathy*. It most frequently presents with distal sensory loss. Hyperesthesia, parathesia, and pain also occur. Any combination of these symptoms may develop as neuropathy progresses. Physical examination reveals sensory loss, loss of ankle reflexes, and abnormal position sense. Parethesia is characteristically perceived as a sensation of numbness, tingling, sharpness, or burning that begins in the feet and spreads proximally. Neuropathic pain develops in some of these individuals, occasionally preceded by improvement in their glycemic control. Pain typically involves the lower extremities, is usually present at rest, and worsens at night. Both an acute

(lasting<12 months) and a chronic form of painful diabetic neuropathy have been described. As diabetic neuropathy progresses, the pain subsides and eventually disappears, and a sensory deficit in the lower extremities persists.

Diabetic polyradiculopathy is a syndrome characterized by severe disabling pain in the distribution of one or more nerve roots. It may be accompanied by motor weakness. Intercostal or truncal radiculopathy causes pain over the thorax or abdomen. Involvement of the lumbar plexus or femoral nerve may cause pain in the thigh or hip and may be associated with muscle weakness in the hip flexors or extensors (diabetic amyotrophy). Fortunately, diabetic polyradiculopathies are usually self-limited and resolve over 6 to 12 months.

Mononeuropathy (dysfunction of isolated cranial or peripheral nerves) is less common than polyneuropathy inDM and presents with pain and motor weakness in the distribution of a single nerve. A vascular etiology is favored, but the pathogenesis is unknown. Involvement of the third cranial nerve is most common and is heralded by diplopia. Physical examination reveals ptosis and opthalmoplegia with normal papillary constriction to light. Sometimes cranial nerves IV, VI, or VII (Bell's palsy) are affected. Peripheral mononeuropathies or simultaneous involvement of more than one nerve (mononeuropathy multiplex) may also occur.

Autonomic Neuropathy Individuals with long-standing type 1 or 2DM may develop signs of autonomic dysfunction involving the cholinergic, noradrenergic, and peptidergic (peptides such as pancreatic polypeptide, substance P, etc.) systems. DM-related autonomic neuropathy can involve multiple systems, including: the cardiovascular, gastrointestinal, genitourinary, sudomotor, and metabolic systems. Autonomic neuropathies affecting the cardiovascular system cause a resting tachycardia and orthostatic hypotension. Reports of sudden death have also been attributed to autonomic neuropathy. Gastroparesis and bladder-emptying abnormalities are also likely related to the autonomic neuropathy seen in DM (discussed below). Hyperhidrosis of the upper extremities and anhidrosis of the lower extremities result from sympathetic nervous system dysfunction. Anhidrosis of the feet can promote dry skin with cracking, which increases the risk of skin ulceration. Autonomic neuropathy may reduce counterregulatory hormone release, leading to an inability to sense hypoglycemia appropriately (*hypoglycemia unawareness*;Chap. 334), thereby subjecting the patient to the risk of severe hypoglycemia and complicating efforts to improve glycemic control.

TREATMENT

Treatment of diabetic neuropathy is less than satisfactory. Improved glycemic control should be pursued and will improve nerve conduction velocity, but the symptoms of diabetic neuropathy may not necessarily improve. Efforts to improve glycemic control may be confounded by autonomic neuropathy and hypoglycemia unawareness. Avoidance of neurotoxins (alcohol), supplementation with vitamins for possible deficiencies (B_{12}, B_6, folate; Chap. 75), and symptomatic treatment are the mainstays of therapy. Aldose reductase inhibitors do not currently offer significant symptomatic relief. Loss of sensation in the foot places the patient at risk for ulceration and its sequelae; consequently, prevention of such problems is of paramount importance. Since the pain of acute diabetic neuropathy may resolve over the first year, analgesics may be

discontinued as progressive neuronal damage fromDMoccurs. Chronic, painful diabetic neuropathy is difficult to treat but may respond to tricyclic antidepressants (amitriptyline, desipramine, nortriptyline), gabapentin, nonsteroidal anti-inflammatory agents (avoid in renal dysfunction), and other agents (mexilitine, phenytoin, carbamazepine, capsaicin cream). Referral to a pain management center may be necessary.

Therapy of orthostatic hypotension secondary to autonomic neuropathy is difficult. A variety of agents have limited success (fludrocortisone, midodrine, clonidine, octreotide, and yohimbine) but have significant side effects. Nonpharmacologic maneuvers (adequate salt intake, avoidance of dehydration and diuretics, and lower extremity support hose) may offer some benefit.

GASTROINTESTINAL/GENITOURINARY DYSFUNCTION

Long-standing type 1 and 2DM may affect the motility and function of gastrointestinal (GI) and genitourinary systems. The most prominent GI symptoms are delayed gastric emptying (gastroparesis) and altered small- and large-bowel motility (constipation or diarrhea). *Gastroparesis* may present with symptoms of anorexia, nausea, vomiting, early satiety, and abdominal bloating. Nuclear medicine scintigraphy after ingestion of a radiolabeled meal is the best study to document delayed gastric emptying, but noninvasive "breath tests" following ingestion of a radiolabeled meal are under development. Though parasympathetic dysfunction secondary to chronic hyperglycemia is important in the development of gastroparesis, hyperglycemia itself also impairs gastric emptying. Nocturnal diarrhea, alternating with constipation, is a common feature of DM-related GI autonomic neuropathy. In type 1 DM, these symptoms should also prompt evaluation for celiac sprue because of its increased frequency. Esophageal dysfunction in long-standing DM is common but usually asymptomatic.

Diabetic autonomic neuropathy may lead to genitourinary dysfunction including cystopathy, erectile dysfunction, and female sexual dysfunction (reduced sexual desire, dyspareunia, reduced vaginal lubrication). Symptoms of diabetic cystopathy begin with an inability to sense a full bladder and a failure to void completely (Chap. 48). As bladder contractility worsens, bladder capacity and the postvoid residual increase, leading to symptoms of urinary hesitancy, decreased voiding frequency, incontinence, and recurrent urinary tract infections. Diagnostic evaluation includes cystometry and urodynamic studies.

Erectile dysfunction and retrograde ejaculation are very common inDM and may be one of the earliest signs of diabetic neuropathy. Erectile dysfunction, which increases in frequency with the age of the patient and the duration of diabetes, may occur in the absence of other signs of diabetic autonomic neuropathy.

TREATMENT

Current treatments for these complications ofDM are inadequate. Improved glycemic control should be a primary goal, as some aspects (neuropathy, gastric function) may improve as near-normoglycemia is achieved. Smaller, more frequent meals that are easier to digest (liquid) and low in fat and fiber may minimize symptoms of gastroparesis. Cisapride (10 to 20 mg before each meal) is probably the most effective

medication but has been removed from use in the U.S. market except under special circumstances. Other agents with some efficacy include dopamine agonists (metoclopramide, 5 to 10 mg, and domperidone, 10 to 20 mg, before each meal) and bethanechol (10 to 20 mg before each meal). Erythromycin interacts with the motilin receptor and may promote gastric emptying. Diabetic diarrhea in the absence of bacterial overgrowth is treated symptomatically with loperamide but may respond to clonidine at higher doses (0.6 mg tid) or octreotide (50 to 75 ug tid subcutaneously). Treatment of bacterial overgrowth with antibiotics is sometimes useful (Chap. 286).

Diabetic cystopathy should be treated with timed voiding or self-catherization. Medications (bethanechol) are inconsistently effective. The drug of choice for erectile dysfunction is sildenafil, but the efficacy in individuals withDM is slightly lower than in the nondiabetic population (Chap. 51). Sexual dysfunction in women may be improved with use of vaginal lubricants, treatment of vaginal infections, and systemic or local estrogen replacement.

CARDIOVASCULAR MORBIDITY AND MORTALITY

Cardiovascular disease is increased in individuals with type 1 or type 2DM. The Framingham Heart Study revealed a marked increase in several cardiovascular diseases in DM including peripheral vascular disease, congestive heart failure, coronary artery disease, myocardial infarction, and sudden death (risk increase from one- to fivefold). The American Heart Association recently designated DM as a major risk factor for cardiovascular disease (same category as smoking, hypertension, and hyperlipidemia). Because of the extremely high frequency of underlying cardiovascular disease in individuals with diabetes (especially in type 2 DM), evidence of atherosclerotic vascular disease should be sought in the individual with diabetes who has symptoms suggestive of cardiac ischemia, peripheral or carotid arterial disease, a resting electrocardiogram indicative of prior infarction, plans to initiate an exercise program, proteinuria, or two other cardiac risk factors (ADA recommendations). The absence of chest pain ("silent ischemia") is common in individuals with diabetes, and a thorough cardiac evaluation is indicated in individuals undergoing major surgical procedures.

The increase in morbidity and mortality appears to relate to the synergism of hyperglycemia with other cardiovascular risk factors. For example, after controlling for all known cardiovascular risk factors, type 2DMincreases the cardiovascular death rate by twofold in men and fourfold in women. Risk factors for macrovascular disease in diabetic individuals include dyslipidemia, hypertension, obesity, reduced physical activity, and cigarette smoking. Additional risk factors specific to the diabetic population include microalbuminuria, gross proteinuria, an elevation in serum creatinine, and altered platelet function. Insulin resistance, as reflected by elevated serum insulin levels, is associated with an increased risk of cardiovascular complications in individuals with and without DM. Individuals with insulin resistance and type 2 DM have elevated levels of plasminogen activator inhibitors (especially PAI-1) and fibrinogen, which enhances the coagulation process and impairs fibrinolysis, thus favoring the development of thrombosis.

Despite proof that improved glycemic control reduces microvascular complications

inDM, it is possible that macrovascular complications may be unaffected or even worsened by such therapy. Concerns about the anabolic and atherogenic potential of insulin remain, since in nondiabetic individuals, higher serum insulin levels (indicative of insulin resistance) are associated with a greater risk of cardiovascular morbidity and mortality. In theDCCT, the number of cardiovascular events did not differ between the standard and intensively treated groups. However, the duration of DM in these individuals was relatively short, and the total number of events was very low. An improvement in the lipid profile of individuals in the intensive group [lower total and low-density lipoprotein (LDL) cholesterol, lower triglycerides] suggested that intensive therapy may reduce the risk of cardiovascular morbidity and mortality associated with DM. In theUKPDS, improved glycemic control did not conclusively reduce cardiovascular mortality. Importantly, treatment with insulin and the sulfonylureas did not appear to increase the risk of cardiovascular disease in individuals with type 2 DM, refuting prior claims about the atherogenic potential of these agents.

In addition to coronary artery disease, cerebrovascular disease is increased in individuals withDM(threefold increase in stroke). Individuals with DM have an increased incidence of congestive heart failure (diabetic cardiomyopathy). The etiology of this abnormality is probably multifactorial and includes factors such as myocardial ischemia from atherosclerosis, hypertension, and myocardial cell dysfunction secondary to chronic hyperglycemia.

TREATMENT

In general, the treatment of coronary disease is no different in the diabetic individual (Chap. 244), though overall prognosis after myocardial infarction is worse in the diabetic population. Revascularization procedures for coronary artery disease, including percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass grafting (CABG), are less efficacious in the diabetic individual. Initial success rates of PTCA in diabetic individuals are similar to those in the nondiabetic population, but diabetic patients have higher rates of restenosis and lower long-term patency and survival rates. Perioperative mortality from CABG is not altered inDM, but both short- and long-term survival are reduced. Recent trials indicate that diabetic individuals with multivessel coronary artery disease or who recently suffered a Q-wave myocardial infarction have better long-term survival with CABG than PTCA.

Results of studies investigating the effect of intensive diabetes management on survival rates and cardiovascular events after myocardial infarction have been conflicting. In the face of conflicting data, theADA has emphasized the importance of glycemic control and aggressive cardiovascular risk modification in all individuals withDM. Despite past trepidation about using beta blockers in individuals who have diabetes, these agents clearly benefit diabetic patients after myocardial infarction, analogous to the benefit in nondiabetic individuals.ACEinhibitors may also be particularly beneficial in reducing mortality after myocardial infarction in patients with DM.

Antiplatelet therapy reduces cardiovascular events in individuals withDM who have coronary artery disease. Current recommendations by theADAsuggest the use of aspirin as secondary prevention of additional coronary events. Although data demonstrating efficacy in primary prevention of coronary events are lacking, antiplatelet

therapy should be considered, especially in diabetic individuals with other coronary risk factors such as hypertension, smoking, or hyperlipidemia. The aspirin dose (81 to 325 mg) is the same as that in nondiabetic individuals. Aspirin therapy does not have detrimental effects on renal function or hypertension, nor does it influence the course of diabetic retinopathy or maculopathy.

Cardiovascular Risk Factors

Dyslipidemia Individuals withDM may have several forms of dyslipidemia (Chap. 344). Because of the additive cardiovascular risk of hyperglycemia and hyperlipidemia, lipid abnormalities should be aggressively detected and treated as part of comprehensive diabetes care (Fig. 333-11). The most common pattern of dyslipidemia is hypertriglyceridemia and reducedHDLcholesterol levels. DM itself does not increase levels ofLDL, but the small dense LDL particles found in type 2 DM are more atherogenic because they are more easily glycated and susceptible to oxidation.

According to guidelines of theADA and the American Heart Association, the lipid profile in diabetic individuals without cardiovascular disease (primary prevention) should be:LDL< 3.4 mmol/L (130 mg/dL);HDL> 0.9 mmol/L (35 mg/dL) in men and>1.2 mmol/L (45 mg/dL) in women; and triglycerides< 2.3 mmol/L (200 mg/dL). In diabetic individuals with cardiovascular disease, the LDL goal is < 2.6 mmol/L (100 mg/dL). Because of the risk of cardiovascular disease in diabetic individuals, many authorities recommend that optimal lipid levels for all individuals withDM (with or without cardiovascular disease) should be: LDL <2.6 mmol/L (100 mg/dL), HDL > 1.15 mmol/L (45 mg/dL) in men and > 1.41 mmol/L (55 mg/dL) in women; and triglycerides < 2.3 mmol/L (200 mg/dL). The ADA recommends dietary modification in diabetic individuals without cardiovascular disease and a LDL cholesterol of 2.6 to 3.3 mmol/L (100 to 129 mg/dL). If multiple cardiovascular risk factors are present, the goal should be a LDL < 2.6 mmol/L (100 mg/dL) even without known cardiovascular disease.

Almost all studies of diabetic dyslipidemia have been performed in individuals with type 2DMbecause of the greater frequency of dyslipidemia in this form of diabetes. Interventional studies have shown that the beneficial effects ofLDLreduction are similar in the diabetic and nondiabetic populations. Large prospective trials of primary and secondary intervention for coronary heart disease have included a small number of individuals with type 2 DM, and subset analyses have consistently found that reductions in LDL reduce cardiovascular events and morbidity in individuals with DM (Fig. 333-CD1). Most clinical trials used HMG CoA reductase inhibitors, although a fibric acid derivative was also beneficial in one trial. No prospective studies have addressed similar questions in individuals with type 1 DM.

Based on the guidelines provided by theADA and the American Heart Association, the order of priorities in the treatment of hyperlipidemia is: (1) lower theLDLcholesterol, (2) raise theHDLcholesterol, and (3) decrease the triglycerides. A treatment strategy depends on the pattern of lipoprotein abnormalities (Fig. 333-11). Initial therapy for all forms of dyslipidemia should include dietary changes, as well as the same life-style modifications recommended in the nondiabetic population (smoking cessation, control of blood pressure, weight loss, increased physical activity). The dietary recommendations for individuals withDM are similar to those advocated by the National Cholesterol

Education Program (Chap. 344) and include an increase in monounsaturated fat and carbohydrates and a reduction in saturated fats and cholesterol. Though viewed as important, the response to dietary alterations is often modest [<0.6-mmol/L (<25-mg/dL) reduction in the LDL]. Improvement in glycemic control will lower triglycerides and have a modest beneficial effect on raising HDL. Most medications that improve glycemic control are useful in lowering triglycerides and may raise the HDL slightly. Though fibric acid derivatives have some efficacy and are well tolerated, nicotinic acid may worsen glycemic control and increase insulin resistance; thus, niacin is relatively contraindicated in diabetic patients on oral glucose-lowering agents. As noted above, HMG CoA reductase inhibitors have proven benefit in patients with DM, even with modest elevations in LDL. Combination therapy with an HMG CoA reductase inhibitor and fibric acid derivative may be useful but increases the possibility of myositis. Bile acid-binding resins should not be used if hypertriglyceridemia is present.

Hypertension Hypertension can accelerate other complications ofDM, particularly cardiovascular disease and nephropathy. Hypertension therapy should first emphasize life-style modifications such as weight loss, exercise, stress management, and sodium restriction (Chap. 35). Antihypertensive agents should be selected based on the advantages and disadvantages of the therapeutic agent in the context of an individual patient's risk factor profile.ACEinhibitors are glucose- and lipid-neutral and thus positively impact the cardiovascular risk profile. For example, captopril actually improves insulin resistance, reducesLDLslightly, and increasesHDLslightly. In one study of nondiabetic individuals, the ACE inhibitor ramipril reduced the risk of developing type 2 DM. Other effective agents includea-adrenergic blockers (prazocin, terazosin, doxazosin), calcium channel blockers, beta blockers (both$b_1$selective and nonselective), thiazide diuretics (hydrochlorothiazide and its derivatives), central adrenergic antagonists (clonidine, methyldopa), and vasodilators (minoxidil, hydralazine). DM-related considerations include the following:

1. a-Adrenergic blockers slightly improve insulin resistance and positively impact the lipid profile, whereas beta blockers and thiazide diuretics can increase insulin resistance, negatively impact the lipid profile, and slightly increase the risk of developing type 2 diabetes.

2. Beta blockers, often questioned because of the potential masking of hypoglycemic symptoms, are effective agents and hypoglycemic events are rare when cardioselective (b_1) agents are used.

3. Central adrenergic antagonists and vasodilators are lipid- and glucose-neutral.

4. Sympathetic inhibitors anda-adrenergic blockers may be associated with orthostatic hypotension in the diabetic individual with autonomic neuropathy.

5. Calcium channel blockers are glucose- and lipid-neutral, and some evidence suggests that they reduce cardiovascular morbidity and mortality in type 2 DM, particularly in elderly patients with systolic hypertension.

If microalbuminuria or overt albuminuria is present, the optimal antihypertensive agent is anACEinhibitor. If albumin excretion is normal, then an ACE inhibitor or other

antihypertensive agent may be used. Low-dose diuretics and beta blockers are sometimes preferred as initial agents because of their clear efficacy in the nondiabetic population. Since hypertension is often difficult to control with a single agent (especially in type 2DM), multiple antihypertensive agents are usually required when blood pressure goals (<130/85 mmHg) are not achieved. In this setting, long-acting calcium channel antagonists should be considered as additional, or second-line, agents, as these drugs appear to provide protection against cardiovascular events. ACE inhibitors are contraindicated in pregnant diabetic patients and those anticipating pregnancy. Because of the high prevalence of atherosclerotic disease in individuals with DM, the possibility of renovascular hypertension should be considered when the blood pressure is not readily controlled.

LOWER EXTREMITY COMPLICATIONS

DMis the leading cause of nontraumatic lower extremity amputation in the United States. Foot ulcers and infections are also a major source of morbidity in individuals with DM. The reasons for the increased incidence of these disorders in DM are complex and involve the interaction of several pathogenic factors: neuropathy, abnormal foot biomechanics, peripheral vascular disease, and poor wound healing. The peripheral sensory neuropathy interferes with normal protective mechanisms and allows the patient to sustain major or repeated minor trauma to the foot, often without knowledge of the injury. Disordered proprioception causes abnormal weight bearing while walking and subsequent formation of callus or ulceration. Motor and sensory neuropathy leads to abnormal foot muscle mechanics and to structural changes in the foot (hammer toe, claw toe deformity, prominent metatarsal heads). Autonomic neuropathy results in anhidrosis and altered superficial blood flow in the foot, which promote drying of the skin and fissure formation. Peripheral vascular disease and poor wound healing impede resolution of minor breaks in the skin, allowing them to enlarge and to become infected.

Approximately 15% of individuals withDMdevelop a foot ulcer, and a significant subset of those individuals will at some time undergo amputation (14 to 24% risk with that ulcer or subsequent ulceration). Risk factors for foot ulcers or amputation include: male sex, diabetes >10 years' duration, peripheral neuropathy, abnormal structure of foot (bony abnormalities, callus, thickened nails), peripheral vascular disease, smoking, and history of previous ulcer or amputation. Glycemic control is also a risk factor -- each 2% increase in the HbA1c increases the risk of a lower extremity ulcer by 1.6 times and the risk of lower extremity amputation by 1.5 times.

TREATMENT

The optimal therapy for foot ulcers and amputations is prevention through identification of high-risk patients, education of the patient, and institution of measures to prevent ulceration. High-risk patients should be identified during the routine foot examination performed on all patients withDM (see "Ongoing Aspects of Comprehensive Diabetes Care," below). Patient education should emphasize: (1) careful selection of footwear, (2) daily inspection of the feet to detect early signs of poor-fitting footwear or minor trauma, (3) daily foot hygiene to keep the skin clean and moist, (4) avoidance of self-treatment of foot abnormalities and high-risk behavior (e.g., walking barefoot), and (5) prompt consultation with a health care provider if an abnormality arises. Patients at high risk for

ulceration or amputation may benefit from evaluation by a foot care specialist. Interventions directed at risk factor modification include orthotic shoes and devices, callus management, nail care, and prophylactic measures to reduce increased skin pressure from abnormal bony architecture. Attention to other risk factors for vascular disease (smoking, dyslipidemia, hypertension) and improved glycemic control are also important.

Despite preventive measures, foot ulceration and infection are common and represent a potentially serious problem. Due to the multifactorial pathogenesis of lower extremity ulcers, management of these lesions must be multidisciplinary and often demands expertise in orthopedics, vascular surgery, endocrinology, podiatry, and infectious diseases. The plantar surface of the foot is the most common site of ulceration. Cellulitis without ulceration is also frequent and should be treated with antibiotics that provide broad-spectrum coverage, including anaerobes (see below).

An infected ulcer is a clinical diagnosis, since superficial culture of any ulceration will likely find multiple possible bacterial pathogens. The infection surrounding the foot ulcer is often the result of multiple organisms (gram-positive and -negative cocci and anaerobes), and gas gangrene may develop in the absence of clostridial infection. Cultures taken from the debrided ulcer base or from purulent drainage are most helpful. Wound depth should be determined by inspection and probing with a blunt-tipped sterile instrument. Plain radiographs of the foot should be performed to assess the possibility of osteomyelitis in chronic ulcers that have not responded to therapy. Nuclear medicine bone scans may be helpful, but overlying subcutaneous infection is often difficult to distinguish from osteomyelitis. Indium-labeled white cell studies are more useful in determining if the infection involves bony structures or only soft tissue, but they are technically demanding. Magnetic resonance imaging of the foot may be the most specific modality, although distinguishing bony destruction due to osteomyelitis from destruction secondary to Charcot arthropathy is difficult. If surgical debridement is necessary, bone biopsy and culture usually provide the answer.

Osteomyelitis is best treated by a combination of prolonged antibiotics and debridement of infected bone. The possible contribution of vascular insufficiency should be considered in all patients. Noninvasive blood-flow studies are often unreliable inDM, and angiography may be required, recognizing the risk of contrast-induced nephrotoxicity. Peripheral vascular bypass procedures are often effective in promoting wound resolution and in decreasing the need for amputation of the ischemic limb.

A growing number of possible treatments for diabetic foot ulcers exist, but they have yet to demonstrate clear efficacy in prospective, controlled trials. A recent consensus statement from theADAidentified six interventions with demonstrated efficacy in diabetic foot wounds: (1) off-loading, (2) debridement, (3) wound dressings, (4) appropriate use of antibiotics, (5) revascularization, and (6) limited amputation. Off-loading is the complete avoidance of weight bearing on the ulcer, which removes the mechanical trauma that retards wound healing. Bed rest and a variety of orthotic devices limit weight bearing on wounds or pressure points. Surgical debridement of neuropathic wounds is important and effective, but clear efficacy of other modalities for wound cleaning (enzymes, soaking, whirlpools) is lacking. Dressings promote wound healing by creating a moist environment and protecting the wound. Antiseptic agents and topical antibiotics

should be avoided. Referral for physical therapy, orthotic evaluation, and rehabilitation may be useful once the infection is controlled.

Mild or non-limb-threatening infections can be treated with oral antibiotics (cephalosporin, clindamycin, amoxicillin/clavulanate, and fluoroquinolones), surgical debridement of necrotic tissue, local wound care (avoidance of weight bearing over the ulcer), and close surveillance for progression of infection. More severe ulcers may require intravenous antibiotics as well as bed rest and local wound care. Urgent surgical debridement may be required. Intravenous antibiotics should provide broad-spectrum coverage directed toward *Staphylococcus aureus*, streptococci, gram-negative aerobes, and anaerobic bacteria. Initial antimicrobial regimens include cefotetan, ampicillin/sulbactam, or the combination of clindamycin and a fluoroquinolone. Severe infections, or infections that do not improve after 48 h of antibiotic therapy, require expansion of antimicrobial therapy to treat methicillin-resistant *S. aureus* (e.g., vancomycin) and *Pseudomonas aeruginosa*. If the infection surrounding the ulcer is not improving with intravenous antibiotics, reassessment of antibiotic coverage and reconsideration of the need for surgical debridement or revascularization are indicated. With clinical improvement, oral antibiotics and local wound care can be continued on an outpatient basis with close follow-up. As infection improves, a comprehensive assessment of modifiable risk factors for foot ulceration should be performed and should involve health professionals with expertise in podiatry, orthotics, vascular surgery, and orthopedics.

New information about wound biology has led to a number of new technologies (e.g., living skin equivalents and growth factors such as basic fibroblast growth factor) that may prove useful. Recombinant platelet-derived growth factor has some benefit and complements the basic therapies of off-loading, debridement, and antibiotics. Hyperbaric oxygen has been used, but rigorous proof of efficacy is lacking.

INFECTIONS

Individuals with DMexhibit a greater frequency and severity of infection. The reasons for this increase include incompletely defined abnormalities in cell-mediated immunity and phagocyte function associated with hyperglycemia, as well as diminished vascularization secondary to long-standing diabetes. Hyperglycemia likely aids the colonization and growth of a variety of organisms (*Candida* and other fungal species). Many common infections are more frequent and severe in the diabetic population, whereas several rare infections are seen almost exclusively in the diabetic population. Examples of this latter category includes rhinocerebral mucormycosis and malignant otitis externa, which is usually secondary to *P. aeruginosa* infection in the soft tissue surrounding the external auditory canal. Malignant otitis externa begins with pain and discharge and may progress rapidly to osteomyelitis and meningitis. These infections should be sought, in particular, in patients presenting withNKHS.

Pneumonia, urinary tract infections, and skin and soft tissue infections are all more common in the diabetic population. In general, the organisms that cause pulmonary infections are similar to those found in the nondiabetic population; however, gram-negative organisms, *S. aureus*, and *Mycobacterium tuberculosis* are more frequent pathogens. Urinary tract infections (either lower tract or pyelonephritis) are the

result of common bacterial agents such as *Escherichia coli*, though several yeast species (*Candida* and *Torulopsis glabrata*) are commonly observed. Complications of urinary tract infections include emphysematous pyelonephritis and emphysematous cystitis. Bacteriuria occurs frequently in individuals with diabetic cystopathy. Susceptibility to furunculosis, superficial candidal infections, and vulvovaginitis is increased. Poor glycemic control is a common denominator in individuals with these infections. Diabetic individuals have an increased rate of colonization of *S. aureus* in the skin folds and nares. Diabetic patients also have a greater risk of postoperative wound infections.

DERMATOLOGIC MANIFESTATIONS

The most common skin manifestations ofDM are protracted wound healing and skin ulcerations. Diabetic dermopathy, sometimes termed *pigmented pretibial papules*, or "diabetic skin spots," begins as an erythematous area and evolves into an area of circular hyperpigmentation (Fig. 333-CD2). These lesions result from minor mechanical trauma in the pretibial region and are more common in elderly men with DM. Bullous diseases (shallow ulcerations or erosions in the pretibial region) are also seen. *Necrobiosis lipoidica diabeticorum* is a rare disorder of DM that predominantly affects young women with type 1 DM, neuropathy, and retinopathy. It usually begins in the pretibial region as an erythematous plaque or papules that gradually enlarge, darken, and develop irregular margins, with atrophic centers and central ulceration. They may be painful. *Acanthosis nigricans* (hyperpigmented velvety plaques seen on the neck or extensor surfaces) is sometimes a feature of severe insulin resistance and accompanying diabetes (Fig. 333-CD3). Generalized or localized *granuloma annulare* (erythematous plaques on the extremities or trunk) and *scleredema* (areas of skin thickening on the back or neck at the site of previous superficial infections) are more common in the diabetic population. *Lipoatrophy* and *lipohypertrophy* can occur at insulin injection sites but are unusual with the use of human insulin. Xerosis and pruritus are common and are relieved by skin moisturizers.

Approach to the Patient

DMand its complications produce a wide range of symptoms and signs; those secondary to acute hyperglycemia may occur at any stage of the disease, whereas those related to chronic complications begin to appear during the second decade of hyperglycemia. Individuals with previously undetected type 2 DM may present with chronic complications of DM at the time of diagnosis. The history and physical examination should assess for symptoms or signs of acute hyperglycemia and should screen for the chronic complications and conditions associated with DM.

History A complete medical history should be obtained with special emphasis onDM-relevant aspects such as weight, family history of DM and its complications, risk factors for cardiovascular disease, prior medical conditions, exercise, smoking, and ethanol use. Symptoms of hyperglycemia include polyuria, polydipsia, weight loss, fatigue, weakness, blurry vision, frequent superficial infections (vaginitis, fungal skin infections), and slow healing of skin lesions after minor trauma. Metabolic derangements relate mostly to hyperglycemia (osmotic diuresis, reduced glucose entry into muscle) and to the catabolic state of the patient (urinary loss of glucose and

calories, muscle breakdown due to protein degradation and decreased protein synthesis). Blurred vision results from changes in the water content of the lens and resolves as the hyperglycemia is controlled.

In a patient with establishedDM, the initial assessment should also include special emphasis on prior diabetes care, including the type of therapy, prior HbA1c levels, self-monitoring blood glucose results, frequency of hypoglycemia, presence of DM-specific complications, and assessment of the patient's knowledge about diabetes. The chronic complications may afflict several organ systems, and an individual patient may exhibit some, all, or none of the symptoms related to the complications of DM (see above). In addition, the presence of DM-related comorbidities should be sought (cardiovascular disease, hypertension, dyslipidemia).

PHYSICAL EXAMINATION

In addition to a complete physical examination, special attention should be given toDM-relevant aspects such as weight or body mass index, retinal examination, orthostatic blood pressure, foot examination, peripheral pulses, and insulin injection sites. Careful examination of the lower extremities should seek evidence of peripheral neuropathy, calluses, superficial fungal infections, nail disease, and foot deformities (such as hammer or claw toes and Charcot foot) in order to identify sites of potential skin ulceration. Vibratory sensation (128-MHz tuning fork at the base of the great toe) and the ability to sense touch with a monofilament (5.07, 10-g monofilament) are useful to detect moderately advanced diabetic neuropathy. Since dental disease is more frequent in DM, the teeth and gums should also be examined.

Classification of DM in an Individual Patient The etiology of diabetes in an individual with new-onset disease can usually be assigned on the basis of clinical criteria. Individuals with type 1DM tend to have the following characteristics: (1) onset of disease prior to age 30; (2) lean body habitus; (3) requirement of insulin as the initial therapy; (4) propensity to develop ketoacidosis; and (5) an increased risk of other autoimmune disorders such as autoimmune thyroid disease, adrenal insufficiency, pernicious anemia, and vitiligo. In contrast, individuals with type 2 DM often exhibit the following features: (1) develop diabetes after the age of 30; (2) are usually obese (80% are obese, but elderly individuals may be lean); (3) may not require insulin therapy initially; and (4) may have associated conditions such as insulin resistance, hypertension, cardiovascular disease, dyslipidemia, or polycystic ovary syndrome. In type 2 DM, insulin resistance is often associated with abdominal obesity (as opposed to hip and thigh obesity) and hypertriglyceridemia. Although most individuals diagnosed with type 2 DM are older, the age of diagnosis appears to be declining in some ethnic groups, and there is a marked increase among overweight teenagers. On the other hand, some individuals (<10%) with the phenotypic appearance of type 2 DM do not have absolute insulin deficiency but have autoimmune markers suggestive of type 1 DM. Thus, despite the revised classification of DM, it is remains difficult to categorize some patients unequivocally. Individuals who deviate from the clinical profile of type 1 and type 2 DM, or who have other associated defects such as deafness, pancreatic exocrine disease, and other endocrine disorders, should be classified accordingly (Table 333-1).

Laboratory Assessment The laboratory assessment should first determine whether

the patient meets the diagnostic criteria forDM(Table 333-2) and should then assess the degree of glycemic control (HbA1c, discussed below). In addition to the standard laboratory evaluation, the patient should be screened for DM-associated conditions (e.g., microalbuminuria, dyslipidemia, thyroid dysfunction). Individuals at high risk for cardiovascular disease should be screened for asymptomatic coronary artery disease by appropriate cardiac stress testing, when indicated.

The classification of the type ofDM does not usually require laboratory assessments. Serum insulin or C-peptide measurements do not clearly distinguish type 1 from type 2 DM at the time of diabetes onset; a low C-peptide level merely confirms a patient's need for insulin. Conversely, many individuals with new-onset type 1 DM retain some C-peptide production. Measurement of islet cell antibodies at the time of diabetes onset may be useful if the type of DM is not clear based on the characteristics discussed above, but this knowledge does not usually alter therapy, which is based primarily on empirical metabolic features.

LONG-TERM TREATMENT

OVERALL PRINCIPLES

The goals of therapy for type 1 or type 2DM are to: (1) eliminate symptoms related to hyperglycemia, (2) reduce or eliminate the long-term microvascular and macrovascular complications of DM, and (3) allow the patient to achieve as normal a life-style as possible. To reach these goals, the physician should identify a target level of glycemic control for each patient, provide the patient with the educational and pharmacologic resources necessary to reach this level, and monitor/treat DM-related complications. Symptoms of diabetes usually resolve when the plasma glucose is<11.1 mmol/L (200 mg/dL), and thus most DM treatment focuses on achieving the second and third goals.

The care of an individual with either type 1 or type 2DMrequires a multidisciplinary team. Central to the success of this team are the patient's participation, input, and enthusiasm, all of which are essential for optimal diabetes management. Members of the health care team include the primary care provider and/or the endocrinologist or diabetologist, a certified diabetes educator, and a nutritionist. In addition, when the complications of DM arise, subspecialists (including neurologists, nephrologists, vascular surgeons, cardiologists, ophthalmologists, and podiatrists) with experience in DM-related complications are essential.

A number of names are sometimes applied to different approaches to diabetes care, such as intensive insulin therapy, intensive glycemic control, and "tight control." The current chapter, however, will use the term *comprehensive diabetes care* to emphasize the fact that optimal diabetes therapy involves more than plasma glucose management. Though glycemic control is central to optimal diabetes therapy, comprehensive diabetes care of both type 1 and type 2DMshould also detect and manage DM-specific complications and modify risk factors for DM-associated diseases.

In addition to assessing the physical aspects of the patient withDM, the physician and members of the diabetes management team should consider social, family, financial, cultural, and employment-related issues that may have an impact on diabetes care.

With this information, the physician can work with the patient and his or her family to establish therapeutic goals and design a comprehensive and feasible plan for optimal diabetes care.

EDUCATION OF THE PATIENT ABOUT DM, NUTRITION, AND EXERCISE

Patient participation is an essential component of comprehensive diabetes care. The patient with type 1 or type 2DMshould receive education about nutrition, exercise, care of diabetes during illness, and medications to lower the plasma glucose. Along with improved compliance, patient education allows individuals with DM to assume greater responsibility for their care. Patient education should be viewed as a continuing process with regular visits for reinforcement; it should *not*be a process that is completed after one or two visits to a nurse educator or nutritionist.

Diabetes Education The diabetes educator is a health care professional (nurse, dietician, or pharmacist) with specialized patient education skills who is certified in diabetes education (indicating demonstrated skills in diabetes knowledge and education and certification by the American Association of Diabetes Educators). The educator is a vital member of the comprehensive diabetes care program and educates the patient about a number of issues important for optimal diabetes care, including self-monitoring of blood glucose; urine ketone monitoring (type 1 DM); insulin administration; guidelines for diabetes management during illnesses; management of hypoglycemia; foot and skin care; diabetes management before, during, and after exercise; and risk factor-modifying activities.

Nutrition *Medical nutrition therapy* (MNT) is a term used by theADA to describe the optimal coordination of caloric intake with other aspects of diabetes therapy (insulin, exercise, weight loss). Historically, nutrition has imposed restrictive, complicated regimens on the patient. Current practices have greatly changed, though many patients and health care providers still view the diabetic diet as monolithic and static. For example, modern MNT now includes foods with sucrose and seeks to modify other risk factors such as hyperlipidemia and hypertension rather than focusing exclusively on weight loss in individuals with type 2DM. Like other aspects of DM therapy, MNT must be adjusted to meet the goals of the individual patient. Furthermore, MNT education is an important component of comprehensive diabetes care and should be reinforced by regular patient education. In general, the components of optimal MNT are similar for individuals with type 1 or type 2 DM (Table 333-8).

The goal of MNTin the individual with type 1DM is to coordinate and match the caloric intake, both temporally and quantitatively, with the appropriate amount of insulin. MNT in type 1 DM and self-monitoring of blood glucose must be integrated to define the optimal insulin regimen. MNT must be flexible enough to allow for exercise, and the insulin regimen must allow for deviations in caloric intake. An important component of MNT in type 1 DM is to minimize the weight gain often associated with intensive diabetes management.

The goals ofMNT in type 2DM are slightly different and address the greatly increased prevalence of cardiovascular risk factors (hypertension, dyslipidemia, obesity) and disease in this population. The majority of these individuals are obese, and weight loss

is still strongly encouraged and should remain an important goal. Medical treatment of obesity is a rapidly evolving area and is discussed inChap. 77. Hypocaloric diets and modest weight loss often result in rapid and dramatic glucose lowering in individuals with new-onset type 2 DM. Nevertheless, numerous studies document that long-term weight loss is uncommon. Therefore, current MNT for type 2 DM should emphasize modest caloric reduction, increased physical activity, and reduction of hyperlipidemia and hypertension. Increased consumption of soluble, dietary fiber may improve glycemic control in individuals with type 2 DM.

Exercise Exercise is an integral component of comprehensive diabetes care that can have multiple positive benefits (cardiovascular benefits, reduced blood pressure, maintenance of muscle mass, reduction in body fat, weight loss, etc.). For individuals with type 1 or type 2DM, exercise is also useful for lowering plasma glucose (during and following exercise) and increasing insulin sensitivity.

Despite its benefits, exercise presents several challenges for individuals withDMbecause they lack the normal glucoregulatory mechanisms. Skeletal muscle is a major site for metabolic fuel consumption in the resting state, and the increased muscle activity during vigorous, aerobic exercise greatly increases fuel requirements. Individuals with type 1 DM are prone to either hyperglycemia or hypoglycemia during exercise, depending on the preexercise plasma glucose, the circulating insulin level, and the level of exercise-induced catecholamines. If the insulin level is too low, the rise in catecholamines may increase the plasma glucose excessively, promote ketone body formation, and possibly lead to ketoacidosis. Conversely, if the circulating insulin level is excessive, this relative hyperinsulinemia may reduce hepatic glucose production (decreased glycogenolysis, decreased gluconeogenesis) and increase glucose entry into muscle, leading to hypoglycemia.

To avoid exercise-related hyper- or hypoglycemia, individuals with type 1DMshould: (1) monitor blood glucose before, during, and after exercise; (2) delay exercise if blood glucose is >14 mmol/L (250 mg/dL), <5.5 mmol/L (100 mg/dL), or if ketones are present; (3) eat a meal 1 to 3 h before exercise and take supplemental carbohydrate feedings at least every 30 min during vigorous or prolonged exercise; (4) decrease insulin doses (based on previous experience) before exercise and inject insulin into a nonexercising area; and (5) learn individual glucose responses to different types of exercise and increase food intake for up to 24 h after exercise, depending on intensity and duration of exercise. In individuals with type 2 DM, exercise-related hypoglycemia is less common but can occur in individuals taking either insulin or sulfonylureas.

Because asymptomatic cardiovascular disease appears at a younger age in both type 1 and type 2DM, formal exercise tolerance testing may be warranted in diabetic individuals with any of the following: age ³35 years, long-standing type 1 DM (>20 to 25 years' duration), microvascular complications of DM (retinopathy, microalbuminuria, or nephropathy), peripheral vascular disease, other risk factors of coronary artery disease, or autonomic neuropathy. Untreated proliferative retinopathy is a relative contraindication to vigorous exercise, since this may lead to vitreous hemorrhage or retinal detachment.

MONITORING THE LEVEL OF GLYCEMIC CONTROL

Optimal monitoring of glycemic control involves plasma glucose measurements by the patient and an assessment of long-term control by the physician (measurement of HbA1c and review of the patient's self-measurements of plasma glucose). These measurements are complementary: the patient's measurements provide a picture of short-term glycemic control, whereas the HbA1c reflects average glycemic control over the previous 2 to 3 months. Integration of both measurements provides an accurate assessment of the glycemic control achieved.

Self-Monitoring of Blood Glucose Self-monitoring of blood glucose (SMBG) is the standard of care in diabetes management and allows the patient to monitor his or her blood glucose at any time. In SMBG, a small drop of blood and an easily detectable enzymatic reaction allow measurement of the capillary plasma glucose. By combining glucose measurements with diet history, medication changes, and exercise history, the physician and patient can improve the treatment program.

The frequency ofSMBGmeasurements must be individualized and adapted to address the goals of diabetes care as defined by the patient and the health care provider. Individuals with type 1DMshould routinely measure their plasma glucose four to eight times per day to estimate and select mealtime boluses of short-acting insulin and to modify long-acting insulin doses. Most individuals with type 2 DM require less frequent monitoring, though the optimal frequency of SMBG has not been clearly defined. Individuals with type 2 DM who are on oral medications should utilize SMBG as a means of assessing the efficacy of their medication and diet. Since plasma glucose levels fluctuate less in these individuals, one to two SMBG measurements per day (or fewer) may be sufficient. Individuals with type 2 DM who are on insulin should utilize SMBG more frequently than those on oral agents.

Two devices for continuous blood glucose monitoring have been recently approved by the U.S. Food and Drug Administration (FDA). The Glucowatch uses iontophoresis to assess glucose in interstitial fluid, whereas the Minimed device uses an indwelling subcutaneous catheter to monitor interstitial fluid glucose. Both devices utilize immobilized glucose oxidase to generate electrons in response to changing glucose levels. Though clinical experience with these devices is limited, they perform well in clinical trials and appear to provide useful short-term information about the patterns of glucose changes as well as an enhanced ability to detect hypoglycemic episodes.

Although urine glucose testing does not provide an accurate assessment of glycemic control, urine ketones are a sensitive indicator of early diabetic ketoacidosis and should be measured in individuals with type 1 DM when the plasma glucose is consistently >16.7 mmol/L (300 mg/dL); during a concurrent illness; or with symptoms such as nausea, vomiting, or abdominal pain.

Assessment of Long-Term Glycemic Control Measurement of glycated hemoglobin is the standard method for assessing long-term glycemic control. When plasma glucose is consistently elevated, there is an increase in nonenzymatic glycation of hemoglobin; this alteration reflects the glycemic history over the previous 2 to 3 months, since erythrocytes have an average life span of 120 days. There are numerous laboratory methods for measuring the various forms of glycated hemoglobin, and these have

significant interassay variations. Because of its superior specificity and reliability, the HbA1c assay performed by the high-performance liquid chromatography (HPLC) method has become the standard reference method for most glycated hemoglobin measurements. Since glycated hemoglobin measurements are usually compared to prior measurements, it is essential for the assay results to be comparable. Depending on the assay methodology for HbA1c, hemoglobinopathies, hemolytic anemia, and uremia may interfere with the HbA1c result.

Glycated hemoglobin or HbA1c should be measured in all individuals withDMduring their initial evaluation and as part of their comprehensive diabetes care. As the primary predictor of long-term complications of DM, the HbA1c should mirror, to a certain extent, the short-term measurements ofSMBG. These two measurements are complementary in that recent intercurrent illnesses may impact the SMBG measurements but not the HbA1c. Likewise, postprandial and nocturnal hyperglycemia may not be detected by the SMBG of fasting and preprandial capillary plasma glucose but will be reflected in the HbA1c. When measured byHPLC, the HbA1c approximates the following mean plasma glucose values: an HbA1c of 6% is 6.6 mmol/L (120 mg/dL), 7% is 8.3 mmol/L (150 mg/dL), 8% is 10.0 mmol/L (180 mg/dL), etc. [A 1% rise in the HbA1c translates into a 1.7-mmol/L (30 mg/dL) increase in the mean glucose.] The degree of glycation of other proteins, such as albumin, has been used as an alternative indicator of glycemic control when the HbA1c is inaccurate (hemolytic anemia, hemoglobinopathies). The fructosamine assay (using albumin) is an example of an alternative measurement of glycemic control and reflects the glycemic status over the 2 to 4 prior weeks. Current consensus statements do not favor the use of alternative assays of glycemic control, as there are no studies to indicate whether such assays accurately predict the complications of DM.

TREATMENT

Establishment of a Target Level of Glycemic Control Because the complications ofDM are related to glycemic control, normoglycemia or near normoglycemia is the desired, but often elusive, goal for most patients. However, normalization of the plasma glucose for long periods of time is extremely difficult, as demonstrated by theDCCT. Regardless of the level of hyperglycemia, improvement in glycemic control will lower the risk of diabetes complications (Fig. 333-8).

The target for glycemic control (as reflected by the HbA1c) must be individualized, and the health care provider should establish the goals of therapy in consultation with the patient after considering a number of medical, social, and life-style issues. Some important factors to consider include the patient's age, ability to understand and implement a complex treatment regimen, presence and severity of complications of diabetes, ability to recognize hypoglycemic symptoms, presence of other medical conditions or treatments that might alter the response to therapy, life-style and occupation (e.g., possible consequences of experiencing hypoglycemia on the job), and level of support available from family and friends.

TheADA has established suggested glycemic goals based on the premise that glycemic control predicts development ofDM-related complications. In general, the target HbA1c should be<7.0% (Table 333-9). Other consensus groups (such as the Veterans

Administration) have suggested HbA1c goals that take into account the patient's life expectancy at the time of diagnosis and the presence of microvascular complications. Such recommendations strive to balance the financial and personal costs of glycemic therapy with anticipated benefits (reduced health care costs, reduced morbidity). One limitation to this approach is that the onset of hyperglycemia in type 2 DM is difficult to ascertain and likely predates the diagnosis. Furthermore, though the life expectancy can be predicted for a patient population, the physician must treat an individual patient; consequently, the target HbA1c must be individualized to accommodate these other considerations.

Type 1 Diabetes Mellitus

General Aspects Comprehensive diabetes care should be instituted in all individuals with type 1DM and should involve attention to nutrition, exercise, and risk factor management in addition to insulin administration. TheADArecommendations for fasting and bedtime glycemic goals and HbA1c targets are summarized in Table 333-9. The goal is to design and implement insulin regimens that mimic physiologic insulin secretion. Because individuals with type 1 DM lack endogenous insulin production, administration of basal, exogenous insulin is essential for regulating glycogen breakdown, gluconeogenesis, lipolysis, and ketogenesis. Likewise, postprandial insulin replacement should be appropriate for the carbohydrate intake and promote normal glucose utilization and storage.

Intensive Management Intensive diabetes management is defined by theADA as "...a mode of treatment for the person withDM that has the goal of achieving euglycemia or near-normal glycemia using all available resources to accomplish this goal." These resources include thorough and continuing patient education, comprehensive recording of plasma glucose measurements and nutrition intake by the patient, and a variable insulin regimen that matches glucose intake and insulin dose. Insulin regimens usually include multiple-component insulin regimens, multiple daily injections (MDI), or insulin infusion devices (all discussed below).

The benefits of intensive diabetes management and improved glycemic control include a reduction in the microvascular complications ofDM and a possible delay or reduction in the macrovascular complications of DM. From a psychological standpoint, the patient experiences greater control over his or her diabetes and often notes an improved sense of well-being, greater flexibility in the timing and content of meals, and the capability to alter insulin dosing with exercise. In addition, intensive diabetes management in pregnancy reduces fetal malformation and morbidity. Intensive diabetes management is also strongly encouraged in newly diagnosed patients with type 1 DM because it may prolong the period of C-peptide production, which may result in better glycemic control and a reduced risk of serious hypoglycemia.

Although intensive management confers impressive benefits, it is also accompanied by significant personal and financial costs and is therefore not appropriate for all individuals. It requires a combination of dedication, persistence, and motivation on the part of the patient, as well as medical, educational, nursing, nutritional, and psychological expertise on the part of the diabetes management team. Circumstances in which intensive diabetes management should be strongly considered are listed in

Table 333-10.

Insulin Preparations Current insulin preparations are generated by recombinant DNA technology and consist of the amino acid sequence of human insulin. Animal insulin (beef or pork) is no longer used. Human insulin has been formulated with distinctive pharmacokinetics to mimic physiologic insulin secretion (Table 333-11). In the United States, all insulin is formulated as U-100 (100 units/mL), whereas in some other countries it is available in other units (e.g., U-40 = 40 units/mL). One short-acting insulin formulation, lispro, is an insulin analogue in which the 28th and 29th amino acids (lysine and proline) on the insulin B chain have been reversed by recombinant DNA technology. This insulin analogue has full biologic activity but less tendency toward subcutaneous aggregation, resulting in more rapid absorption and onset of action and a shorter duration of action. These characteristics are particularly advantageous for allowing entrainment of insulin injection and action to rising plasma glucose levels following meals, although improvement in HbA1c values have not been found consistently. The shorter duration of action also appears to be associated with a decreased number of hypoglycemic episodes, primarily because the decay of lispro action corresponds better to the decline in plasma glucose after a meal. Insulin glargine is a long-acting biosynthetic human insulin that differs from normal insulin in that asparagine is replaced by glycine at amino acid 21, and two arginine residues are added to the C-terminus of the B chain. Compared to NPH insulin, the onset of insulin glargine action is later, the duration of action is longer (~24 h), and there is no pronounced peak. A lower incidence of hypoglycemia, especially at night, was reported in one trial with insulin glargine when compared to NPH insulin. Since glargine has only recently approved, clinical experience is limited. Additional insulin analogues are currently under development.

Basal insulin requirements are provided by intermediate (NPH or lente) or long-acting (ultralente or glargine) insulin formulations. These are usually combined with short-acting insulin in an attempt to mimic physiologic insulin release with meals. Although mixing of intermediate and short-acting insulin formulations is common practice, this mixing may alter the insulin absorption profile (especially those of short-acting insulins). For example, the absorption of regular insulin is delayed when mixed for even short periods of time (<5 min) with lente or ultralente insulin, but not when mixed with NPH insulin. Lispro absorption is delayed by mixing with NPH but not ultralente. Insulin glargine should not be mixed with other insulins. The miscibility of human regular and NPH insulin allows for the production of combination insulins that contain 75% NPH and 25% regular (75/25), 70% NPH and 30% regular (70/30), or equal mixtures of NPH and regular. These combinations of insulin are more convenient for the patient but prevent adjustment of only one component of the insulin formulation. The alteration in insulin absorption when the patient mixes different insulin formulation should not discourage the patient from mixing insulin. However, the following guidelines should be followed: (1) mix the different insulin formulations in the syringe immediately before injection (inject within 2 min after mixing); (2) if possible, do not store insulin as a mixture; and (3) follow the same routine in terms of insulin mixing and administration to standardize the physiologic response to injected insulin.

Insulin Regimens Representations of the various insulin regimens that may be utilized in type 1DM are illustrated in Fig. 333-12. Although the insulin profiles are depicted as

"smooth," symmetric curves, there is considerable patient-to-patient variation in the peak and duration. In all regimens, long-acting insulins (NPH, lente, ultralente, or glargine insulin) supply basal insulin, whereas prandial insulin is provided by either regular or lispro insulin. Lispro should be injected just before a meal; regular insulin is given 30 to 45 min prior to a meal.

A shortcoming of current insulin regimens is that injected insulin immediately enters the systemic circulation, whereas endogenous insulin is secreted into the portal vein. Thus, exogenous insulin administration exposes the liver to subphysiologic insulin levels. No insulin regimen reproduces the precise insulin secretory pattern of the pancreatic islet. However, the most physiologic regimens entail more frequent insulin injections, greater reliance on short-acting insulin, and more frequent capillary plasma glucose measurements. In general, individuals with type 1DMrequire 0.5 to 1.0 U/kg per day of insulin divided into multiple doses. Initial insulin-dosing regimens should be conservative; approximately 40 to 50% of the insulin should be given as basal insulin. A single daily injection of insulin is not appropriate therapy in type 1 DM.

One commonly used regimen consists of twice-daily injections of an intermediate insulin (NPH or lente) mixed with a short-acting insulin before the morning and evening meal (Fig. 333-12*A*). Such regimens usually prescribe two-thirds of the total daily insulin dose in the morning (with about two-thirds given as intermediate-acting insulin and one-third as short-acting) and one-third before the evening meal (with approximately one-half given as intermediate-acting insulin and one-half as short-acting). The drawback to such a regimen is that it enforces a rigid schedule on the patient, in terms of daily activity and the content and timing of meals. Although it is simple and effective at avoiding severe hyperglycemia, it does not generate near-normal glycemic control in most individuals with type 1DM. Moreover, if the patient's meal pattern or content varies or if physical activity is increased, hyperglycemia or hypoglycemia may result. Moving the intermediate insulin from before the evening meal to bedtime may avoid nocturnal hypoglycemia and provide more insulin as glucose levels rise in the early morning (so-called dawn phenomenon). The insulin dose in such regimens should be adjusted based onSMBGresults with the following general assumptions: (1) the fasting glucose is primarily determined by the prior evening intermediate-acting insulin; (2) the pre-lunch glucose is a function of the morning short-acting insulin; (3) the pre-supper glucose is a function of the morning intermediate-acting insulin; and (4) the bedtime glucose is a function of the pre-supper, short-acting insulin.

Multiple-component insulin regimens refer to the combination of basal insulin; preprandial short-acting insulin; and changes in short-acting insulin doses to accommodate the results of frequentSMBG, anticipated food intake, and physical activity. Sometimes also referred to as *multiple daily injections*, such regimens offer the patient maximal flexibility in terms of life-style and the best chance for achieving near normoglycemia. One such regimen, shown inFig. 333-12*B*, consists of a basal insulin with ultralente twice a day and preprandial lispro. The lispro dose is based on individualized algorithms that integrate the preprandial glucose and the anticipated carbohydrate intake. An alternative multiple-component insulin regimen consists of bedtime intermediate insulin, a small dose of intermediate insulin at breakfast (20 to 30% of bedtime dose), and preprandial short-acting insulin. There are numerous variations of these regimens that can be optimized for individual patients. Frequent

SMBG (four to 8 times per day) is absolutely essential for these types of insulin regimens.

Continuous subcutaneous insulin infusion (CSII) is another multiple-component insulin regimen (Fig. 333-12*C*). Sophisticated insulin infusion devices are now available that can accurately deliver small doses of insulin (microliters per hour). For example, multiple basal infusion rates can be programmed to: (1) accommodate nocturnal versus daytime basal insulin requirement, (2) alter infusion rate during periods of exercise, or (3) select different waveforms of insulin infusion. A preprandial insulin ("bolus") is delivered by the insulin infusion device based on instructions from the patient, which follow individualized algorithms that account for preprandial plasma glucose and anticipated carbohydrate intake. These devices require a health professional with considerable experience with insulin infusion devices and very frequent patient interactions with the diabetes management team. Insulin infusion devices present unique challenges, such as infection at the infusion site, unexplained hyperglycemia because the infusion set becomes obstructed, or diabetic ketoacidosis if the pump becomes disconnected. Since most physicians use lispro insulin in CSII, the extremely short half-life of this insulin quickly leads to insulin deficiency if the delivery system is interrupted. Essential to the safe use of infusion devices is thorough patient education about pump function and frequentSMBG.

Type 2 Diabetes Mellitus

General Aspects The goals of therapy for type 2DM are similar to those in type 1: improved glycemic control with near normalization of the HbA1c. While glycemic control tends to dominate the management of type 1 DM, the care of individuals with type 2 DM must also include attention to the treatment of conditions associated with type 2 DM (obesity, hypertension, dyslipidemia, cardiovascular disease) and detection/management of DM-related complications (Fig. 333-13). DM-specific complications may be present in up to 20 to 50% of individuals with newly diagnosed type 2 DM. Reduction in cardiovascular risk is of paramount importance as this is the leading cause of mortality in these individuals.

Diabetes management should begin withMNT(discussed above). An exercise regimen to increase insulin sensitivity and promote weight loss should also be instituted. After MNT and increased physical activity have been instituted, glycemic control should be reassessed; if the patient's glycemic target is not achieved after 3 to 4 weeks of MNT, pharmacologic therapy is indicated. Pharmacologic approaches to the management of type 2DMinclude both oral glucose-lowering agents and insulin; most physicians and patients prefer oral glucose-lowering agents as the initial choice. Any therapy that improves glycemic control reduces "glucose toxicity" to the islet cells and improves endogenous insulin secretion.

Glucose-Lowering Agents Recent advances in the therapy of type 2DM have generated considerable enthusiasm for oral glucose-lowering agents that target different pathophysiologic processes in type 2 DM. Based on their mechanisms of action, oral glucose-lowering agents are subdivided into agents that increase insulin secretion, reduce glucose production, or increase insulin sensitivity (Table 333-12). Oral glucose-lowering agents (with the exception of a-glucosidase inhibitors) are ineffective

in type 1 DM and should not be used for glucose management of severely ill individuals with type 2 DM. Insulin is sometimes the initial glucose-lowering agent.

INSULIN SECRETAGOGUES Insulin secretagogues stimulate insulin secretion by interacting with the ATP-sensitive potassium channel on the beta cell (Fig. 333-1). These drugs are most effective in individuals with type 2DM of relatively recent onset (<5 years), who have endogenous insulin production and tend to be obese. At maximum doses, first-generation sulfonylureas are similar in potency to second-generation agents but have a longer half-life, a greater incidence of hypoglycemia, and more frequent drug interactions (Table 333-13). Thus, second-generation sulfonylureas are generally preferred. An advantage to a more rapid onset of action is better coverage of the postprandial glucose rise, but the shorter half-life of such agents requires more than once-a-day dosing. Sulfonylureas reduce both fasting and postprandial glucose and should be initiated at low doses and increased at 1- to 2-week intervals based onSMBG. In general, sulfonylureas increase insulin acutely and thus should be taken shortly before a meal; with chronic therapy, though, the insulin release is more sustained. Replaglinide is not a sulfonylurea but also interacts with the ATP-sensitive potassium channel. Because of its short half-life, it is usually given with or immediately before each meal to reduce meal-related glucose excursions.

Insulin secretagogues are well tolerated in general. All of these agents, however, have the potential to cause profound and persistent hypoglycemia, especially in elderly individuals. Hypoglycemia is usually related to delayed meals, increased physical activity, alcohol intake, or renal insufficiency. Individuals who ingest an overdose of these agents develop prolonged and serious hypoglycemia and should be monitored closely in the hospital (Chap. 334). Most sulfonylureas are metabolized in the liver to compounds that are cleared by the kidney. Thus, their use in individuals with significant hepatic or renal dysfunction is not advisable. Weight gain, a common side effect of sulfonylurea therapy, results from the increased insulin levels and improvement in glycemic control. Some sulfonylureas have significant drug interactions with other medications such as alcohol, warfarin, aspirin, ketoconazole, a-glucosidase inhibitors, and fluconazole. Despite prior concerns that use of sulfonylureas might increase cardiovascular risk, recent trials have refuted this claim.

BIGUANIDES Metformin is representative of this class of agents. It reduces hepatic glucose production through an undefined mechanism and may improve peripheral glucose utilization slightly (Table 333-12). Metformin reduces fasting plasma glucose and insulin levels, improves the lipid profile, and promotes modest weight loss. The initial starting dose of 500 mg once or twice a day can be increased to 850 mg tid or 1000 mg bid. Because of its relatively slow onset of action and gastrointestinal symptoms with higher doses, the dose should be escalated every 2 to 3 weeks based onSMBGmeasurements. The major toxicity of metformin, lactic acidosis, can be prevented by careful patient selection. Metformin should not be used in patients with renal insufficiency [serum creatinine >133 umol/L (1.5 mg/dL) in men or >124 umol/L (1.4 mg/dL) in women, with adjustments for age], any form of acidosis, congestive heart failure, liver disease, or severe hypoxia. Metformin should be discontinued in patients who are seriously ill, in patients who can take nothing orally, and in those receiving radiographic contrast material. Insulin should be used until metformin can be restarted. Though well tolerated in general, some individuals develop gastrointestinal side effects

(diarrhea, anorexia, nausea, and metallic taste) that can be minimized by gradual dose escalation. Because the drug is metabolized in the liver, it should not be used in patients with liver disease or heavy ethanol intake.

a-GLUCOSIDASE INHIBITORS a-Glucosidase inhibitors (acarbose and miglitol) reduce postprandial hyperglycemia by delaying glucose absorption; they do not affect glucose utilization or insulin secretion (Table 333-12). Postprandial hyperglycemia, secondary to impaired hepatic and peripheral glucose disposal, contributes significantly to the hyperglycemic state in type 2DM. These drugs, taken just before each meal, reduce glucose absorption by inhibiting the enzyme that cleaves oligosaccharides into simple sugars in the intestinal lumen. Therapy should be initiated at a low dose (25 mg of acarbose or miglitol) with the evening meal and may be increased to a maximal dose over weeks to months (50 to 100 mg for acarbose or 50 mg for miglitol with each meal). The major side effects (diarrhea, flatulence, abdominal distention) are related to increased delivery of oligosaccharides to the large bowel and can be reduced somewhat by gradual upward dose titration.a-Glucosidase inhibitors may increase levels of sulfonylureas and increase the incidence of hypoglycemia. Simultaneous treatment with bile acid resins and antacids should be avoided. These agents should not be used in individuals with inflammatory bowel disease, gastroparesis, or a serum creatinine >177 umol/L (2.0 mg/dL). This class of agents is not as potent as other oral agents in lowering the HbA1c but is unique in that it reduces the postprandial glucose rise even in individuals with type 1 DM.

THIAZOLIDINEDIONES Thiazolidinediones represent a new class of agents that reduce insulin resistance. These drugs bind to a nuclear receptor (peroxisome proliferator-activated receptor, PPAR-g) that regulates gene transcription. The PPAR-g receptor is found at highest levels in adipocytes but is expressed at lower levels in many other insulin-sensitive tissues. Agonists of this receptor promote adipocyte differentiation and may reduce insulin resistance in skeletal muscle indirectly. Thiazolidinediones reduce the fasting plasma glucose by improving peripheral glucose utilization and insulin sensitivity (Table 333-12). Circulating insulin levels decrease with use of the thiazolidinediones, indicating a reduction in insulin resistance. Although direct comparisons are not available, the two currently available thiazolidinediones appear to have similar efficacy; the therapeutic range for pioglitazone is 15 to 45 mg/d in a single daily dose and for rosiglitazone is 2 to 8 mg/d -- once a day at lower doses and bid at higher doses. The ability of thiazolidinediones to influence other features of the insulin resistance syndrome is under investigation.

The prototype of this class of drugs, troglitazone, was withdrawn from the U.S. market after reports of hepatotoxicity and an association with an idiosyncratic liver reaction that sometimes led to hepatic failure. The two other thiazolidinediones, rosiglitazone and pioglitazone, thus far do not appear to induce the liver abnormalities seen with troglitazone. However, long-term experience with the newer agents is limited. Consequently, theFDArecommends measurement of liver function tests prior to initiating therapy with a thiazolidinedione and at regular intervals (every two months for the first year and then periodically). The thiazolidinediones raiseLDL andHDLslightly and lower triglycerides by 10 to 15%, but the clinical significance of these changes is not known. Thiazolidinediones are associated with minor weight gain (1 to 2 kg), a small reduction in the hematocrit, and a mild increase in plasma volume. Cardiac function is not

affected, but the incidence of peripheral edema is increased. They are contraindicated in patients with liver disease or congestive heart failure (class III or IV). Thiazolidinediones have been shown to induce ovulation in premenopausal women with polycystic ovary syndrome (see "Insulin Resistance Syndromes," above). Women should be warned about the risk of pregnancy, since the safety of thiazolidinediones in pregnancy is not established.

INSULIN THERAPY IN TYPE 2 DM Modest doses of insulin are quite efficacious in controlling hyperglycemia in newly diagnosed type 2DM. Insulin should be considered as the initial therapy in type 2 DM, particularly in lean individuals or those with severe weight loss, in individuals with underlying renal or hepatic disease that precludes oral glucose-lowering agents, or in individuals who are hospitalized or acutely ill. Insulin therapy is ultimately required by a substantial number of individuals with type 2 DM because of the progressive nature of the disorder and the relative insulin deficiency that develops in patients with long-standing diabetes.

Because endogenous insulin secretion continues and is capable of providing some coverage of mealtime caloric intake, insulin is usually initiated in a single dose of intermediate-acting insulin (0.3 to 0.4 U/kg per day), given either before breakfast or just before bedtime (or ultralente at bedtime). Since fasting hyperglycemia and increased hepatic glucose production are prominent features of type 2DM, bedtime insulin is more effective in clinical trials than a single dose of morning insulin. Some physicians prefer a relatively low, fixed starting dose of intermediate-acting insulin (~15 to 20 units in the morning and 5 to 10 units at bedtime) to avoid hypoglycemia. The insulin dose may then be adjusted in 10% increments as dictated bySMBGresults. Both morning and bedtime intermediate insulin may be used in combination with oral glucose-lowering agents (biguanides,a-glucosidase inhibitors, or thiazolidinediones).

CHOICE OF INITIAL GLUCOSE-LOWERING AGENT Though insulin is an effective primary therapy for type 2DM, most patients and physicians currently prefer oral glucose-lowering drugs as the initial pharmacologic approach. The level of hyperglycemia should influence the initial choice of therapy. Assuming maximal benefit ofMNT and increased physical activity has been realized, patients with mild to moderate hyperglycemia [fasting plasma glucose <11.1 to 13.9 mmol/L (200 to 250 mg/dL)] often respond well to a single oral glucose-lowering agent. Patients with more severe hyperglycemia [fasting plasma glucose>13.9 mmol/L (250 mg/dL)] may respond partially but are unlikely to achieve normoglycemia with oral monotherapy. Nevertheless, many physicians prefer a stepwise approach that starts with a single agent and adds a second agent to achieve the glycemic target (see "Combination Therapy," below). Some physicians begin insulin in individuals with severe hyperglycemia [fasting plasma glucose >13.9 to 16.7 mmol/L (250 to 300 mg/dL)]. This approach is based on the rationale that more rapid glycemic control will reduce "glucose toxicity" to the islet cells, improve endogenous insulin secretion, and possibly allow oral glucose-lowering agents to be more effective. If this occurs, the insulin may be discontinued.

Insulin secretagogues, biguanides, a-glucosidase inhibitors, thiazolidinediones, and insulin are approved for monotherapy of type 2DM. Although each class of oral glucose-lowering agents has unique advantages and disadvantages, certain generalizations apply: (1) insulin secretagogues, biguanides, and thiazolidinediones

improve glycemic control to a similar degree (1 to 2% reduction in HbA1c) and are more effective thana-glucosidase inhibitors; (2) assuming a similar degree of glycemic improvement, no clinical advantage to one class of drugs has been demonstrated, and any therapy that improves glycemic control is beneficial; (3) insulin secretagogues and a-glucosidase inhibitors begin to lower the plasma glucose immediately, whereas the glucose-lowering effects of the biguanides and thiazolidinediones are delayed by several weeks to months; (4) not all agents are effective in all individuals with type 2 DM (primary failure); (5) biguanides, a-glucosidase inhibitors, and thiazolidinediones do not directly cause hypoglycemia; and (6) most individuals will eventually require treatment with more than one class of oral glucose-lowering agents, reflecting the progressive nature of type 2 DM.

Considerable clinical experience exists with sulfonylureas and metformin because they have been available for several decades. It is assumed that the a-glucosidase inhibitors and thiazolidinediones, which are newer classes of oral glucose-lowering drugs, will reduceDM-related complications by improving glycemic control, although long-term data are not yet available. The thiazolidinediones are theoretically attractive because they target a fundamental abnormality in type 2 DM, namely insulin resistance. However, these agents are currently more costly than others and require liver function monitoring.

A reasonable treatment algorithm for initial therapy proposes either a sulfonylurea or metformin as initial therapy because of their efficacy, known side-effect profile, and relatively low cost (Fig. 333-14). Metformin has the advantage that it promotes mild weight loss, lowers insulin levels, improves the lipid profile slightly, and may have a lower secondary failure rate. However, there is no difference in response rate or degree of glycemic control when metformin and sulfonylureas are compared in randomized, prospective clinical trials. Based onSMBGresults and the HbA1c, the dose of either the sulfonylurea or metformin should be increased until the glycemic target is achieved.a-Glucosidase inhibitors and thiazolidinediones are alternative, initial agents (Fig. 333-14).

When used as monotherapy, approximately one-third of individuals will reach their target glycemic goal with either a sulfonylurea or metformin. Approximately 25% of individuals will not respond to sulfonylureas or metformin; under these circumstances, the drug usually should be discontinued. Some individuals respond to one agent but not the other. The remaining individuals treated with either sulfonylureas or metformin alone will exhibit some improvement in glycemic control but will not achieve their glycemic target and should be considered for combination therapy.

COMBINATION THERAPY WITH GLUCOSE-LOWERING AGENTS A number of combinations of therapeutic agents are successful in type 2DM, and the dosing of agents in combination is the same as when the agents are used alone. Because mechanisms of action of the first and second agents are different, the effect on glycemic control is usually additive. Commonly used regimens include: (1) insulin secretagogue with metformin or thiazolidinedione, (2) sulfonylurea with a-glucosidase inhibitor, and (3) insulin with metformin or thiazolidinedione. The combination of metformin and a thiazolidinedione is also effective and complementary. If adequate control is not achieved with two oral agents, bedtime insulin or a third oral agent may be added stepwise. However, long-term experience with any triple combination is lacking, and

experience with two-drug combinations is relatively limited.

Insulin becomes required as type 2DMenters the phase of relative insulin deficiency (as seen in long-standing DM) and is signaled by inadequate glycemic control on one or two oral glucose-lowering agents. Insulin can be used in combination with any of the oral agents in patients who fail to reach the glycemic target. For example, a single dose of intermediate-acting insulin at bedtime is effective in combination with metformin. As endogenous insulin production falls further, multiple injections of intermediate-acting and short-acting insulin regimens are necessary to control postprandial glucose excursions. These combination regimens are identical to the intermediate- and short-acting combination regimens discussed above for type 1 DM. Since the hyperglycemia of type 2 DM tends to be more "stable," these regimens can be increased in 10% increments every 2 to 3 days usingSMBGresults. The daily insulin dose required can become quite large (1 to 2 units/kg per day) as endogenous insulin production falls and insulin resistance persists. Individuals who require >1 unit/kg per day of intermediate-acting insulin should be considered for combination therapy with metformin or a thiazolidinedione. The addition of a thiazolidinedione can reduce insulin requirements in some individuals with type 2 DM, while maintaining or even improving glycemic control.

Intensive diabetes management (Table 333-10) is a treatment option in type 2 patients who cannot achieve optimal glycemic control and are capable of implementing such regimens. A recent study from the Veterans Administration found that intensive diabetes management is not associated with a greater degree of side effects (hypoglycemia, weight gain) than standard insulin therapy. The effect of higher insulin levels associated with intensive diabetes management on the prognosis of diseases commonly associated with type 2DM(cardiovascular disease, hypertension) is still debated. In selected patients with type 2 DM, insulin pumps improve glycemic control and are well tolerated.

Emerging Therapies Whole pancreas transplantation (conventionally performed concomitantly with a renal transplant) may normalize glucose tolerance and is an important therapeutic option in type 1 diabetes, though it requires substantial expertise and is associated with the side effects of immunosuppression. Pancreatic islet transplantation has been plagued by limitations in pancreatic islet isolation and graft survival, but recent advances in specific immunomodulation have greatly improved the results. Islet transplantation is an area of active clinical investigation.

Advances in molecular biology and new insights into normal mechanisms of glucose homeostasis have led to a number of emerging therapies for diabetes and its complications. For example, glucagon-like peptide 1, a potent insulin secretagogue, may be efficacious in type 2DM. Inhaled insulin and additional insulin analogues are in advanced stages of clinical trials. Aminoguanidine, an inhibitor of the formation of advanced glycosylation end products, and inhibitors of protein kinase C may reduce the complications of DM. Closed-loop pumps that infuse the appropriate amount of insulin in response to changing glucose levels are potentially feasible now that continuous glucose-monitoring technology has been developed.

COMPLICATIONS OF THERAPY FOR DIABETES MELLITUS

As with any therapy, the benefits of efforts directed towards glycemic control must be weighed against the risks of treatment. Side effects of intensive treatment include an increased frequency of serious hypoglycemia, weight gain, increased economic costs, and greater demands on the patient. In theDCCT, quality of life was very similar in the intensive therapy and standard therapy groups. The most serious complication of therapy forDM is hypoglycemia (Chap. 334). Weight gain occurs with most (insulin, insulin secretagogues, thiazolidinediones) but not all (metformin anda-glucosidase inhibitors) therapies that improve glycemic control due to the anabolic effects of insulin and the reduction in glucosuria. In the DCCT, individuals with the greatest weight gain exhibited increases inLDLcholesterol and triglycerides as well as increases in blood pressure (both systolic and diastolic) similar to those seen in individuals with type 2 DM and insulin resistance. These effects could increase the risk of cardiovascular disease in intensively managed patients. As discussed previously, improved glycemic control is sometimes accompanied by a transient worsening of diabetic retinopathy or neuropathy.

ONGOING ASPECTS OF COMPREHENSIVE DIABETES CARE

The morbidity and mortality ofDM-related complications can be greatly reduced by timely and consistent surveillance procedures (Table 333-14). These screening procedures are indicated for all individuals with DM, but numerous studies have documented that most individuals with diabetes do not receive comprehensive diabetes care. Screening for dyslipidemia and hypertension should be performed annually. In addition to routine health maintenance, individuals with diabetes should also receive the pneumococcal and tetanus vaccines (at recommended intervals) and the influenza vaccine (annually).

An annual comprehensive eye examination should be performed by a qualified optometrist or ophthalmologist. If abnormalities are detected, further evaluation and treatment require an ophthalmologist skilled in diabetes-related eye disease. Because many individuals with type 2DM have had asymptomatic diabetes for several years before diagnosis, a consensus panel from theADArecommends the following ophthalmologic examination schedule: (1) individuals with onset of DM at <29 years should have an initial eye examination within 3 to 5 years of diagnosis, (2) individuals with onset of DM at >30 years should have an initial eye examination at the time of diabetes diagnosis, and (3) women with DM who are contemplating pregnancy should have an eye examination prior to conception and during the first trimester.

An annual foot examination should: (1) assess blood flow, sensation, and nail care; (2) look for the presence of foot deformities such as hammer or claw toes and Charcot foot; and (3) identify sites of potential ulceration. Calluses and nail deformities should be treated by a podiatrist; the patient should be discouraged from self-care of even minor foot problems.

An annual microalbuminuria measurement is advised in individuals with type 1 or type 2DM and no protein on a routine urinalysis (Fig. 333-10). If the urinalysis detects proteinuria, the amount of protein should be quantified by standard urine protein measurements. If the urinalysis was negative for protein in the past, microalbuminuria should be the annual screening examination. Routine urine protein measurements do

not detect low levels of albumin excretion. Screening should commence 5 years after the onset of type 1 DM and at the time of onset of type 2 DM.

SPECIAL CONSIDERATIONS IN DIABETES MELLITUS

PSYCHOSOCIAL ASPECTS

As with any chronic, debilitating disease, the individual withDM faces a series of challenges that affect all aspects of daily life. The individual with DM must accept that he or she may develop complications related to DM. Even with considerable effort, normoglycemia can be an elusive goal, and solutions to worsening glycemic control may not be easily identifiable. The patient should view him- or herself as an essential member of the diabetes care team and not as someone who is cared for by the diabetes team. Emotional stress may provoke a change in behavior so that individuals no longer adhere to a dietary, exercise, or therapeutic regimen. This can lead to the appearance of either hyper- or hypoglycemia. Depression and eating disorders (in women) are more common in individuals with type 1 or type 2 DM (Chap. 78).

MANAGEMENT IN THE HOSPITALIZED PATIENT

Virtually all medical and surgical subspecialties may be involved in the care of hospitalized patients with diabetes. General anesthesia, surgery, and concurrent illness raise the levels of counterregulatory hormones (cortisol, growth hormone, catecholamines, and glucagon), and infection may lead to transient insulin resistance. These factors increase insulin requirements by increasing glucose production and impairing glucose utilization and thus may worsen glycemic control. On the other hand, the concurrent illness or surgical procedure may prevent the patient withDM from eating normally and may promote hypoglycemia. Glycemic control should be assessed (with HbA1c) and, if feasible, should be optimized prior to surgery. Electrolytes, renal function, and intravascular volume status should be assessed as well. The extremely high prevalence of asymptomatic cardiovascular disease in individuals with DM (especially in type 2 DM) may require preoperative cardiovascular evaluation.

The goals of diabetes management during hospitalization are avoidance of hypoglycemia, optimization of glycemic control, and transition back to the outpatient diabetes treatment regimen. Attention to each stage in this process requires integrating information regarding the plasma glucose, diabetes treatment regimen, and clinical status of the patient. For example, some surgical procedures utilizing local anesthesia or epidural anesthesia may have minimal effects on glycemic control. If the patient is eating soon after the procedure and there is no disruption of the patient's regular meal plans, then glycemic control is usually maintained.

The physician caring for an individual with diabetes in the perioperative period, during times of infection or serious physical illness, or simply when fasting for a diagnostic procedure must monitor the plasma glucose vigilantly, adjust the diabetes treatment regimen, and provide glucose infusion as needed. Several different treatment regimens (intravenous or subcutaneous insulin regimens) can be employed successfully. Individuals with type 1DMrequire continued insulin administration to maintain the levels of circulating insulin necessary to preventDKA. Prolongation of a surgical procedure or

delay in the recovery room is not uncommon and may result in periods of insulin deficiency. Even relatively brief periods without insulin may lead to mild DKA. Individuals with type 1 DM who are undergoing general anesthesia and surgery, or who are seriously ill, should receive continuous insulin, either through an intravenous insulin infusion or by subcutaneous administration of a reduced dose of long-acting insulin. Short-acting insulin alone is insufficient.

Individuals with type 2DM can be managed with either insulin infusion or a reduced dose of subcutaneous insulin. Oral glucose-lowering agents are discontinued at the time a combined insulin/glucose infusion is started. Oral agents such as sulfonylureas, metformin, acarbose, and thiazolidinediones are not useful in regulating the plasma glucose in clinical situations where the insulin requirements and glucose intake are changing rapidly. Moreover, these oral agents may be dangerous if the patient is fasting (e.g., hypoglycemia with sulfonylureas). Metformin should be withheld when radiographic contrast media will be given or if severe congestive heart failure, acidosis, or declining renal function is present.

Insulin infusions can effectively control plasma glucose in the perioperative period and when the patient is unable to take anything by mouth. The absorption of subcutaneous insulin may be variable in such situations because of changes in blood flow. The physician must consider carefully the clinical setting in which an insulin infusion will be utilized, including whether adequate ancillary personnel are available to monitor the plasma glucose frequently and whether they can adjust the insulin infusion rate, either based on an algorithm or in consultation with the physician. The initial rate for an insulin infusion may range from 0.5 to 5 units/h, depending on the degree of insulin resistance and the clinical situation. Based on hourly capillary glucose measurements, the insulin infusion rate is adjusted to maintain the plasma glucose within the desired range [5.6 to 11.1 mmol/L (100 to 200 mg/dL)]. Glucose infusion, initiated at the time the patient begins fasting, should be adjusted to deliver the equivalent of 50 to 150 mL of D_5W/h until the patient is reliably taking nutrition orally. The insulin infusion can be temporarily discontinued if hypoglycemia occurs and may be resumed at a lower infusion rate once the plasma glucose exceeds 5.6 mmol/L (100 mg/dL).

Insulin infusion is the preferred method for managing patients with type 1DM in the perioperative period or when serious concurrent illness is present. Individuals with type 2 DM can be managed with an insulin infusion, but subcutaneous insulin in reduced doses can be used effectively as well. If the diagnostic or surgical procedure is brief and performed under local or regional anesthesia, a reduced dose of subcutaneous, long-acting insulin may suffice. This approach facilitates the transition back to the long-acting insulin after the procedure. The dose of long-acting insulin should be reduced by 30 to 40%, and short-acting insulin is either held or, likewise, reduced by 30 to 40%. Glucose should be infused to prevent hypoglycemia.

Total Parenteral Nutrition (See Chap. 76) Total parenteral nutrition (TPN) greatly increases insulin requirements. In addition, individuals not previously known to haveDM may become hyperglycemic during TPN and require insulin treatment. Intravenous insulin infusion is the preferred treatment for hyperglycemia, and rapid titration to the required insulin dose is done most efficiently using a separate insulin infusion. After the total insulin dose has been determined, insulin may be added directly to the TPN

solution. Often, individuals receiving either TPN or enteral nutrition receive their caloric loads continuously and not at "meal times"; consequently, subcutaneous insulin regimens must be adjusted.

GLUCOCORTICOIDS

Glucocorticoids increase insulin resistance, decrease glucose utilization, increase hepatic glucose production, and impair insulin secretion. These changes lead to a worsening of glycemic control in individuals withDM and may precipitate diabetes in other individuals ("steroid-induced diabetes"). The effects of glucocorticoids on glucose homeostasis are dose-related, usually reversible, and most pronounced in the postprandial period. If the fasting plasma glucose is near the normal range, oral diabetes agents (sulfonylureas and acarbose) may be sufficient to reduce hyperglycemia. If the fasting plasma glucose >11.1 mmol/L (200 mg/dL), oral agents are usually not efficacious and insulin therapy is required. Short-acting insulin may be required to supplement long-acting insulin in order to control postprandial glucose excursions.

REPRODUCTIVE ISSUES

Reproductive capacity in either men or women withDMappears to be normal. Menstrual cycles may be associated with alterations in glycemic control in women with DM. Pregnancy is associated with marked insulin resistance; the increased insulin requirements often precipitate DM and lead to the diagnosis ofGDM. Glucose, which at high levels is a teratogen to the developing fetus, readily crosses the placenta, but insulin does not. Thus, hyperglycemia or hypoglycemia from the maternal circulation may stimulate insulin secretion in the fetus. The anabolic and growth effects of insulin may result in macrosomia. GDM complicates approximately 4% of pregnancies in the United States. The incidence of GDM is greatly increased in certain ethnic groups, including African Americans and Hispanic Americans, consistent with a similar increased risk of type 2 DM. Current recommendations advise screening for glucose intolerance between weeks 24 and 28 of pregnancy in women with high risk for GDM (³25 years; obesity; family history of DM; member of an ethnic group such as Hispanic American, Native American, Asian American, African American, or Pacific Islander). Therapy for GDM is similar to that for individuals with pregnancy-associated diabetes and involvesMNT and insulin, if hyperglycemia persists. Oral glucose-lowering agents have not been approved for use during pregnancy. With current practices, the morbidity and mortality of the mother with GDM and the fetus are no different from those in the nondiabetic population. Individuals who develop GDM are at marked increased risk for developing type 2 DM in the future and should be screened periodically for DM. After delivery, glucose homeostasis should be reassessed in the mother. Most individuals with GDM revert to normal glucose tolerance, but some will continue to have overt diabetes or impairment of glucose tolerance. In addition, children of women with GDM appear to be at risk for obesity and glucose intolerance and have an increased risk of diabetes beginning in the later stages of adolescence.

Pregnancy in individuals with known DMrequires meticulous planning and adherence to strict treatment regimens. Intensive diabetes management and normalization of the HbA1c are the standard of care for individuals with existing DM who are planning

pregnancy. The crucial period of glycemic control is extremely early following fertilization. The risk of fetal malformations is increased 4 to 10 times in individuals with uncontrolled DM at the time of conception. The goals are normal plasma glucose during the preconception period and throughout the periods of organ development in the fetus.

LIPODYSTROPHIC DM (See alsoChap. 354)

Lipodystrophy, or the loss of subcutaneous fat tissue, may be generalized in certain genetic conditions such as leprechaunism. Generalized lipodystrophy is associated with severe insulin resistance and is often accompanied by acanthosis nigricans and dyslipidemia. Localized lipodystrophy associated with insulin injections has been reduced considerably by the use of human insulin.

Protease Inhibitors and Lipodystrophy Protease inhibitors used in the treatment of HIV disease (Chap. 309) have been associated with a centripetal accumulation of fat (visceral and abdominal area), accumulation of fat in the dorsocervical region, loss of extremity fat, decreased insulin sensitivity (elevations of the fasting insulin level and reduced glucose tolerance on intravenous glucose tolerance testing), and dyslipidemia. Although many aspects of the physical appearance of these individuals resemble Cushing's syndrome, derangements in cortisol secretion have not been found consistently and do not appear to account for this appearance. Although some individuals haveIGT, diabetes is not a common feature. The possibility remains that this is related to HIV infection by some undefined mechanism, since some features of the syndrome were observed before the introduction of protease inhibitors. Therapy for HIV-related lipodystrophy is not well established.

334. HYPOGLYCEMIA - *Philip E. Cryer*

Hypoglycemia occurs most commonly as a result of treating patients with diabetes mellitus. However, a number of other disorders, including insulinoma, large mesenchymal tumors, end-stage organ failure, alcoholism, endocrine deficiencies, postprandial reactive hypoglycemic conditions, and inherited metabolic disorders, are also associated with hypoglycemia (Table 334-1). Hypoglycemia is sometimes defined as a plasma glucose level <2.5 to 2.8 mmol/L (<45 to 50 mg/dL). However, as discussed below, the glucose thresholds for hypoglycemia-induced symptoms and physiologic responses vary widely, depending on the clinical setting. Therefore, *Whipple's triad* provides an important framework for making the diagnosis of hypoglycemia: (1) symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration, and (3) relief of symptoms after the plasma glucose level is raised. Hypoglycemia can cause significant morbidity and can be lethal, if severe or prolonged; it should be considered in any patient who presents with confusion, altered level of consciousness, or seizures.

SYSTEMIC GLUCOSE BALANCE AND COUNTERREGULATION

Glucose is an obligate metabolic fuel for the brain under physiologic conditions. By contrast, other organs can use fatty acids, in addition to glucose, to generate energy. The brain cannot synthesize glucose and stores only a few minutes' supply as glycogen. It therefore requires a continuous supply of glucose, which is delivered by facilitated diffusion from arterial blood. As the plasma glucose concentration falls below the physiologic range, blood-to-brain glucose transport becomes insufficient for adequate brain energy metabolism and functioning. It is therefore not surprising that redundant physiologic mechanisms prevent or rapidly correct hypoglycemia.

Plasma glucose levels are maintained within a narrow range, usually between 3.3 and 8.3 mmol/L (60 and 150 mg/dL), despite wide variation in food intake and activity level. This delicate balance requires dynamic regulation of glucose influx into the circulation as glucose utilization in various tissues can change rapidly. The diet is normally a major source of glucose. However, between meals or during fasting, serum glucose levels are maintained primarily by the breakdown of glycogen in the liver and by gluconeogenesis (Fig. 334-1). In most people, hepatic glycogen stores are sufficient to maintain plasma glucose levels for 8 to 12 h, but this time period can be shorter if glucose demand is increased by exercise or if glycogen stores are depleted by illness or starvation.

As glycogen stores are depleted, glucose is generated by gluconeogenesis, which occurs primarily in the liver but also in the kidney. Gluconeogenesis requires a coordinated supply of precursors from liver, muscle, and adipose tissue. Muscle provides lactate, pyruvate, alanine, and other amino acids; triglycerides in adipose tissue are broken down into glycerol, which is a precursor for gluconeogenesis, and free fatty acids, which generate acetyl CoA for gluconeogenesis and provide an alternative fuel source to tissues other than brain.

The balance of glucose production and its uptake and utilization in peripheral tissues is exquisitely regulated by a network of hormones, neural pathways, and metabolic signals (Chap. 333). Among the factors that control glucose production and utilization, insulin

plays a dominant and pivotal role. In the fasting state, insulin is suppressed, allowing increased gluconeogenesis in the liver and the kidney and enhancing glucose generation by the breakdown of liver glycogen. Low insulin levels also reduce glucose uptake and utilization in peripheral tissues and allow lipolysis and proteolysis to occur, leading to the release of precursors for gluconeogenesis and providing alternative energy sources. In the fed state, insulin release from the pancreaticb cells reverses these processes. Glycogenolysis and gluconeogenesis are inhibited, thereby reducing hepatic and renal glucose output; peripheral glucose uptake and utilization are enhanced; lipolysis and proteolysis are restrained; and energy storage is promoted by the conversion of substrates into glycogen, triglycerides, and proteins. Other hormones including glucagon, epinephrine, growth hormone, and cortisol play less important roles in the control of glucose flux during normal physiologic circumstances. However, as described below, these hormones are critically important in the response to hypoglycemia.

As glucose levels approach, and ultimately enter, the hypoglycemic range, a characteristic sequence of *counterregulatory hormone responses* occurs. Glucagon is the first and most important of these responses. It promotes glycogenolysis and gluconeogenesis. Epinephrine can also play an important role in the acute response to hypoglycemia, particularly when glucagon is insufficient. It, too, stimulates glycogenolysis and gluconeogenesis as well as limiting glucose utilization by insulin-sensitive tissues. When hypoglycemia is prolonged, growth hormone and cortisol also reduce glucose utilization and support its production.

The glucose thresholds at which various counterregulatory hormone responses occur are quite similar in healthy subjects (Table 334-2). Nonetheless, these thresholds are dynamic and can be influenced by recent metabolic events. A person with poorly controlled diabetes can have symptoms of hypoglycemia at higher-than-normal glucose levels. Recurrent hypoglycemia, as may occur in individuals with diabetes or in the setting of an insulinoma, shifts thresholds for symptoms and counterregulatory responses to lower glucose levels.

CLINICAL MANIFESTATIONS

Symptoms of hypoglycemia can be divided into two categories, neuroglycopenic and neurogenic (or autonomic) responses. Neuroglycopenic symptoms are the direct result of central nervous system neuronal glucose deprivation. They include behavioral changes, confusion, fatigue, seizure, loss of consciousness, and, if hypoglycemia is severe and prolonged, death. Hypoglycemia-induced autonomic responses include adrenergic symptoms such as palpitations, tremor, and anxiety as well as cholinergic symptoms such as sweating, hunger, and paresthesia. Adrenergic symptoms are mediated by norepinephrine released from sympathetic postganglionic neurons and the release of epinephrine from the adrenal medullae. Increased sweating is mediated by cholinergic sympathetic nerve fibers. Patients with diabetes mellitus learn to recognize the characteristic symptoms of hypoglycemia, but these are less familiar to individuals with other causes of hypoglycemia. Symptoms may be less pronounced with repeated hypoglycemic episodes (see below).

Common signs of hypoglycemia include pallor and diaphoresis. Heart rate and the

systolic blood pressure are typically raised, but these findings may not be prominent. The neuroglycopenic manifestations are valuable, albeit nonspecific, signs. Transient focal neurologic deficits occur occasionally.

CAUSES

Hypoglycemia is traditionally classified as *postprandial* or *fasting*. However, in the clinical setting, hypoglycemia most commonly results from the treatment of diabetes. This topic is therefore addressed before considering the other causes of hypoglycemia.

HYPOGLYCEMIA IN DIABETES

Frequency and Impact Were it not for hypoglycemia, diabetes would be rather easy to treat by administering enough insulin (or any effective drug) to lower plasma glucose concentrations to, or below, the normal range. Because of imperfections in all current insulin-replacement regimens, individuals with type 1 diabetes are at ongoing risk for periods of relative hyperinsulinemia with resultant hypoglycemia. Those attempting to achieve near-normal glycemic control may experience several episodes of asymptomatic or symptomatic hypoglycemia each week. Plasma glucose levels may be <2.8 mmol/L (<50 mg/dL) as much as 10% of the time. At least 25% of such patients suffer an episode of severe, temporarily disabling hypoglycemia, often with seizure or coma, in a given year. Although seemingly complete recovery from the latter is the rule, the possibility of persistent cognitive deficits has been raised, but permanent neurologic defects are rare. About 2 to 4% of deaths associated with type 1 diabetes are estimated to result from hypoglycemia. Fear of hypoglycemia also can lead to disabling psychosocial morbidity.

Hypoglycemia is a less frequent problem in type 2 diabetes but occurs nevertheless in those treated with insulin or sulfonylureas. Transient, mild hypoglycemia may be seen with the shorter-acting sulfonylureas and repaglinide, which also acts by enhancing insulin secretion. Patients taking the long-acting sulfonylureas, chlorpropamide and glyburide, occasionally experience episodes of severe hypoglycemia that may last up to 24 to 36 h.

Conventional Risk Factors Insulin excess is the primary determinant of risk from iatrogenic hypoglycemia. Relative or absolute insulin excess occurs when: (1) insulin (or oral agent) doses are excessive, ill timed, or of the wrong type; (2) the influx of exogenous glucose is reduced, as during an overnight fast or following missed meals or snacks; (3) insulin-independent glucose utilization is increased, as during exercise; (4) insulin sensitivity is increased, as occurs with effective intensive therapy, in the middle of the night, late after exercise, or with increased fitness or weight loss; (5) endogenous glucose production is reduced, as following alcohol ingestion; and (6) insulin clearance is reduced, as in renal failure. However, analyses of the Diabetes Control and Complications Trial (DCCT) indicate that these conventional risk factors explain only a minority of episodes of severe iatrogenic hypoglycemia and that other causes are involved in the majority of episodes.

Hypoglycemia-Associated Autonomic Failure It is now clear that inadequate physiologic counterregulatory and behavioral responses greatly compound the problem

of hypoglycemia caused by insulin excess. Hypoglycemia-associated autonomic failure has two main components: (1) reduced counterregulatory hormone responses, which result in impaired glucose generation; and (2) hypoglycemia unawareness, which precludes appropriate behavioral responses, such as eating.

Defective Glucose Counterregulation The counterregulatory hormone response is fundamentally altered in all people with established (e.g., absent C peptide) type 1 diabetes. As the patient becomes totally insulin-deficient over the first few months or years of the disease, circulating insulin levels are no longer tightly coordinated with glucose levels and are a passive function of administered insulin. Thus, insulin levels do not always decline as glucose levels fall; the first defense against hypoglycemia is lost. Over the same time frame, the glucagon response to falling glucose levels diminishes, and the second defense against hypoglycemia is lost. The cause of defective glucagon production by the pancreatic islet a cells is unknown, but it is tightly linked to the loss of insulin production by the bcells. It is a functional abnormality rather than an absolute deficiency of glucagon, as responses to stimuli other than hypoglycemia are intact. The third defense against hypoglycemia is compromised when the epinephrine response to hypoglycemia is reduced. In contrast to the absent glucagon response, epinephrine deficiency is a threshold abnormality; an epinephrine response can still be elicited, but a lower plasma glucose concentration is required. This threshold shift is largely the result of recent antecedent hypoglycemia, although an additional anatomic component may be present as well in patients affected by classic diabetic autonomic neuropathy. The development of a reduced epinephrine response is a critical pathophysiologic event. Prospective studies have shown that patients with combined deficiencies of glucagon and epinephrine suffer severe hypoglycemia at rates 25-fold or greater than individuals with absent glucagon but intact epinephrine responses.

Hypoglycemia Unawareness Hypoglycemia unawareness refers to loss of the warning symptoms of hypoglycemia that normally alert individuals to the presence of hypoglycemia and prompt them to eat to abort the episode. Under these circumstances, the first manifestation of hypoglycemia is neuroglycopenia, and it is often too late for patients to treat themselves. Like defective counterregulation, the presence of hypoglycemia unawareness has been shown in prospective studies to be associated with a high frequency of severe hypoglycemia.

The interplay of factors involved in hypoglycemia-associated autonomic failure in type 1 diabetes, and consequent hypoglycemia unawareness, is summarized in Fig. 334-2. Periods of relative or absolute therapeutic insulin excess, in the setting of absent glucagon responses, lead to episodes of iatrogenic hypoglycemia. These episodes, in turn, cause reduced autonomic (including adrenomedullary) responses to falling glucose concentrations. These impaired autonomic responses result in reduced symptoms of impending hypoglycemia (e.g., hypoglycemia unawareness) and, because epinephrine responses are reduced in the setting of absent glucagon responses, impaired physiologic defense against developing hypoglycemia. Thus, a vicious cycle of recurrent hypoglycemia is created and perpetuated. The syndrome of hypoglycemia unawareness and the reduced epinephrine component of defective glucose counterregulation are reversible after as little as 2 weeks of scrupulous avoidance of hypoglycemia. This involves a shift of glycemic thresholds back to higher plasma glucose concentrations.

Hypoglycemia Risk Factor Reduction It is possible to minimize the risk of hypoglycemia by applying the principles of modern therapy -- patient education and empowerment, frequent self-monitoring of blood glucose, flexible insulin (and other drug) regimens, rational glycemic goals, and ongoing professional guidance and support. With respect to the latter, the issue of hypoglycemia needs to be addressed in every patient contact. If hypoglycemia is a recognized problem, first consider each of the conventional risk factors summarized earlier and recommend the appropriate adjustments of medications, diet, and life-style. Nonselective beta blockers may attenuate the recognition of hypoglycemia and they impair glycogenolysis; a relatively selectiveb_1-antagonist (e.g., metoprolol or atenolol) is preferable when a beta blocker is indicated. One should consider the issue of compromised glucose counterregulation. Although it is possible to test for this abnormality using a low-dose insulin infusion test, this is not practical. A diagnosis of hypoglycemia unawareness can usually be made from the history. It should be remembered that hypoglycemia unawareness implies that previous episodes of hypoglycemia have occurred, whether these are documented or not. If low glucose levels are not apparent from the patient's self-monitoring log, one should suspect hypoglycemia during the night. The presence of clinical hypoglycemia unawareness makes defective glucose counterregulation quite likely. A 2 to 3 week period of conscientious avoidance of hypoglycemia is advisable.

REACTIVE HYPOGLYCEMIA

The postprandial (reactive) hypoglycemias occur only after meals, and hypoglycemia is self-limited. Postprandial hypoglycemia occurs in children with certain rare enzymatic defects in carbohydrate metabolism such as hereditary fructose intolerance and galactosemia (Chap. 350). Reactive hypoglycemia also occurs in some individuals who have undergone gastric surgery that results in the rapid passage of food from the stomach to the small intestine. This type of *alimentary hypoglycemia* causes a rapid postprandial rise in plasma glucose levels and the release of gut incretins, which induce an exuberant insulin response and subsequent hypoglycemia. Administration of ana-glucosidase inhibitor, which delays carbohydrate digestion and thus glucose absorption from the intestine, can be considered for treatment of reactive hypoglycemia, although its efficacy remains to be established in controlled trials.

If postprandial symptoms occur as an idiopathic disorder, caution should be exercised before labeling a person with the diagnosis of hypoglycemia. Indeed, a self-diagnosis of hypoglycemia has often been reinforced by the finding of a "low" venous glucose concentration late after glucose ingestion. An oral glucose tolerance test should not be used in this setting. Plasma glucose falls as low as 2.4 mmol/L (43 mg/dL) after a 100-g glucose load in 5% of normal asymptomatic individuals, making it difficult to identify hypoglycemia based on the results of this test. The diagnosis of postprandial hypoglycemia requires documentation of Whipple's triad after a typical mixed meal. The cause of repetitive postprandial symptoms in certain individuals is unknown, but they may be particularly sensitive to the normal autonomic responses that follow ingestion of a meal.

FASTING HYPOGLYCEMIA

There are many causes of fasting hypoglycemia (Table 334-1). In addition to insulin and

sulfonylureas used in the treatment of diabetes, ethanol use is a relatively common cause of hypoglycemia. Sepsis and renal failure are often complicated by hypoglycemia, but it is less common in other critical illnesses. Endocrine deficiencies, non-b-cell tumors, and endogenous hyperinsulinemia (including that caused by an insulinoma) are rare causes of hypoglycemia. Enzymatic metabolic errors that cause hypoglycemia are also rare but are being recognized more frequently in infants and children (Chaps. 350 and352).

Drugs In contrast to the sulfonylureas and benzoic acid derivatives (e.g., repaglinide), other oral hypoglycemic agents -- biguanides (e.g., metformin),a-glucosidase inhibitors (e.g., acarbose, miglitol), and thiazolidinediones (e.g., troglitazone, rosiglitazone, pioglitazone) -- do not act by stimulating insulin secretion. Therefore, with these agents, insulin levels usually decrease appropriately as plasma glucose levels fall. Nonetheless, these drugs can contribute to hypoglycemia in other ways. Treatment with ana-glucosidase inhibitor alters the management of hypoglycemia; pure glucose should be used rather than ingestion of complex carbohydrates. Thiazolidinediones, as well as metformin, can predispose to hypoglycemia in patients receiving combined treatment with insulin or an insulin secretagogue.

Ethanol blocks gluconeogenesis but not glycogenolysis. Thus, alcohol-induced hypoglycemia typically occurs after a several-day ethanol binge during which the person eats little food, thereby causing glycogen depletion. Hypoglycemia in this setting can be profound, with mortality rates as high as 10%. Blood ethanol levels correlate poorly with plasma glucose concentrations at the time of diagnosis, as hypoglycemia occurs late in the sequence and often precludes further alcohol consumption.

Pentamidine, which is used to treat *Pneumocystis* pneumonia and other parasitic infections, is toxic to the pancreatic b cell. It causes insulin release initially, with hypoglycemia in about 10% of treated patients, and predisposes to the development of diabetes mellitus later. Quinine also stimulates insulin secretion. However, the relative contribution of hyperinsulinemia to the pathogenesis of hypoglycemia in quinine-treated patients who are critically ill with malaria is debated. Salicylates and sulfonamides can cause hypoglycemia but do so rarely. There are reports of hypoglycemia attributed to nonselectiveb-adrenergic antagonists (e.g., propranolol) and a variety of other drugs.

Critical Illness Rapid and extensive hepatic destruction (e.g., severe toxic hepatitis) causes fasting hypoglycemia because the liver is the major site of endogenous glucose production. The mechanism of hypoglycemia reported in patients with cardiac failure is unknown but likely involves hepatic congestion. Although the kidneys are a source of glucose production, it is perhaps too simplistic to attribute hypoglycemia in people with renal failure to this mechanism alone. The clearance of insulin is reduced substantially in renal failure, and reduced mobilization of gluconeogenic precursors has been reported.

Sepsis is sometimes complicated by hypoglycemia, which is multifactorial in origin. There is impaired endogenous glucose production, perhaps the result of hepatic hypoperfusion, and increased glucose utilization, which is induced by cytokines in macrophage-rich tissues such as the liver, spleen, and ileum and in muscle. Nutrition is also often inadequate in the setting of sepsis. Hypoglycemia can be seen with

prolonged starvation, perhaps as a result of the loss of whole-body fat stores and the subsequent depletion of gluconeogenic precursors (e.g., amino acids), which necessitate increased glucose utilization.

Endocrine Deficiencies Neither cortisol nor growth hormone is critical to the prevention of acute hypoglycemia, at least in adults. Nonetheless, hypoglycemia can occur with prolonged fasting in patients with untreated primary adrenocortical failure (Addison's disease) or hypopituitarism. Anorexia and weight loss are typical features of chronic cortisol deficiency and likely result in glycogen depletion with increased reliance on gluconeogenesis. Cortisol deficiency is associated with low levels of gluconeogenic precursors, suggesting that substrate-limited gluconeogenesis, in the setting of glycogen depletion, is the cause of the impaired ability to tolerate fasting in cortisol-deficient individuals. Growth hormone deficiency can cause hypoglycemia in young children. In addition to extended fasting, high rates of glucose utilization (e.g., during exercise, pregnancy) or low rates of glucose production (e.g., following alcohol ingestion) can precipitate hypoglycemia in adults with hypopituitarism. Cortisol and growth hormone secretion should be evaluated in patients with fasting hypoglycemia when the history suggests pituitary or adrenal disease and when other causes of hypoglycemia are not apparent.

As discussed earlier, the combined loss of counterregulatory glucagon and epinephrine responses plays a central role in the pathogenesis of hypoglycemia in diabetes mellitus. However, hypoglycemia is not a feature of the epinephrine-deficient state that results from bilateral adrenalectomy when glucocorticoid replacement is adequate, nor does it occur during pharmacologic adrenergic blockage when other glucoregulatory systems are intact. There are case reports of fasting hypoglycemia attributed to isolated glucagon or epinephrine deficiency, although hyperinsulinemia was not excluded convincingly in the neonatal cases and other counterregulatory defects may have contributed in the adults. Thus, the regular assessment of glucagon and epinephrine secretion is not warranted.

Non-b-Cell Tumors Fasting hypoglycemia, often termed *non-islet cell tumor hypoglycemia*, occurs in some patients with large mesenchymal or other tumors (e.g., hepatoma, adrenocortical tumors, carcinoids). The glucose kinetic patterns resemble those of hyperinsulinism, but insulin secretion is suppressed appropriately during hypoglycemia. In most instances, hypoglycemia is due to overproduction of an incompletely processed form of insulin-like growth factor (IGF)II. Although total IGF-II levels are not consistently elevated, circulating free IGF-II levels are high. Hypoglycemia may result from IGF-II actions through the insulin or IGF-I receptors. Because of negative-feedback suppression of growth hormone secretion, IGF-I levels tend to be low, causing an increased IGF-II to IGF-I ratio.

Endogenous Hyperinsulinism Hypoglycemia due to excessive endogenous insulin secretion can be caused by: (1) a primary pancreatic islet bcell disorder, typically a b cell tumor (insulinoma), sometimes multiple insulinomas, or, especially in infants or young children, a functional b cell disorder without an anatomic correlate; (2) a b cell secretagogue, often a sulfonylurea, and, theoretically, a b cell-stimulating autoantibody; (3) an autoantibody to insulin; or (4) perhaps ectopic insulin secretion. None of these disorders is common. Endogenous hyperinsulinism is more likely in an overtly well

individual without other apparent causes of hypoglycemia such as a relevant drug history, critical illness, endocrine deficiencies, or a non-b-cell tumor. Accidental, surreptitious, or even malicious administration of a sulfonylurea or insulin should also be considered in such individuals.

The fundamental pathophysiologic feature of endogenous hyperinsulinism is the failure of insulin secretion to fall to very low rates during hypoglycemia. This is assessed by measuring insulin, proinsulin, and C peptide, which is derived from the processing of proinsulin. The critical diagnostic findings are a plasma insulin concentration³36 pmol/L (³6 uU/mL) and a plasma C-peptide concentration ³0.2 mmol/L (³0.6 ng/mL) when the plasma glucose concentration is £2.5 mmol/L (£45 mg/dL) in the fasting state with symptoms of hypoglycemia. Insulin and C-peptide levels do not need to be absolutely high (e.g., relative to euglycemic normal values) but only inappropriately high in the setting of fasting hypoglycemia. Plasma proinsulin concentrations are also inappropriately high, particularly in patients with an insulinoma. Sulfonylureas, because they stimulate insulin secretion, result in a pattern of glucose, insulin, and C-peptide levels that is indistinguishable from that produced by a primary b cell disorder. The measurement of sulfonylureas in plasma or urine distinguishes these conditions. Antibodies to insulin produce *autoimmune hypoglycemia* following the transition from the postprandial to the postabsorptive state, as insulin slowly dissociates from the antibodies. Total and free plasma insulin concentrations are inappropriately high. The distinguishing finding is the presence of circulating antibodies to insulin, but the need to measure these routinely is debated, since autoimmune hypoglycemia appears to be rare. Autoantibodies to the insulin receptor are another rare cause of hypoglycemia and usually occur in the context of other autoimmune diseases. A few cases of apparent ectopic secretion of insulin (from a non-b-cell tumor) have been reported.

Insulinoma and Other Primaryb Cell Disorders Insulinomas are rare, but because approximately 90% are benign, they are a treatable cause of potentially fatal hypoglycemia. The yearly incidence is estimated to be 1 in 250,000. About 60% of cases occur in women. The median age at presentation is 50 years in sporadic cases, but it usually presents in the third decade when associated with multiple endocrine neoplasia type 1 (Chap. 339). Insulinomas arise within the substance of the pancreas in >99% of cases and are usually small (1 to 2 cm). About 5 to 10% of insulinomas are malignant, as evidenced by the presence of metastases.

Insulinomas almost always come to clinical attention because of hypoglycemia rather than mass effects. As noted earlier, unusually low plasma glucose concentrations may be required to produce symptoms and signs of hypoglycemia because recurrent hypoglycemia shifts the glycemic thresholds. Although symptomatic hypoglycemia can be seen after an overnight fast, it often follows exercise. Rarely, symptomatic hypoglycemia occurs following meals, but most such patients have evidence of fasting hypoglycemia as well.

Octreotide scans localize about half of insulinomas. Arteriography has been used extensively in the past, but false-negative and false-positive results occur, and it is generally preferable to use less invasive computed tomography (CT) or magnetic resonance imaging (MRI) scans, which detect 45 to 75% of tumors. Preoperative ultrasound is of value in some patients. Intraoperative ultrasonography has high

sensitivity and may localize tumors not identified by palpation. Surgical resection of a solitary insulinoma is generally curative. Diazoxide, which inhibits insulin secretion, and the somatostatin analogue, octreotide, can be used to treat hypoglycemia in patients with unresectable insulinomas.

Factitious Hypoglycemia Factitious hypoglycemia, caused by malicious or self-administration of insulin or ingestion of a sulfonylurea, shares many clinical and laboratory features with insulinoma. It is most common among health care workers, patients with diabetes or their relatives, and people with a history of other factitious illnesses. When this diagnosis is suspected, it is useful to seek previous medical records, which may reveal admissions for similar episodes as well as relevant laboratory data. In individuals taking exogenous insulin, factitious hypoglycemia can be distinguished from insulinoma by the presence of high insulin levels without a concomitant increase in the C-peptide level, which is suppressed by the exogenous insulin. As noted above, sulfonylureas stimulate endogenous insulin and can therefore be detected only by measuring drug levels in plasma or urine. Factitious or surreptitious hypoglycemia should be considered in every patient requiring a fasting test for hypoglycemia. In addition to laboratory tests, observing the behavior of the patient may help make this diagnosis.

Approach to the Patient

In addition to recognition and documentation of hypoglycemia, and often urgent treatment, diagnosis of the hypoglycemic mechanism is critical for choosing a treatment that prevents, or at least minimizes, recurrent hypoglycemia. A diagnostic algorithm is shown inFig. 334-3.

Recognition and Documentation Urgent treatment is often necessary in patients with suspected hypoglycemia. Nevertheless, blood should be drawn, whenever possible, before the administration of glucose to allow documentation of the plasma glucose level. Convincing documentation of hypoglycemia requires the fulfillment of Whipple's triad. Thus, *the ideal time to test the plasma glucose is during an episode associated with hypoglycemic symptoms*. A normal plasma glucose concentration measured when the patient is free of symptoms does not exclude hypoglycemia at the time of earlier symptoms. When the cause of hypoglycemia is obscure, additional assays should include glucose, insulin, C peptide, sulfonylurea levels, cortisol, and ethanol.

Hypoglycemia is sometimes detected serendipitously. A distinctly low plasma glucose measurement in a person without a history of corresponding symptoms raises the possibility of a laboratory error caused by ongoing metabolism of glucose by the formed elements of the blood after the sample is drawn. This type of artifactually low glucose level is particularly likely when leukocyte, erythrocyte, or platelet counts are abnormally high, but it can also occur if separation of the plasma or serum from the formed elements is delayed.

Diagnosis of the Hypoglycemic Mechanism In an adult patient with documented hypoglycemia, a plausible hypoglycemic mechanism and further diagnostic evaluation can be guided by the history, physical examination, and available laboratory data (Fig. 334-3). Relevant historic elements include: drug history, particularly hypoglycemic

agents or alcohol use; relevant critical illness (hepatic, renal, or cardiac failure, sepsis, or inanition); previous gastric surgery associated with postprandial hypoglycemia; features suggestive of cortisol or growth hormone deficiency; inherited enzyme deficiencies associated with hypoglycemia; or features of a non-b-cell tumor. Absent these, one must consider medication error, endogenous hyperinsulinism, or surreptitious sulfonylurea or insulin administration. In the absence of documented spontaneous hypoglycemia, overnight fasting, or food deprivation during observation in the outpatient setting, will sometimes elicit hypoglycemia and allow diagnostic evaluation. If these maneuvers do not reveal hypoglycemia, and there is a high degree of clinical suspicion, an extended fast lasting up to 72 h is often required to make these diagnoses. This procedure should be performed in the hospital with careful supervision and should be terminated if the plasma glucose drops to<2.5 mmol/L (<45 mg/dL) and the patient has symptoms. It is essential to draw blood samples for appropriate tests before administering glucose or allowing the patient to eat.

Urgent Treatment Oral treatment with glucose tablets or glucose-containing fluids, candy, or food is appropriate if the patient is able and willing to take these. A reasonable initial dose is 20 g of glucose. If neuroglycopenia precludes oral feedings, parenteral therapy is necessary. Intravenous glucose (25 g) should be given using a 50% solution followed by a constant infusion of 5 or 10% dextrose. If intravenous therapy is not practical, subcutaneous or intramuscular glucagon can be used, particularly in people with type 1 diabetes mellitus. Because it acts primarily by stimulating glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g., those with alcohol-induced hypoglycemia). These treatments raise plasma glucose concentrations only transiently, and patients should be encouraged to eat as soon as practical in order to replete glycogen stores.

Prevention of Recurrent Hypoglycemia Prevention of recurrent hypoglycemia requires an understanding of the hypoglycemic mechanism. Offending drugs can be discontinued or their doses reduced. It should be remembered that hypoglycemia caused by sulfonylureas may recur after a period of many hours or days. Underlying critical illnesses can often be treated. Cortisol and growth hormone can be replaced, if deficient. Surgical, radiotherapeutic, or chemotherapeutic reduction of a non-b-cell tumor can alleviate hypoglycemia, even if the tumor cannot be cured; glucocorticoid or growth hormone administration may also reduce hypoglycemic episodes in such patients. Surgical resection of an insulinoma is often curative; medical therapy with diazoxide or octreotide can be used if resection is not possible and in patients with a nontumor primary b cell disorder. The treatment of autoimmune hypoglycemia (e.g., with a glucocorticoid) is more problematic, but this disorder is often self-limited. Failing these treatments, frequent feedings and avoidance of fasting may be required. Uncooked cornstarch at bedtime or an overnight infusion of intragastric glucose may be necessary in some patients.

335. DISORDERS OF THE TESTES - *James E. Griffin, Jean D. Wilson*

The testes produce sperm and the steroid hormones that regulate male sexual function. Both processes are under complex feedback control by the hypothalamic-pituitary system so that the testes have biosynthetic and regulatory features similar to those of the ovary and the adrenal. Testicular hormones are also responsible for the formation of the basic male phenotype during embryogenesis (Chap. 338). Disorders that affect testicular function are common. Infertility occurs in about 5% of men; Klinefelter syndrome (XXY) occurs in 1 in 500 men and often escapes diagnosis; and various disorders cause hypogonadism, a condition that can be treated by hormone replacement. The testes are also a site of malignancies, most of which are highly responsive to radiation and/or chemotherapy (Chap. 96).

PHYSIOLOGY AND REGULATION OF TESTICULAR FUNCTION

The testis consists of two components -- clusters of interstitial or Leydig cells, where androgenic steroids are synthesized, and a system of spermatogenic tubules for the production and transport of sperm. The components are regulated by the pituitary gonadotropins -- luteinizing hormone (LH), which stimulates Leydig cell function, and follicle-stimulating hormone (FSH), which controls Sertoli cell function and spermatogenesis (Fig. 335-1).

GONADOTROPIN REGULATION AND TESTICULAR FUNCTION

Gonadotropin-releasing hormone (GnRH), also called luteinizing hormone-releasing hormone (LHRH), regulates the production of the gonadotropins,LH andFSH(Chap. 328). Because hypothalamic GnRH is secreted in discrete pulses, the plasma concentrations of LH, FSH, and testosterone are not constant, but fluctuate in a pulsatile pattern that mirrors the secretion of GnRH (Fig. 335-2). Pulsatile secretion is most apparent for LH because it has a relatively short plasma half-life by comparison to FSH; pulsatile secretion of testosterone in response to LH is also apparent, although the pulses are dampened because of the need to stimulate steroid synthesis and secretion by the Leydig cell. In contrast to women, in whom the frequency and amplitude of LH pulses vary during the menstrual cycle, the frequency of LH pulses in adult men is relatively constant at about one pulse every 1 to 2 h.

Testosterone secretion is regulated primarily by pituitaryLH.FSH may augment testosterone secretion by stimulating a Sertoli-cell derived factor that enhances testosterone production. Testosterone feeds back to regulate the hypothalamic-pituitary production of LH. It decreases hypothalamic GnRH pulse frequency and diminishes pituitary sensitivity to GnRH, leading to lower LH levels. Although the pituitary can convert testosterone to dihydrotestosterone and to estrogens, testosterone itself is the primary regulator of gonadotropin secretion by the pituitary. Under ordinary circumstances, LH secretion is exquisitely sensitive to the feedback effects of testosterone, with almost complete suppression after the administration of amounts of exogenous androgen that approximate the normal daily secretory rate of testosterone (~20 umol or 6 mg). However, prolonged elevation of plasma LH (as in testicular deficiency) renders the pituitary less sensitive to negative feedback control by androgen.

FSHis regulated byGnRH and also by the gonadal peptides -- inhibins and activins. Inhibins A and B are heterodimeric proteins (composed ofa-bAora-bBsubunits) that selectively suppress FSH without affectingLH; activins are homodimeric proteins (composed ofbA orbBsubunits) that selectively stimulate FSH production. Inhibin B, which is the major form of inhibin in the male, is produced by the Sertoli cell and provides feedback control of FSH production. Activins, which are produced in the pituitary as well as the gonad, stimulate FSH production through an autocrine-paracrine mechanism.

The interlocking system in which two pituitary hormones (LH andFSH) regulate testicular function provides a precise dual-control mechanism in which hormonal signals from Leydig cells and the spermatogenic tubules feed back on the hypothalamic-pituitary system to regulate their own function (Fig. 335-1).

THE LEYDIG CELL

Testosterone Synthesis The biochemical pathway by which the 27-carbon sterol cholesterol is converted to androgens and estrogens is depicted inFig. 335-3. Cholesterol, which can be either synthesized de novo in the Leydig cell or derived from plasma lipoproteins, is converted to testosterone as the result of five enzymatic reactions: (1) cholesterol side chain cleavage (CYP11A1); (2) 3b-hydroxysteroid dehydrogenase/isomerase 2 (3b-HSD2); (3) 17a-hydroxylase (CYP17); (4) 17,20-lyase (CYP17); and (5) 17b-hydroxysteroid dehydrogenase 3 (17b-HSD3). Both the 17a-hydroxylase and the 17,20-lyase reactions are catalyzed by a single cytochrome CYP17; post-translational modification (phosphorylation) of the enzyme and the presence of enzyme cofactors confers 17,20-lyase activity, thereby allowing androgen synthesis in the testis and zona reticularis of the adrenal gland. The first four reactions take place in the adrenal as well as the testis. The rate-limiting process in testosterone synthesis is the delivery of cholesterol by the steroid acute regulatory (StAR) protein to the inner mitochondrial membrane where it can undergo side chain cleavage by CYP11A1 to form pregnenolone.LH from the pituitary stimulates the activity of StAR protein and the enzymes in the steroid pathway. Additional steroids including estradiol are synthesized in small amounts in the Leydig cell.

TESTOSTERONE SECRETION AND TRANSPORT

Only about 70 nmol (20 ug) of testosterone is stored in the normal testes, so the total hormone content turns over about 200 times each day to provide the average of 17 to 20 umol (5 to 6 mg) that is secreted into plasma in normal young men (Fig. 335-4). Testosterone is transported in plasma bound to protein, largely to albumin and to a specific transport protein, sex hormone-binding globulin (SHBG), also called testosterone-binding globulin (TeBG). The bound and unbound fractions in plasma are in dynamic equilibrium, only ~1 to 3% being unbound. Because of rapid dissociation from albumin, the fraction of circulating testosterone available for entry into tissues (bioavailable testosterone) approximates the sum of the free and albumin-bound fractions or about half the total plasma level.

Peripheral Metabolism of Androgens Testosterone serves as a circulating precursor (or prohormone) for the formation of two other hormones that mediate many of the

physiologic processes involved in androgen action (Fig. 335-3). Testosterone can be 5a-reduced to dihydrotestosterone, which is responsible for many of the differentiative, growth-promoting, and functional aspects of male sexual differentiation and virilization. Circulating testosterone (and androstenedione) also can be converted to estrogens by aromatase (CYP19) in extraglandular tissues (Fig. 335-4). All estrone production [averaging about 240 nmol (66 ug) per day] can be accounted for by formation from circulating precursors. The mean estradiol production is approximately 170 nmol (45 ug) per day; ~35% is derived from circulating testosterone, 50% is derived from the estrone, and 15% is secreted directly by the testes. When gonadotropin levels are elevated, estradiol secretion by the testes increases. Thus, the physiologic effects of testosterone are the result of the combined actions of testosterone itself plus those of the active androgen and estrogen metabolites of the parent molecule.

The 5a-reduced and estrogenic metabolites can exert local (paracrine) actions in the tissues in which they are formed or enter the circulation and act as hormones at other sites. Circulating dihydrotestosterone is formed principally in the androgen target tissues; estrogen formation takes place in many tissues, the most significant being adipose tissue. The overall rate of extraglandular estrogen formation increases with age and with increased mass of adipose tissue.

Testosterone and its active metabolites are catabolized in the liver and excreted predominantly in the urine, approximately half in the form of urinary 17-ketosteroids (primarily androsterone and etiocholanolone) and half as polar metabolites (diols, triols, and conjugates).

Androgen Action The major functions of androgen are formation of the male phenotype during sexual differentiation, regulation ofLHsecretion, and induction of sexual maturation at puberty. The cellular process by which androgens perform these functions is schematized inFig. 335-5. Testosterone enters the cell by passive diffusion and can be converted to dihydrotestosterone by either steroid 5a-reductase 1 or 2; 5a-reductase 2 is responsible for dihydrotestosterone formation in most androgen target tissues. Testosterone or dihydrotestosterone is then bound to the androgen-receptor protein in the nucleus. The hormone-receptor complex binds to specific DNA sequences to regulate the transcription of messenger RNA and, ultimately, the synthesis of cellular proteins. The androgen receptor, which is encoded by a gene on the long arm of the X chromosome, contains 917 amino acids and has a molecular mass of about 110 kDa. A polymorphic region in the amino terminus of the receptor, which contains a variable number of glutamine repeats, appears to modify the activity of the receptor. The androgen receptor is similar in structure to other steroid hormone receptors and has distinct hormone-binding, DNA-binding, and transcriptional regulatory domains (Chap. 327). Estradiol acts by a similar mechanism but has its own distinct estrogen receptors a andb (Chap. 336).

Although testosterone and dihydrotestosterone bind to the same receptor, their physiologic roles differ. The testosterone-receptor complex regulates gonadotropin secretion, spermatogenesis, and the virilization of the wolffian ducts during sexual differentiation (Chap. 338), whereas the dihydrotestosterone-receptor complex is responsible for external virilization during embryogenesis and for most androgen actions during sexual maturation and adult sexual life. The mechanism by which two hormones

can interact with the same receptor but have different physiologic effects is not well understood. However, dihydrotestosterone binds to the receptor much more tightly than does testosterone, and hence its formation serves to amplify the hormonal signal.

THE SEMINIFEROUS TUBULES AND SPERMATOGENESIS

Spermatogenesis is dependent on both pituitaryFSH and androgen production by the adjacent Leydig cells (Fig. 335-1). The function of FSH in gametogenesis has been clarified by rare, naturally occurring mutations in the *FSHb* gene and in the FSH receptor. Females with these mutations are hypogonadal and infertile because ovarian follicles do not mature, whereas males with mutations in the FSH pathway exhibit variable degrees of impaired spermatogenesis. Thus, while FSH is not absolutely required for spermatogenesis, it increases the number and maturation of sperm. The major site of FSH action is the Sertoli cell, which regulates germ cell proliferation and maturation in the seminiferous tubules. Androgen, which reaches very high concentrations locally in the testis, appears to be essential for spermatogenesis, acting through receptors located in the seminiferous tubules. Several cytokines and growth factors are also involved in the regulation of spermatogenesis by paracrine and autocrine mechanisms. The normal adult testes produce >100 million sperm per day.

The Sertoli cell cannot synthesize steroid hormones de novo but can convert testosterone that diffuses from adjacent Leydig cells to estradiol and to dihydrotestosterone. The Sertoli cell also produces inhibin B. Damage to the seminiferous tubules (e.g., by radiation) reduces inhibin B production, causing a selective increase inFSH.

ASSESSMENT OF TESTICULAR FUNCTION

LEYDIG CELL FUNCTION

History and Physical Examination The assessment of Leydig cell function and androgen status should include inquiry about the presence of developmental abnormalities of the urogenital tract; the timing and extent of sexual maturation at puberty; the rate of beard growth; and the current libido, sexual function, strength, and energy. Inadequate Leydig cell function or androgen action during embryogenesis may cause hypospadias, cryptorchidism, or microphallus. If Leydig cell failure occurs before puberty, sexual maturation will not occur, and the individual will develop the features termed *eunuchoidism*, including an infantile amount and distribution of body hair, poor development of skeletal muscles, and delayed closure of the epiphyses, so that the arm span is more than 5 cm greater than the height and the lower body segment (heel to pubic bone) is more than 5 cm longer than the upper body segment (pubic bone to crown). Detection of postpubertal Leydig cell failure requires a high index of suspicion and appropriate laboratory assessment because some functions that require androgens for initiation continue unabated when Leydig cell failure occurs, and functions that eventually regress may do so very slowly. For example, the frequency of shaving may not decrease for months or years because of slow decline in the rate of beard growth once established. Furthermore, decreased sexual function in adult men may be caused by nonendocrine as well as endocrine factors (Chap. 51).

Plasma Testosterone and Dihydrotestosterone Levels Plasma testosterone is measured by immunoassay. Testosterone is secreted into plasma in a pulsatile fashion every 60 to 90 min (Fig. 335-2). A single random testosterone sample provides a result within ±20% of the true mean value only two-thirds of the time; a pool of three samples spaced 15 to 20 min apart provides a more accurate assessment. The plasma testosterone level in normal adult men ranges from 10 to 35 nmol/L (3 to 10 ng/mL). However, in some normal men with long interpulse intervals of LH, testosterone levels can transiently fall below this normal range, emphasizing the importance of using pooled or repeated samples before making a diagnosis of testosterone deficiency. In adult men, plasma testosterone levels also vary somewhat throughout the day and at different times of the year. In young adult men the plasma testosterone level is ~30% higher in the morning than in the evening. Estimation ofSHBGconcentration by radioimmunoassay is sometimes useful in the interpretation of total plasma testosterone levels. Bioavailable testosterone in plasma can be estimated by measuring the non-SHBG-bound fraction of testosterone.

The plasma testosterone level is slightly higher in prepubertal boys than in girls, ranging in both from 0.2 to 0.7 nmol/L (0.05 to 0.2 ng/mL). The rise in plasma testosterone level at the start of male puberty begins as a result of sleep-related nocturnal gonadotropin surges, so that levels of plasma testosterone andLH are initially higher at night than during the day. Random daytime levels of plasma testosterone increase gradually as puberty progresses and reach adult levels at about age 17.

Dihydrotestosterone is also measured by immunoassay. In young men the plasma dihydrotestosterone level is about one-tenth the value for testosterone, averaging ~2 nmol/L (0.6 ng/mL). In older men with benign prostatic hyperplasia, plasma dihydrotestosterone levels average ~3 nmol/L (0.9 ng/mL).

Urinary 17-Ketosteroids The measurement of urinary 17-ketosteroids is not a valid way to assess testicular function because testosterone contributes only ~40% of urinary 17-ketosteroids in men, the bulk being derived from adrenal androgens.

PlasmaLHPlasma LH is also measured by immunoassay. Dual-site immunometric assays have largely replaced radioimmunoassays. Because LH is secreted in a pulsatile fashion, assay of a pool of three samples drawn 15 to 20 min apart, as described above, provides a value approaching the true mean. In early puberty, plasma LH secretion increases only during sleep, but in the adult the pulsatile secretion is of similar magnitude during sleep and waking periods. The normal plasma LH values should be established for a given laboratory with an appropriate reference standard. A low plasma testosterone level can be interpreted correctly only if plasma LH is measured simultaneously, and, likewise, the "appropriateness" of a given plasma LH value must be interpreted in relation to the plasma testosterone level. For example, a low plasma testosterone level coupled with a low LH level implies hypothalamic or pituitary disease, whereas the finding of a low plasma testosterone level and a high LH level suggests primary testicular insufficiency.

Response to Gonadotropin Stimulation Leydig cell function is difficult to assess before puberty, when bothLH and testosterone levels are low, but it is possible to measure response of plasma testosterone to gonadotropin stimulation as an index of

Leydig cell capacity. Normal prepubertal boys respond to 3 to 5 days of injection of 1000 to 2000 IU of human chorionic gonadotropin (hCG) with an increase in the plasma testosterone level to ~7 nmol/L (2 ng/mL); the response increases with the initiation of puberty and peaks in early puberty.

Response to GnRH Before puberty, there is minimal response of plasma LH and FSH to the administration of GnRH because the pituitary has not been "primed" by previous exposure to GnRH or gonadal steroids. After pubertal development, the LH response to acute administration of GnRH increases, while the FSH response is less robust. The amount of LH released after acute administration of GnRH probably reflects the amount of stored hormone in the pituitary. When 100 ug GnRH is given subcutaneously or intravenously to normal men, LH levels usually increase four- to fivefold, with the peak level at 30 min. However, the range of response is broad, and some normal men exhibit less than a doubling of LH levels. In primary testicular failure, measurement of basal LH is usually sufficient, and assessment of GnRH response is of little aid in diagnosis. Since men with either pituitary or hypothalamic disease can have a normal or an abnormal LH response to acute administration of GnRH, a normal response does not clearly distinguish these causes of gonadal deficiency. A subnormal response is, however, of value in establishing that an abnormality exists, even though the site of the defect is not clearly determined. If pulsatile GnRH or daily infusions of GnRH for a week lead to the development of a normal acute LH response, a hypothalamic etiology is likely.

SEMINIFEROUS TUBULE FUNCTION

Examination of the Testes Evaluation of the testes is an essential portion of the physical examination. The prepubertal testis measures about 2 cm in length and 2 mL in volume and grows during puberty to reach the adult proportions by age 16. When damage to the seminiferous tubules occurs before puberty, the testes are small and firm, whereas the testes are usually soft after postpubertal damage (the capsule, once enlarged, does not contract to its previous size). Testes in adult men average 4.6 cm in length (range, 3.5 to 5.5 cm), corresponding to a volume of 12 to 25 mL, and the seminiferous tubules account for ~60% of testicular mass. Advanced age does not influence testicular size, so the significance of small testes in the adult is the same at all ages. Asian men have smaller testes than western Europeans, independent of differences in body size. Because of its possible causal role in infertility, the presence of varicocele should be sought by palpation with the patient standing.

Semen Analysis Seminal fluid is analyzed on samples obtained by masturbation into a glass container after 24 to 36 h of abstinence. Analysis should be performed within an hour of collection. The normal ejaculate volume is 2 to 6 mL. Immediately after ejaculation, the seminal fluid coagulates, followed in 15 to 30 min by liquefaction. Motility should be assessed in undiluted seminal fluid;>60% of the sperm should be motile and of normal morphology. The normal range for sperm density is generally considered to be>20 million per milliliter, with a total count of>60 million per ejaculate, but the definition of a minimally adequate ejaculate is not clear. Some men with low sperm counts are nevertheless fertile. This uncertainty as to the lower level of sperm density, percent motility, and percent normal forms in fertile semen stems from two issues. First, the seminal fluid is routinely evaluated by tests that do not assess the

functional capacity of sperm. Second, many factors produce temporary aberrations in sperm count; in men with semen of equivocal quality, it is necessary to examine three or more ejaculates to determine whether the abnormal findings are permanent.

PlasmaFSHPlasma FSH, as measured by immunoassay, usually correlates inversely with spermatogenesis. When damage to the germinal epithelium is severe, plasma levels of inhibin B fall and plasma levels of FSH increase.

Testicular Biopsy Testicular biopsy is useful in some patients with oligospermia and azoospermia both as an aid in diagnosis and as an indication of the feasibility of treatment. For example, normal findings on testicular biopsy and a normalFSHlevel in an azoospermic man suggest obstruction of the vas deferens, which may be correctable surgically. In some men with severe oligospermia, testicular biopsy allows retrieval of sperm for intracytoplasmic sperm injections (ICSI) into oocytes (Chap. 54).

ESTROGENIC FUNCTION

Examination of the Breasts Breast enlargement (gynecomastia) is the most consistent feature of feminizing states in men (Chap. 337). Gynecomastia is due to an increase in both glandular and adipose tissue. The presence of gynecomastia should be sought by examining the sitting patient, using the fingers to grasp glandular tissue. Early or minimal breast enlargement may be missed if the breast is palpated with the flat of the hand while the patient is supine. In obese men it is important to try to define the rim of the glandular tissue where it meets the adipose tissue of the chest wall.

Plasma Estrogen As discussed above, most of the estradiol and all of the estrone produced in normal men is formed by extraglandular aromatization of circulating androgens. The plasma level of estradiol usually is<180 pmol/L (50 pg/mL) in normal men; the plasma estrone level is somewhat higher but usually is<300 pmol/L (80 pg/mL). Elevations in estrogen production and estrogen plasma levels can be due to increases in plasma precursors (liver or adrenal disease), to increased extraglandular aromatization (obesity), or to increased production by the testes (testicular tumors, androgen resistance, gonadotropin stimulation).

PHASES OF NORMAL TESTICULAR FUNCTION

The phases of male sexual life can be defined in terms of the plasma testosterone value (Fig. 335-6). In the male embryo the production of testosterone by the testes commences at about 7 weeks of gestation and is stimulated in part by placental hCG. Shortly thereafter, plasma testosterone attains a high level that is maintained until late in gestation. The level then falls so that at the time of birth the plasma testosterone level is only slightly higher in males than in females. Shortly after birth, a transient increase of pituitary gonadotropins raises the plasma testosterone level in the male infant for ~3 months, before hormone levels again decrease to low levels by age 6 months to 1 year. The significance of the rise in plasma testosterone level during the first year of life is not certain. However, in other primates neonatal activation of the hypothalamic-pituitary-testicular axis is important for subsequent normal pubertal development. The testosterone concentration then remains low (but slightly higher in boys than in girls) until the onset of puberty, when it begins to rise in boys, reaching

adult levels by about age 17. The level of bioavailable testosterone remains constant until the 40s when it begins to decline at a rate of ~1.2% per year; the level ofSHBGincreases by ~1.2% per year so that there is little decline in total testosterone until the later decades of life. During the third, or adult, phase of male sexual life, sperm production becomes sufficient to allow reproduction to take place. The physiologic events during these various phases differ, as do the pathologic consequences of derangements in testicular function. Male sexual differentiation during embryogenesis is considered inChap. 338.

ABNORMALITIES OF TESTICULAR FUNCTION

PUBERTY

The control of puberty is poorly understood and may reside in the hypothalamic-pituitary system, the testes, or the adrenals (Chap. 8). Before the onset of puberty, gonadotropin secretion by the pituitary is low, but prepubertal castration causes a rise in plasma gonadotropin levels. This finding suggests that before puberty the negative feedback control of gonadotropin secretion is exquisitely sensitive to the small amount of circulating testosterone. The onset of puberty is heralded by sleep-associated surges in gonadotropin secretion. Later in puberty the rises in LHand FSHlevels persist throughout the day. Thus, with maturation, the hypothalamic-pituitary system becomes less sensitive to negative feedback control, and the consequences are higher mean plasma levels of testosterone and gonadotropins, maturation of the testes, and the onset of spermatogenesis. The rise in gonadotropin secretion is the consequence of an increase both inGnRHsecretion and in the sensitivity of the pituitary to GnRH.

The somatic changes at the time of puberty are secondary to the rise in plasma testosterone, which induces the growth of the accessory organs of male reproduction (the penis, the prostate, the seminal vesicles, and the epididymides). Accelerated linear growth is accompanied by growth of muscle and connective tissue, which account for the major portion of nitrogen retention at puberty. The principal androgen-sensitive muscles are those of the pectoral region and the shoulder. The characteristic hair growth of male puberty involves development of mustache and beard; regression of the scalp line; appearance of body, extremity, and perianal hair; and extension of the pubic hair upward into a diamond-shaped pattern. Growth of axillary and pubic hair is initiated under the control of adrenal androgens and is promoted by testicular androgens. The larynx enlarges, and the vocal cords thicken, resulting in a lowering of the pitch of the voice. Hemoglobin levels increase by ~1 g/dL. These various androgen-mediated growth and maturation processes reach some limiting value, so that once puberty is completed, the administration of pharmacologic doses of androgen has no further effect. The entire process is heralded by testicular enlargement beginning at age 11 to 12 and is usually completed within 5 years, although some aspects of virilization, such as growth of the chest hair, may continue over a decade or more.

The events of normal male puberty are variable in onset, duration, and sequence. The central issue in dealing with disorders of puberty is separating true absence or precocity from the extremes of normal variation. The use of staging criteria that correlate developmental and anatomic landmarks with chronologic age is useful in making this distinction (Chap. 8).

Sexual Precocity Premature development of sexual characteristics that are phenotypically appropriate -- i.e., virilization in boys -- is termed *isosexual precocity*. *Heterosexual precocity* refers to feminizing syndromes in boys.

Isosexual precocity Sexual development before age 9 in boys is generally considered abnormal. *True precocious puberty* or *complete isosexual precocity* occurs when both virilization and spermatogenesis are premature. *Precocious pseudopuberty* or *incomplete isosexual precocity* refers to virilization unaccompanied by spermatogenesis. This distinction is blurred in practice, because pure virilizing syndromes may cause activation of gonadotropin secretion secondarily and thus be followed by development of spermatogenesis. Furthermore, local androgen production in the testis, as in Leydig cell tumors, can cause local areas of spermatogenesis and limited sperm production around the tumor. We therefore prefer a two-part classification: virilizing syndromes (in which hypothalamic-pituitary activity is appropriate for age) and premature activation of the hypothalamic-pituitary system.

Virilizing syndromes can result from Leydig cell tumors,hCG-secreting tumors, adrenal tumors, congenital adrenal hyperplasia (most commonly 21-hydroxylase deficiency), androgen administration, or Leydig cell hyperplasia. In these disorders plasma testosterone levels are inappropriately elevated for the age. Leydig cell tumors are rare in children but should be suspected when the testes are asymmetric in size (Chap. 96). Virilizing adrenal tumors mainly secrete androstenedione and dehydroepiandrosterone, some of which is converted to testosterone; consequently, they cause increased 17-ketosteroid excretion. Glucocorticoid administration does not reduce 17-ketosteroid excretion to normal in patients with testicular or adrenal tumors, in contrast to the prompt decrease that occurs after such treatment in patients with congenital adrenal hyperplasia. Congenital adrenal hyperplasia leads to elevated 17-hydroxyprogesterone levels and, as a consequence, elevated androgen levels (Chaps. 331 and338). When this disorder is treated with glucocorticoids, true precocious puberty can then result if the increased androgen levels have caused sufficient hypothalamic maturation.

Gonadotropin-independent sexual precocity in boys may occur as a result of autonomous Leydig cell hyperplasia in the absence of a Leydig cell tumor. The disorder can occur sporadically or can be inherited as a male-limited autosomal disorder either from affected fathers or from mothers who are unaffected carriers. It is due to point mutations in theLHreceptor that cause constitutive activation of the receptor in the absence of LH. Virilization usually begins by age 2. Testosterone levels are elevated, often to the adult male range; however, immunoreactive and bioactive LH levels and the LH response toGnRH are prepubertal. In the past many of these boys were mistakenly thought to have true precocious puberty because spermatogenesis may be present.

Premature activation of the hypothalamic-pituitary system Central precocious puberty may be "idiopathic" or due to central nervous system (CNS) tumors, infections, or injuries. Early hypothalamic-pituitary activation typically is associated with features of normal puberty, i.e., sleep-related gonadotropin secretion, elevated plasma bioactiveLH, and enhanced gonadotropin response toGnRH. Since the diagnosis of idiopathic true precocious puberty is one of exclusion, patients may later prove to have been misclassified and to have a CNS abnormality. With improved means of diagnosis, such

as magnetic resonance imaging, delays in diagnosis will probably be less frequent.

Management of sexual precocity due to steroid- or gonadotropin-producing tumors, congenital adrenal hyperplasia, orCNSabnormality is directed toward the primary disease. In boys with Leydig cell hyperplasia, attempts have been made to lower plasma testosterone with medroxyprogesterone acetate or ketoconazole, or to blunt hormone action with spironolactone, but treatment remains suboptimal. Idiopathic true precocious puberty and true precocious puberty due to inoperable CNS lesions are treated with long-actingGnRHanalogue therapy, which inhibits gonadotropin production and testosterone synthesis, reversing pubertal maturation and decreasing the rate of skeletal development.

Heterosexual precocity Feminization in prepubertal boys can result from absolute or relative increases in estrogen due to a variety of causes (Chap. 337).

Delayed or Incomplete Puberty Separating failure of puberty from variants of normal development is one of the most difficult problems in endocrinology. Some boys fail to show the normal spurt of growth and sexual development at the usual time but eventually commence puberty by age 16 or older. Adolescence may then either progress rapidly, or slow pubertal development and growth may continue until age 20 to 22. Many men with delayed onset of puberty attain heights within the normal adult range. The history may reveal that a parent or sibling had a similar pattern of development. Panhypopituitarism and hypothyroidism can cause pubertal failure (Chaps. 328 and330). Absent puberty also can result from primary testicular disease; this diagnosis is suspected on the basis of low plasma testosterone levels and elevatedFSH andLHlevels. Hereditary androgen resistance (in which plasma testosterone and LH levels are both high) usually causes male pseudohermaphroditism but in mild form may be manifested by absent or incomplete puberty (Chap. 338).

Most boys with absent puberty have low plasma levels of both testosterone and gonadotropins; in these boys it is necessary to distinguish delayed puberty from isolated gonadotropin deficiency or idiopathic *hypogonadotropic hypogonadism (Kallman syndrome)*. The manifestations of isolated gonadotropin deficiency vary from boys with eunuchoidal features and testes of prepubertal size to those with partialLHand/orFSHdeficiency and some degree of testicular enlargement and pubertal development. Ansomia or hyposmia is caused by abnormal development of the olfactory tracts (which share progenitor cells withGnRHneurons) and is characteristically seen in Kallmann syndrome. X-linked *adrenal hypoplasia congenita (AHC)* is characterized by primary adrenal insufficiency, which usually presents in infancy, and hypogonadotropic hypogonadism, caused by deficient GnRH production and abnormal gonadotrope function. Congenital hypogonadotropic hypogonadism is frequently associated with cryptorchidism and a prepubertal manifestation can be microphallus, in which the size of the penis is below the fifth percentile for the age.

The pathogenesis of hypogonadotropic hypogonadism can involve several distinct abnormalities ofGnRHformation or action. Some cases are inherited as an X-linked recessive trait associated with defects in a neural cell adhesion molecule (KAL) involved in the migration of GnRH neurons into the olfactory bulb. Other causes involve autosomal dominant disorders with variable expressivity; rare autosomal recessive

cases are due to mutations that impair the GnRH receptor. SerumFSH andLHlevels are usually below the normal male range, and plasma testosterone levels are low for age. The secretion of other pituitary hormones is normal. The administration of pulsatile GnRH corrects the endocrine abnormalities and initiates spermatogenesis in patients with GnRH deficiency; all patients respond to gonadotropin replacement. If untreated, these patients usually remain in the prepubertal state indefinitely.

It is particularly difficult to distinguish hypogonatropic hypogonadism from delayed puberty in boys of early or midpubertal age; the presence of microphallus, anosmia, or a family history may suggest the diagnosis. In the absence of such evidence, observation through the teenage years may be required before it becomes clear whether a patient has delayed puberty or a permanent form of hypogonadotropic hypogonadism. Since delayed puberty is associated with a decreased bone mass, therapy should not be delayed too long. In some cases the response of plasmaLH toGnRHstimulation may be helpful in suggesting that puberty is imminent.

ADULTHOOD

At the completion of puberty, plasma testosterone levels reach the adult level of 10 to 35 nmol/L (3 to 10 ng/mL) throughout the day, plasma gonadotropins are in the normal adult range, and sperm production is sufficient to allow reproduction. The adult pattern of hypothalamic-pituitary-gonadal regulation is sustained in the normal man for more than 40 years. However, the system is subject to a variety of influences, at the level of both the testes and the hypothalamic-pituitary system. Spermatogenesis is exquisitely sensitive to alterations in scrotal temperature, and brief increases in either systemic or local temperature (as in a hot bath) can be followed by temporary decreases in sperm production. The system also is influenced by diet, drugs, alcohol, environmental agents, and psychological stress, any of which may cause temporary decreases in sperm count.

Persistent abnormalities of testicular function in adult men can be due to hypothalamic-pituitary disorders (Chap. 328), testicular defects, or abnormalities of sperm transport. Certain of these conditions tend to affect Leydig cell function or spermatogenesis selectively, but most impair both androgenization and fertility (Table 335-1). The interlocking of Leydig cell function and fertility is due to the dependence of spermatogenesis on androgen. Even a partial decrease in testosterone production can cause infertility. Certain conditions (hyperprolactinemia, radiation therapy, cyclophosphamide therapy, autoimmunity, paraplegia, androgen resistance) can cause either isolated infertility or a combined defect in testicular function.

Hypothalamic-Pituitary Disorders Disorders of the hypothalamus and pituitary can impair the secretion of gonadotropins either as one manifestation of a generalized disease of the anterior pituitary (Chap. 328) or as an isolated defect. In the latter case the cause is usually hypogonadotropic hypogonadism, in which secretion of bothLH andFSH are impaired. This disorder usually is congenital but may be acquired. Alternatively, gonadotropin secretion can be altered by factors other than hypothalamic-pituitary pathology. For example, elevation of plasma cortisol, as in the *Cushing syndrome*, can depress LH secretion independent of a space-occupying lesion of the pituitary. Critical illness also suppresses plasma gonadotropin levels. Some patients with uncontrolled *congenital adrenal hyperplasia* have elevated levels of

adrenal androgens, suppressed gonadotropin secretion, and consequent infertility. Likewise, the use of *androgens* for purposes other than replacement therapy can inhibit gonadotropin secretion and impair sperm production (see below). *Hyperprolactinemia* (as the consequence either of pituitary adenomas or of drugs such as phenothiazines) can cause combined Leydig cell and seminiferous tubule dysfunction, presumably due to inhibition of LH and FSH secretion by prolactin. Occasionally, impaired fertility in hyperprolactinemia is associated with normal gonadotropin and androgen levels and is presumed to result from direct inhibition of spermatogenesis by prolactin. *Hemochromatosis* usually impairs testicular function as the result of effects on the pituitary; less often it affects the testis directly (Chap. 345). In some conditions, testosterone levels may be decreased in association with normal LH levels, and the mechanism is less clear. Men with massive obesity have decreased levels ofSHBG and of total and bioavailable testosterone, which return toward normal with weight loss. Obesity may also contribute to the decreased testosterone levels in the subset of such men with Pickwickian syndrome (Chap. 263). Some men with temporal lobe seizures also have hypogonadotropic hypogonadism.

Testicular Defects Abnormalities of testicular function in the adult man can be grouped into several categories: developmental and structural defects of the testes, acquired testicular defects, and disorders secondary to systemic disease.

Developmental abnormalities The *Klinefelter syndrome* (*XXY*, both the classic and the mosaic forms) and the *XX male syndrome* are usually not recognized until after the time of expected puberty (Chap. 338). Some developmental defects cause infertility in the presence of normal androgen production. These include varicocele, germinal cell aplasia, deletions or mutations of the azoospermia factor (*AZF*) genes on the Y chromosome, and cryptorchidism. *Varicocele* may be of etiologic importance in as much as one-third of all cases of male infertility. It is caused by retrograde flow of blood into the internal spermatic vein that eventuates in progressive, often palpable dilation of the peritesticular pampiniform plexus of veins. Varicocele occurs in ~10 to 15% of men in the general population and in 20 to 40% of men with infertility. It is thought to result from incompetence of the valve between the internal spermatic vein and the renal vein and is more common on the left side (85%). Unilateral varicocele increases the blood flow and the temperature of both testes as a result of the extensive anastomoses of the venous systems. The increased scrotal (and testicular) temperature is believed to be the cause of the poor-quality semen and infertility (the testes no longer are 2°C cooler than the abdominal cavity). The findings on semen analysis are usually nonspecific, with all parameters showing some abnormality. Surgical repair of varicocele results in fertility in about half of men, with the best results (70% pregnancy rate) in those whose preoperative sperm counts are >10 million per milliliter.

Some patients with *germinal cell aplasia* (the Sertoli cell-only syndrome) have a positive family history and may constitute a specific group in whom the germinal epithelium is missing with resulting azoospermia; plasma testosterone andLHvalues are normal, and plasmaFSHlevels are elevated. Other patients with identical histologic and clinical findings have androgen resistance or a history of viral orchitis or cryptorchidism; microdeletions of one or more genes (e.g., *Deleted in Azoospermia, DAZ*) on the Y chromosome have been documented in 10 to 20% of men with azoospermia or oligospermia (many of whom have germinal cell aplasia), depending on the criteria used

for selection.

Unilateral *cryptorchidism*, even when corrected before puberty, is associated with abnormal semen in many individuals, indicating that the testes can be bilaterally abnormal even in unilateral cryptorchidism.

The *immotile cilia syndrome* is an autosomal recessive defect characterized by immotility or poor motility of the cilia of the airways and of the sperm. Kartagener's syndrome is a subgroup of the immotile cilia syndrome associated with situs inversus, chronic sinusitis, and bronchiectasis (Chap. 256). The structural abnormality leading to impaired motility of cilia can usually be defined by the electron-microscopic appearance showing defects in the dynein arms, spokes, or microtubule doublets. Cilia from epithelia and sperm tails exhibit the same defects, but the pulmonary manifestations may be minor. Other less well understood structural defects can cause immotility of sperm without involvement of cilia in the lung.

Acquired testicular defects Acquired testicular failure in the adult man can be due to *viral orchitis*. The responsible viruses include mumps virus, echovirus, lymphocytic choriomeningitis virus, and group B arboviruses. The orchitis is due to actual infection of the tissue by virus rather than to indirect effects of infection. Orchitis occurs in as many as one-fourth of adult men with mumps; in about two-thirds the orchitis is unilateral, and in the remainder it is bilateral. Orchitis usually develops a few days after the onset of parotitis but may precede it. The testis may return to normal size and function or undergo atrophy. Atrophy is believed to be due both to direct effects of the virus on the seminiferous tubules and to ischemia secondary to pressure and edema within the taut tunica albuginea. Semen analysis returns to normal in three-fourths of men with unilateral involvement and in only one-third of men with bilateral orchitis. Atrophy is usually perceptible within 1 to 6 months after the acute illness, and the degree of atrophy is not necessarily proportional to the severity of the acute orchitis. Unilateral atrophy occurs in about one-third of patients, and bilateral atrophy occurs in about one-tenth.

Trauma, including torsion, can also cause secondary atrophy of the testes. The exposed position of the testes in the scrotum renders them susceptible to both thermal and physical trauma -- particularly in men with hazardous occupations.

The testes are sensitive to *radiation damage*; decreased secretion of testosterone appears to be a consequence of diminished testicular blood flow. Doses>200 mGy (20 rad) cause increases in plasmaFSH andLHlevels and damage to the spermatogonia. After about 800 mGy (80 rad), oligospermia or azoospermia develops, and higher doses may obliterate the germinal epithelium, except for occasional stem and Sertoli cells. Fractionated radiation may have a more profound effect than single-dose radiation. Recovery of sperm density occurs in a dose-related fashion, and complete recovery of sperm density may require as long as 5 years. Permanent infertility can occur after radiation therapy for malignant lymphoma despite shielding of the testes. Permanent androgen deficiency in adult men is uncommon after therapeutic radiation; however, most boys given direct testicular radiation therapy for acute lymphoblastic leukemia have permanently low plasma testosterone levels. Sperm banking should be considered in patients before they undergo radiation treatment or chemotherapy.

In general, *drugs* interfere with testicular function in one of four ways -- inhibition of testosterone synthesis, blockade of androgen action, enhancement of estrogen levels, or direct inhibition of spermatogenesis. Spironolactone and ketoconazole block the synthesis of androgen by interfering with the late steps in androgen biosynthesis. Spironolactone and cimetidine compete with androgen for binding to the androgen receptor and thus block androgen action in target cells. Testosterone levels may be low, and estradiol levels may be elevated in persons using marijuana, heroin, or methadone, although the exact reasons are unclear. Alcohol, when consumed in excess for prolonged periods, causes decreased plasma testosterone levels, independent of liver disease or malnutrition. Elevated plasma estradiol and decreased plasma testosterone levels may occur in men taking digitalis.

Antineoplastic and chemotherapeutic agents commonly interfere with spermatogenesis. Cyclophosphamide causes azoospermia or extreme oligospermia within a few weeks after the initiation of therapy. Cessation of therapy is followed by a return of spermatogenesis within 3 years in about half of patients. Combination chemotherapy for acute leukemia, Hodgkin's disease, and other malignancies also may impair Leydig cell function. In pubertal boys this impairment is manifested by decreased serum testosterone and elevatedLHlevels; in adult men testosterone levels do not decline, and the impaired Leydig cell function may be detected only as an enhanced LH response toGnRH. The alkylating agents in the chemotherapeutic regimens seem to be responsible for Leydig cell toxicity.

Because of the toxic effects of many physical and chemical agents on spermatogenesis, the occupational and recreational history should be carefully evaluated in all men with infertility. Known environmental hazards include microwaves, ultrasound, and chemicals such as the nematocide dibromochloropropane, cadmium, and lead. In some populations, sperm density is said to have declined by as much as 40% in the past 50 years, and it has been postulated that environmental estrogens or antiandrogens may be responsible.

Testicular failure also occurs as a part of *polyglandular autoimmune insufficiency* (Chap. 339). Sperm antibodies can cause isolated male infertility. In some instances these antibodies are secondary phenomena resulting from duct obstruction or vasectomy. *Granulomatous diseases* can destroy the testes, and testicular atrophy occurs in 10 to 20% of men with lepromatous leprosy owing to direct invasion of the tissue by the mycobacteria. The tubules are involved initially, followed by endarteritis and destruction of Leydig cells.

Testicular abnormalities associated with systemic disease In *cirrhosis of the liver*, a combined testicular and pituitary abnormality leads to decreased testosterone production independent of the direct toxic effects of ethanol. Although the plasmaLH level is elevated, the level may be below the expected range given the degree of androgen deficiency. This situation most likely results from the inhibition of LH secretion by estrogen in patients with chronic liver disease. Increased estrogen production results from impaired hepatic extraction of adrenal androstenedione and subsequent increased extraglandular conversion to estrone and estradiol. In effect, estrogen precursors are shunted to sites of extraglandular aromatization. Testicular atrophy and gynecomastia

are present in about half of men with cirrhosis, and many such men are impotent. Successful liver transplantation reverses the effects of cirrhosis on the pituitary-testicular axis.

In chronic *renal failure*, androgen synthesis and sperm production decrease despite elevated plasma gonadotropins. The elevatedLH level is due to increased production and reduced clearance but does not restore normal testosterone production. In addition, about one-fourth of men with renal failure have hyperprolactinemia; the role of hyperprolactinemia in decreasing testosterone production is unclear. Low testosterone coupled with normal or increased plasma estrogen levels cause gynecomastia in about half of men on chronic hemodialysis, and about half of men on dialysis have decreased libido and/or impotence. Improvement in testosterone production with hemodialysis is incomplete, but successful transplantation may return testicular function to normal.

Men with *sickle cell anemia* usually have impaired secondary sexual development, and testicular atrophy is present in one-third of them. The defect may be at either the testicular or the hypothalamic-pituitary level. Abnormalities in Leydig cell function, frequently accompanied by decreased sperm density, have been noted in a variety of chronic systemic diseases, including protein-energy *malnutrition*, advanced *Hodgkin's disease* and *cancer* before chemotherapy, and *amyloidosis*. Most of these disorders cause a lowered plasma testosterone level coupled with a normal to increased plasmaLHlevel, suggesting combined hypothalamic-pituitary and testicular defects. Similar hormone changes occur after *surgery*, *myocardial infarction*, and severe *burns* and thus may be a nonspecific effect of illness.

In HIV-infected men, elevation of gonadotropins (a compensated state of hypogonadism) may precede the development of overt hypogonadism, but 35 to 50% of men with AIDS eventually develop low testosterone levels. Elevation ofSHBGlevels may partially mask the fall in testosterone. Some of the hormonal changes in this disorder are likely nonspecific and related to severe illness. Whether testosterone deficiency contributes to the muscle wasting and weight loss characteristic of this disorder is unclear, but androgen replacement therapy may increase muscle and lean body mass.

Sperm density can decrease temporarily after *acute febrile illness* in the absence of a change in testosterone production. Infertility in men with *celiac disease* is associated with a hormonal pattern typical of androgen resistance, namely, elevated testosterone andLHlevels. *Neurologic* diseases associated with altered testicular function include myotonic dystrophy, spinobulbar muscular atrophy, and paraplegia. In myotonic dystrophy, small testes may be associated with impairment of both spermatogenesis and Leydig cell function. Spinobulbar muscular atrophy is caused by an expansion of the glutamine repeat sequences in the amino-terminal region of the androgen receptor; this expansion impairs function of the androgen receptor, but it is unclear how the alteration is related to the neurologic manifestations. Men with spinobulbar muscular atrophy often have as a late manifestation underandrogenization and infertility and the hormonal features of androgen resistance (Chap. 338). *Spinal cord lesions* that cause paraplegia lead to a temporary decrease in testosterone levels and may cause persistent defects in spermatogenesis; some patients retain the capacity for penile erection and ejaculation.

Androgen resistance Defects of the androgen receptor cause resistance to the action of androgen, usually associated with defective male phenotypic development, infertility, and underandrogenization (Chap. 338). Mutations of the androgen receptor that cause mild androgen resistance can cause infertility due to oligo- or azoospermia in otherwise phenotypically normal men.

Impairment of Sperm Transport Disorders of sperm transport may cause infertility in as many as 6% of infertile men with normal virilization. Obstruction of the ejaculatory system may be unilateral or bilateral, congenital or acquired. In men with unilateral obstruction, infertility may result from antisperm antibodies. Congenital defects of the vas deferens can occur as an isolated abnormality associated with absence of the seminal vesicles (and consequently absence of fructose in the ejaculate), in men whose mothers received *diethylstilbestrol* during pregnancy, and in men with *cystic fibrosis*. Furthermore, congenital bilateral absence of the vas deferens can be due to mutations in the cystic fibrosis conductance regulator (*CFTR*) gene; some of these mutations are distinct from those associated with the more typical pulmonary and gastrointestinal manifestations of cystic fibrosis. Acquired obstructive azoospermia can occur at the level of the epididymis in association with chronic infections of the paranasal sinuses and lungs and with tuberculosis, leprosy, and gonorrhea.

Empirical Therapy of Male Infertility Disorders for which there are logical or effective treatments (genital tract obstruction, sperm autoimmunity, gonadotropin deficiency) account for only 10% of infertile men, and pregnancies are infrequent when the male partner has genital tract obstruction or sperm autoimmunity. Severe oligospermia/azoospermia from other causes accounts for about one-fourth of cases of male infertility and has largely been considered untreatable. The other two-thirds of infertile men have a partial reduction in semen parameters and subfertility of a variable degree, and in this group spontaneous fertility may occur in untreated men (as high as 25% in one year). In the past various empirical therapies (e.g., testosterone rebound, gonadotropins, antiestrogens) have been tried without success. The only successful empirical therapy for men with mild to moderate defects in semen quality is in vitro fertilization. However, standard in vitro fertilization does not provide a good outcome in the presence of severe semen abnormalities, such as a sperm density of<5 million per milliliter, poor motility, and many abnormal forms. For such men the technique of intracytoplasmic sperm injection (ICSI) has been a major advance; indeed fertilization and pregnancy rates with this technique are similar to those for standard in vitro techniques in couples with fallopian tube pathology, e.g., a 50 to 70% fertilization rate and a 30% pregnancy rate per cycle. This technique is sometimes successful with spermatozoa recovered from testicular biopsies in men with azoospermia.**The management of male infertility is discussed in Chap. 54.*

Fertility Control in Men (See also Chap. 54) A variety of approaches to fertility control in men have been tried, including use of the condom as an effective barrier that also prevents sexually transmitted diseases. Vasectomy, which involves transection or ligation of the vas deferens, has a high success rate and can be performed on an outpatient basis. The time required for azoospermia to occur after the operation depends on the number of sperm in the terminal vas deferens and ejaculatory ducts at the time of surgery, but it is usually less than 40 days. Azoospermia should be documented in each case to prove effectiveness. No deleterious effects on either

testosterone production or the hypothalamic-pituitary axis have been documented. Despite reports of immune-complex-associated accelerated atherosclerosis in vasectomized nonhuman primates, there does not appear to be any association between vasectomy and atherosclerosis in men. Vasectomy should be recommended only for men requesting permanent sterilization. Only about 30 to 40% of men subjected to vasovasostomy for reanastomosis of the vas subsequently achieve fertility. Suppression of gonadotropins with long-actingGnRHanalogues or GnRH antagonists causes marked reduction in sperm counts but requires concomitant androgen replacement. The efficacy and acceptance of this approach to male contraception remain to be established.

GONADAL FUNCTION DURING AGING

Beginning at about age 40, mean plasma bioavailable testosterone concentrations decline gradually; about 40% of elderly men have low bioavailable testosterone levels. Although statistically lower than the levels in young men, the concentrations of total testosterone usually remain within the normal range, even in elderly men. The cause of the reduced testosterone level is likely a decreased number of Leydig cells. In older men seminiferous tubule function and sperm production also usually decline. PlasmaLH andFSHlevels are often slightly elevated, consistent with a decline in gonadal function. An increase in the conversion of androgen to estrogen in peripheral tissues results in a decrease in the effective ratio of androgen to estrogen. These latter hormonal changes may play a role in the development of prostatic hyperplasia and in the development of gynecomastia in aging men (Chaps. 95 and337). Male sexual function gradually declines after early adulthood, but there is no convincing evidence that hormonal changes have any direct bearing on changes in sexual function with age in healthy men.

Prostatic Hyperplasia SeeChap. 95.

Cancer of the Prostate See Chap. 95.

DISORDERS OF ALL AGES

Testicular Tumors (See alsoChap. 96) Low levels ofhCG are present in normal testes may be elevated in persons with testicular tumors. Indeed, an elevated plasma level of the b subunit of hCG (hCG-b) is a sensitive and specific marker of tumor activity in some men with germ cell tumors. Plasma levels of hCG-b are elevated in all men with choriocarcinoma, in one-third of those with embryonal carcinomas and teratocarcinomas, and rarely in those with seminomas. Changes in hCG-b levels correlate with response to therapy.

Testicular tumors can cause elevated estradiol and testosterone levels by at least two mechanisms: (1) Trophoblastic, Leydig, and Sertoli cell tumors produce both hormones autonomously; pituitary gonadotropin secretion and hormone production by the uninvolved portions of the testes are depressed, and azoospermia is common; (2) hCG secretion by the tumors can increase estradiol and testosterone production in the unaffected areas of the testes; azoospermia is uncommon with such tumors. When estrogens and androgens are formed (directly or indirectly) by the tumors, feminization, virilization, or no obvious change may result, depending on the hormones produced and

the age of the patient.a-Fetroprotein can provde another cellular marker of testicular tumor activity.

Gynecomastia See Chap. 337.

TREATMENT

Androgens

Pharmacologic Preparations When testosterone is taken by mouth, it is absorbed into the portal blood and degraded promptly by the liver, so that only insignificant amounts reach the systemic circulation; when administered parenterally, testosterone is rapidly absorbed from the injection vehicle and rapidly degraded. As a consequence, effective androgen therapy requires the administration of either a slowly absorbed form of testosterone (dermal patches or micronized oral testosterone) or modified analogues. Chemical modifications either retard absorption or catabolism, or enhance the androgenic potency, so that full effects can be achieved at a lower blood level of drug. Three types of modification have had widespread clinical application (Fig. 335-7): (1) esterification of the 17b-hydroxyl group, (2) alkylation at the 17a position, and (3) alteration of the ring structure, particularly by substitutions at the 2, 9, and 11 positions. Most pharmacologic agents actually have combinations of ring structure alterations and either 17a-alkylation or esterification of the 17b-hydroxyl group. Esterification decreases the polarity of the molecule so that the steroid is more soluble in the fat vehicles used for injection, leading to slower release into the circulation. Most esters must be injected parenterally. The larger the acid esterified, the slower the release and the more prolonged the action. Esters such as testosterone cypionate and testosterone enanthate can be injected every 1 to 3 weeks, the usual regimen being 200 mg of either ester intramuscularly every 2 weeks. Because the esters are hydrolyzed before the hormones act, therapy can be monitored by assaying the plasma testosterone level at various times after administration.

The oral effectiveness of 17a-alkylated androgens (such as methyltestosterone and methandrostenolone) is due to slower hepatic catabolism, which allows the alkylated derivatives to reach the systemic circulation. For this reason, 17a-methyl or -ethyl substitution is a feature of most orally active androgens. Unfortunately, all 17a-alkylated steroids can cause abnormal liver function, and for this reason they have a limited role in therapy.

Other alterations of the ring structure have been adopted empirically; some slow the rate of inactivation, others enhance the potency of a given molecule, and some alter the conversion to other active metabolites. For example, the potency of fluoxymesterone may be due to the fact that, unlike most androgens, it is a poor precursor for conversion to estrogens in peripheral tissues.

Three transdermal preparations are available in which a testosterone-loaded patch is applied to the skin each day. One is a scrotal patch (Testoderm) that contains no permeation enhancers, which may irritate the skin, but it has a low rate of acceptance. The other two systems (Androderm, Testosterone TTS) are applied to the trunk, arms, or thighs. Each patch provides physiologic testosterone levels that mimic the normal

diurnal variation with higher levels in the morning hours. High rates of dermatologic problems have been reported with the Androderm transdermal system.

Side Effects of Androgens All androgens carry the risk of inducing virilization in women. Early manifestations include acne, coarsening of the voice, hirsutism, and menstrual irregularities. If treatment is discontinued as soon as these effects develop, the manifestations may slowly subside. Long-term side effects such as male-pattern baldness, marked hirsutism, voice changes, and hypertrophy of the clitoris are largely irreversible. At physiologic replacement doses, testosterone esters have few toxic effects in mature men. At supraphysiologic doses, however, gonadotropin secretion is inhibited, the testes shrink, and the sperm count falls (indeed, androgen abuse can be associated with low sperm counts that may persist for 9 months or longer after cessation of the steroid). In some older men, testosterone therapy may cause polycythemia (hematocrit>52%); in men predisposed to obstructive sleep apnea, androgen therapy may initiate or worsen symptoms. In older men, the presence of benign prostatic hyperplasia is not a contraindication for androgen therapy, but such men should be screened for prostate cancer before initiating androgen replacement (Chap. 95).

The so-called toxic side effects vary among the different agents and with the clinical setting in which they are used. Retention of a limited amount of sodium is an inevitable consequence of androgen therapy and may lead to edema in patients with underlying heart disease or renal failure, or when androgens are administered in enormous amounts. Although androgens do not cause malignancy, they may promote the growth of and intensify pain from carcinomas of the prostate and breast in men.

The feminizing side effects of androgen therapy in men are poorly understood. Testosterone (but not 5a-reduced androgens) can be converted (aromatized) in extraglandular tissues to estradiol. The most common manifestation of feminization is the development of gynecomastia. Such breast enlargement is common in children given androgens, possibly because of a greater capacity to convert androgens to estrogens in childhood. The administration of testosterone esters to men results in an increase in plasma estrogen levels, but in men with normal liver function gynecomastia usually develops only after use of high doses.

All 17a-alkylated androgens can produce liver function abnormalities such as elevated plasma levels of alkaline phosphatase and conjugated bilirubin. The incidence of clinical liver disease probably depends on the previous integrity of the liver, but jaundice may occur in the absence of preexisting liver disease. 17a-Alkylated drugs also increase the levels of a variety of plasma proteins that are synthesized in the liver. The most serious complications of 17a-alkylated androgens are peliosis hepatis (blood-filled cysts in the liver) and hepatoma. These disorders were initially described in patients with aplastic anemia, many of whom had Fanconi anemia, itself a predisposing factor for the development of malignancy. However, both lesions can occur after administration of substituted androgens for other indications, including use by athletes. These tumors may either follow a benign course after discontinuation of the drugs or be rapidly fatal.

One indication for 17a-alkylated androgens is in the treatment of hereditary angioedema in which the desired therapeutic benefit (increased level of the inhibitor of the first

component of complement) may actually be an effect of the 17-alkylated side chain rather than of the parent androgen. As a consequence, weak androgens such as danazol are effective in this disorder (Fig. 335-7). Danazol is also used in the management of endometriosis (Chap. 52).

Replacement Therapy The aim of androgen therapy in hypogonadal men is to restore or bring to normal male secondary sexual characteristics (beard, body hair, external genitalia) and male sexual behavior and to mimic the hormonal effects on somatic development (hemoglobin, muscle mass, nitrogen balance, and epiphyseal closure). Since an assay for plasma testosterone is available for monitoring therapy, the treatment of androgen deficiency is almost universally successful. The parenteral administration of a long-acting testosterone ester such as 100 to 200 mg testosterone enanthate at 1- to 2-week intervals results in a sustained increase in plasma testosterone to the normal male range. Alternatively, testosterone may be administered transdermally. Testosterone patches, which are available in different doses, are replaced daily. If hypogonadism is primary and of long duration (as in the Klinefelter syndrome), suppression of plasmaLH to the normal range may not occur for many weeks, if at all. There is considerable variability in the relation between plasma testosterone and male sexual behavior, but in cases of postpubertal testicular failure (even of many years duration), normal sexual activity usually is resumed after adequate replacement. Androgen administration does not restore spermatogenesis in hypogonadal states, but the volume of the ejaculate (derived largely from the prostate and seminal vesicles) and other male secondary sex characteristics return to normal. The effects of endogenous androgen on hemoglobin, nitrogen retention, and skeletal development are also reproduced.

In men of all ages in whom hypogonadism developed before expected puberty (such as men with isolated gonadotropin deficiency), it is appropriate to bring plasma testosterone into the adult range slowly. When therapy is commenced at the time of expected puberty in such men, the normal events of puberty proceed in the usual fashion. If therapy is delayed until after the time of usual puberty, the degree to which normal virilization will occur is variable, but many patients undergo a relatively complete anatomic and functional maturation. Intermittent low-dose androgen therapy is indicated in prepubertal hypogonadal boys with microphallus to bring the external genitalia into the normal range. If such patients are monitored closely and given androgens for only short periods, therapy usually has no adverse effects on somatic growth.

In boys of pubertal age with either isolated gonadotropin deficiency or primary testicular disease, the usual practice is to institute androgen therapy between the ages of 12 and 14 years, depending on the subjective need for sexual development. The initial administration of small doses of testosterone esters followed by a gradual increase to 100 to 150 mg/m^2 of body surface area every 1 to 3 weeks should result in a normal pubertal growth spurt. The time from the start of treatment to the appearance of secondary sex characteristics is variable. Penile development, deepening of the voice, and the appearance of other secondary sexual characteristics usually commence during the first year of treatment. In normal boys, puberty extends over several years, and treatment designed to replicate normal development does not shorten the process greatly.

Testosterone exerts its full action only in the presence of a balanced hormonal environment and, particularly, in the presence of adequate levels of growth hormone. Consequently, prepubertal boys with coexisting growth hormone and androgen deficiency respond poorly to androgens unless growth hormone is given simultaneously.

Pharmacologic Uses Androgens have been used for a variety of disorders unassociated with hypogonadism in the hope that potential benefits from the nonvirilizing actions of the agents (such as increases in nitrogen retention, muscle mass, and hemoglobin) would outweigh any deleterious actions of the drugs. The most common nonreplacement uses of androgen have been attempts to improve nitrogen balance in catabolic states (e.g., AIDS), self-administration by athletes to increase muscle mass and/or athletic performance, attempts to enhance erythropoiesis in refractory anemias (including the anemia of renal failure), treatment of hereditary angioedema and endometriosis, and management of growth retardation of various etiologies. Most of the expected benefits in these disorders have not been realized for two reasons. First, modest pharmacologic doses of androgens have little physiologic effect in men when superimposed on normal testicular androgen, and in women the virilizing side effects of androgens are formidable. Second, no androgen has been devised that exhibits only the nonvirilizing effects of the hormone. This conclusion is not surprising in view of the fact that the physiologic actions of androgens are mediated by a single, high-affinity receptor (Fig. 335-5).

The most pervasive form of androgen abuse is by male athletes in the expectation that muscle development and athletic performance will be improved. In controlled studies using modest pharmacologic doses (two to four times the usual replacement doses), these agents do not improve performance consistently. However, at the doses frequently taken by athletes (which sometimes exceed 10 times the replacement dose), androgens do enhance nitrogen balance and muscle mass; since the drugs have multiple side effects at high doses, these benefits do not outweigh the risks associated with androgen abuse in man, and the use of androgens by female athletes is associated with disfiguring virilization. Thus this practice cannot be condemned too harshly. The only established indications for androgen therapy outside of male hypogonadism are in selected patients with anemia due to bone marrow failure or hereditary angioedema and as an adjunct to growth hormone therapy.

Gonadotropins Gonadotropin therapy is used to establish or restore fertility in patients with gonadotropin deficiency of any cause. Several gonadotropin preparations are available. Human menopausal gonadotropin (hMG) (purified from the urine of postmenopausal women) contains 75 IUFSH and 75 IU LHper vial.hCG(purified from the urine of pregnant women) has little FSH activity and resembles LH in its ability to stimulate testosterone production by Leydig cells. Because of the expense of hMG, treatment is usually begun with hCG alone, and hMG is added later to promote the FSH-dependent stages of spermatid development. A high ratio of LH to FSH activity and treatment for 6 to 18 months may be necessary to bring about maturation of the prepubertal testes. Recombinant human FSH is also available and has been used mainly for ovulation induction in women. Trials are underway to examine its effects on spermatogenesis in men with hypogonadotropic hypogonadism. Once spermatogenesis is restored with combined FSH and LH therapy, hCG alone is often sufficient to maintain spermatogenesis.

The dose ofhCGrequired to maintain a normal testosterone level varies from 1000 to 5000 IU weekly. A number of regimens have been used to induce maturation of spermatogenesis. Most involve starting with 2000 IU hCG three or more times a week until most of the clinical parameters, including plasma testosterone levels, are normal.hMG(usually one ampule) is then added three times a week to complete the development of spermatogenesis. The length of therapy required to restore spermatogenesis may be as long as 12 months.

GnRHand GnRH Analogues GnRH (gonadorelin) is available for endocrine testing and is used by some physicians for chronic therapy of the infertility of hypogonadotropic hypogonadism. In the latter instance, it is necessary to administer GnRH in frequent boluses (25 to 200 ng/kg of body weight every 2 h) with the use of portable infusion pumps, analogous to those used for insulin administration. In general, pulsatile GnRH does not appear to be more efficacious than gonadotropin in returning sperm counts to normal. GnRH analogues (leuprolide, nafarelin, histrelin) are available for the suppression of gonadotropin secretion, leading to hypogonadism. In prostatic cancer, testicular androgen production can be blocked by monthly injection of 7.5 mg leuprolide in depot form.

336. DISORDERS OF THE OVARY AND FEMALE REPRODUCTIVE TRACT - *Bruce R. Carr*, *Karen D. Bradshaw*

The ovary is the source of ova for reproduction and of the hormones that regulate female sexual life. The anatomic structure, response to hormonal stimuli, and secretory capacity of the ovary vary at different periods of life. This chapter will review normal ovarian physiology as a background for understanding ovarian abnormalities and will consider other disorders of the female reproductive tract.

DEVELOPMENT, STRUCTURE, AND FUNCTION OF THE OVARY

EMBRYOLOGY

During the third week of gestation, the primordial germ cells differentiate from the endoderm lining the yolk sac at the caudal end of the embryo. The germ cells migrate to the genital ridge adjacent to the mesonephric kidney by the fifth week of gestation and undergo mitotic division. The gonads exist in an undifferentiated state until the seventh week of fetal life, at which time the primitive ovary can be distinguished from the testis (Chap. 338). Estrogen formation in the ovary commences between weeks 8 and 10, and by 10 to 11 weeks of gestation, oogonia in the ovarian cortex begin developing into primary oocytes. The ovary contains a finite number of germ cells, the number peaking at about 7 million oogonia by the fifth to sixth month of gestation. Subsequently, the germ cells decrease in number through a process of atresia so that only 1 million remain at birth, 400,000 are present at menarche, and only a few remain at menopause. Two normal X chromosomes are required for development of the ovary; in individuals with a 45,X karyotype, ovarian development occurs, but the rate of atresia is accelerated so that only a fibrous streak remains at birth (Chap. 338).

After the oogonia cease to proliferate, meiosis commences, continues until the diplotene stage of the first meiotic division is completed, and then is arrested until the onset of ovulation at puberty. From the fifth month of fetal life, the primordial follicle consists of the primary oocyte arrested in meiosis, a single surrounding layer of granulosa cells, and a basement membrane that separates the primordial follicle from surrounding stromal (interstitial) tissues.

PUBERTAL MATURATION

The final maturation of ovarian follicles commences during puberty. The two major hormones that regulate follicular development are the pituitary gonadotropins -- follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (Fig. 336-1). During the second trimester of fetal development, the plasma gonadotropins rise to levels similar to those at menopause. This peak in gonadotropin levels may be responsible for the simultaneous peak in oocyte replication. After the second trimester, the hypothalamic-pituitary axis (the so-called gonadostat) becomes functional and is sensitive to negative feedback by steroid hormones, particularly estrogen and progesterone produced in the placenta. The levels of circulating gonadotropins consequently decrease, and gonadotropins are almost undetectable at the time of birth. In the neonate, concomitant with the decrease in estrogen and progesterone levels caused by separation from the placenta, there is a rebound increase in gonadotropin

secretion for the first few months of life. With continued maturation of the hypothalamic-pituitary system, the gonadostat becomes exquisitely sensitive to negative feedback by low levels of circulating steroid hormones, and plasma gonadotropins again decrease.

As the time of puberty nears, a decrease in the sensitivity of the gonadostat allows for increased secretion ofFSH andLH, possibly secondary to increased episodic or pulsatile secretion of gonadotropin-releasing hormone (GnRH) by the hypothalamus (Chap. 328). A sleep-induced, pulsatile pattern of LH secretion then ensues, the first step in the development of a cyclic pattern of gonadotropin secretion (Fig. 336-1). The increase in estrogen secretion exerts a positive feedback, which leads to an exaggeration of the pulsatile release of LH and eventually to menarche and ovulation, after which plasma gonadotropin concentrations reach adult values, which are similar during day and night. After the menopause, plasma gonadotropin levels rise, then plateau 5 to 10 years after menopause and remain fairly constant until the eighth to ninth decade of life, when the levels may fall. Although ovarian function is regulated primarily by LH and FSH, the ovary is a source of peptide and protein hormones and growth factors such as inhibin and activin that may play a role in ovarian function and regulation. The production of inhibin by the mature ovary accounts, in part, for the relative reduction in FSH that is seen during the reproductive years (Fig. 336-1).

With puberty the sensitivity of the hypothalamic-pituitary centers to circulating steroid hormones is decreased, GnRH release by the hypothalamus increases, gonadotropin secretion by the pituitary is enhanced, ovarian estrogen secretion increases, and the anatomic changes of puberty ensue. At age 10 to 11, the first secondary sexual characteristics begin to appear in girls, namely, development of the breast buds (thelarche), followed by the development of pubic hair (pubarche), and later by the development of axillary hair (adrenarche). The growth of pubic and axillary hair is believed to be initiated by adrenal androgens, the levels of which begin to rise at approximately 6 to 8 years of age. A growth spurt ensues, and peak growth rate is attained by age 12.

The culmination of puberty is the onset of predictable, cyclic menses. The average time between the beginning of breast development and the onset of menses (menarche) is 2 years. During the first few years after menarche, menstrual cycles are often irregular and unpredictable due to anovulation. The age of menarche is variable and is influenced by socioeconomic and genetic factors and by general health. In the United States, the mean age of menarche is believed to have decreased at a rate of 3 to 4 months per decade over the past 100 years and is now around 12 years, a change believed to be due to improved nutrition. A body weight of around 48 kg or some critical combination of weight, body water, and body fat is associated with development of hypothalamic insensitivity to feedback by steroids that leads to increased secretion of gonadotropins and finally to menarche. Obese girls have earlier menarche than girls with normal weights. In contrast, active participation in sports or ballet, malnutrition, and chronic debilitating disease can delay menarche.

MATURE OVARY

Morphology The anatomic components and function of the adult ovary are illustrated

schematically inFig. 336-2. Under the influence of gonadotropins, a group of primary follicles are recruited, and by day 6 to 8 of the menstrual cycle, one follicle becomes mature or "dominant," a process characterized by accelerated growth of granulosa cells and enlargement of the fluid-filled antrum. The recruited follicles not destined to ovulate undergo degeneration, similar to the atresia that occurs in other follicles during embryogenesis. Just prior to ovulation, meiosis resumes in the ovum of the dominant follicle, and the first meiotic division results in formation of the first polar body. The antrum rapidly enlarges (up to 10 to 25 mm in size), follicular fluid increases in amount, and the follicular surface thins and forms a conical stigma. Ovulation from the dominant follicle occurs some 16 to 23 h after theLH peak and some 24 to 38 h after the onset of the LH surge as the result of rupture of the follicular wall at the area of the stigma. The ovum is then expelled together with a mass of surrounding granulosa cells called *cumulus cells*. The rupture is believed to result from the action of hydrolytic enzymes on the surface of the follicle, possibly under the control of prostaglandins. The second meiotic division occurs after the egg is fertilized by a sperm, and the second polar body is then extruded. The formation of the *corpus luteum* begins in the retained remnant of the ovulated follicle; the remaining granulosa and theca cells increase in size and accumulate lipids and a yellow pigment, lutein, to become "luteinized." After a period of 14± 2 days (the functional life of the corpus luteum), the corpus luteum begins to atrophy, to be replaced in time by a fibrous scar, the *corpus albicans*. The factors that limit the life span of the human corpus luteum are not known, but if pregnancy occurs, the corpus luteum persists under the influence of placental or chorionic gonadotropins, and progesterone is produced by the corpus luteum for the support of pregnancy.

Hormone Formation

Steroid Hormones Like other steroid hormones, ovarian steroids are derived from cholesterol (Fig. 336-3). The ovary can synthesize cholesterol de novo and can also utilize cholesterol obtained from circulating lipoproteins as substrate for steroid hormone formation (Fig. 336-4). Virtually all ovarian cells are believed to possess the complete complement of enzymes required for the synthesis of estradiol from cholesterol (Fig. 336-3); however, different cell types in the ovary contain different amounts of these enzymes so that the main steroids produced differ in different compartments. For example, the corpus luteum forms mainly progesterone and 17-hydroxyprogesterone, whereas theca and stromal cells convert cholesterol to androstenedione and testosterone. Granulosa cells are particularly rich in the aromatase enzyme responsible for estrogen synthesis and utilize as substrates for this process androgens synthesized in the granulosa cells and the adjacent theca cells.

The principal sites of action ofLH andFSH are also illustrated in Figs. 336-3 and336-4. LH acts primarily to regulate the early steps in steroid hormone biosynthesis, namely, the transport of cholesterol into the mitochondria by steroidogenic acute regulatory (StAR) protein and its conversion to pregnenolone. FSH acts mainly to regulate the final process by which androgens are aromatized to estrogens. As a consequence, LH enhances substrate flow and the formation of androgens and/or progesterone in the absence of FSH, whereas FSH action is impeded in the absence of LH because of diminished substrate for aromatization.

ESTROGENS Naturally occurring estrogens are 18-carbon steroids characterized by an

aromatic A ring, a phenolic hydroxyl group at C-3, and either a hydroxyl group (estradiol) or a ketone (estrone) at C-17 (Fig. 336-3). (For the numbering of the steroid ring, see Fig. 335-1.) The principal estrogen secreted by the ovary and the most potent estrogen is estradiol. Estrone is also produced by the ovary, but most estrone is formed by extraglandular conversion of androstenedione in peripheral tissues. Estriol (16-hydroxyestradiol), the main estrogen in urine, arises from the 16-hydroxylation of estrone and estradiol. Catechol estrogens are formed by hydroxylation of estrogens at the C-2 or C-4 position and may act as the intracellular mediators of some estrogen action. Estrogens promote development of the secondary sexual characteristics in women and cause uterine growth, thickening of the vaginal mucosa, thinning of the cervical mucus, and development of the ductule system of the breasts. Estrogens also alter lipid profiles and exert vascular effects that help prevent cardiovascular disease. The mechanism of estrogen action in target tissues is similar to that for other steroid hormones and involves binding to a nuclear steroid receptor -- either estrogen receptor (ER)a or ERb -- and enhancement of the transcription of messenger RNA, which in turn causes increased protein synthesis in the cell cytoplasm (Chap. 327). These receptors have specific tissue site expression and bind various estrogens with different affinities, thereby conferring selective actions.

PROGESTERONE Progesterone, a 21-carbon steroid (Fig. 336-3), is the principal hormone secreted by the corpus luteum and is responsible for progestational effects, i.e., induction of secretory activity in the endometrium of the estrogen-primed uterus in preparation for implantation of the fertilized egg. Progesterone also induces a decidual reaction in endometrium. Other effects include inhibition of uterine contractions, an increase in the viscosity of cervical mucus, glandular development of the breasts, and an increase in basal body temperature (thermogenic effect).

ANDROGENS The ovary synthesizes a variety of 19-carbon steroids, including dehydroepiandrosterone, androstenedione, testosterone, and dihydrotestosterone, principally in stromal and thecal cells. The major ovarian 19-carbon steroid is androstenedione (Fig. 336-3), part of which is secreted into the plasma and part of which is converted to estrogen in granulosa cells or to testosterone in the interstitium. Androstenedione can also be converted to testosterone and estrogens in peripheral tissues. Only testosterone and dihydrotestosterone are true androgens that interact with the androgen receptor and induce virilizing signs in women (Chaps. 53 and335).

Other Hormones Inhibin is secreted in two forms (A and B) by the follicle and inhibits the release ofFSH by the hypothalamic-pituitary unit. *Activin* is also secreted by the follicle and may enhance FSH secretion as well as having local effects on ovarian steroidogenesis. *Follistatin* is an activin-binding protein that attenuates the actions of activin and other members of the transforming growth factor (TGF)bfamily.

Some ovarian hormones play an uncertain role in human physiology. *Relaxin*, a polypeptide hormone produced by the human corpus luteum and by the decidua, causes softening of the cervix and loosening of the symphysis pubis in preparation for parturition in animals. *Oxytocin*, *vasopressin*, and other hypothalamic and pituitary hormones are also present in granulosa and/or luteal cells, but their function in these cells is unknown. *Follicle regulatory protein* (FRP), found in human follicular fluid, inhibits granulosa secretion and growth. *Gonadocrinins*, peptides purified from rat

follicular fluid, stimulate the release of bothFSH andLH from the pituitary in vitro and in vivo. Granulosa cells secrete *oocyte maturation inhibitor* (OMI), a factor that prevents premature ovulation. In addition, in the gonads of both sexes a *meiosis-inducing substance* (MIS) triggers the onset of meiosis, an event that occurs earlier in ovarian than in testicular development. Local growth factors [including insulin-like growth factors (IGFs) 1 and 2 andTGFa and -b] may also influence steroid secretion by the ovary.

The Normal Menstrual Cycle The menstrual cycle is divided into a follicular or proliferative phase and a luteal or secretory phase (Fig. 336-5). The secretion ofFSH andLH is fundamentally under negative feedback control by ovarian steroids (particularly estradiol) and by inhibin (which selectively suppresses FSH), but the response of gonadotropins to different levels of estradiol varies. FSH secretion is inhibited progressively as estrogen levels increase -- typical negative feedback. In contrast, LH secretion is suppressed maximally by sustained low levels of estrogen and is enhanced by a rising level of estradiol -- positive feedback. Feedback of estrogen involves both the hypothalamus and pituitary. Negative feedback suppressesGnRH and inhibits gonadotropin production. Positive feedback is associated with an increased frequency of GnRH secretion and enhanced pituitary sensitivity to GnRH.

The length of the menstrual cycle is defined as the time from the onset of one menstrual bleeding episode to onset of the next. In women of reproductive age, the cycle averages 28± 3 days and the mean duration of flow is 4± 2 days. Longer menstrual cycles (usually characterized by anovulation) occur at menarche and near the onset of menopause. At the end of a cycle plasma levels of estrogen and progesterone fall, and circulating levels ofFSHincrease. Under the influence of FSH, follicular recruitment results in development of the follicle that will be dominant during the next cycle.

After the onset of menses, follicular development continues, butFSHlevels decrease. Approximately 8 to 10 days prior to the midcycleLHsurge, plasma estradiol levels begin to rise as the result of estradiol formation by the granulosa cells of the dominant follicle. During the second half of the follicular phase, LH levels also begin to rise (owing to positive feedback). Just before ovulation, estradiol secretion reaches a peak and then falls. Immediately thereafter, a further rise in the plasma level of LH mediates the final maturation of the follicle, followed by follicular rupture and ovulation 16 to 23 h after the LH peak. The rise in LH is accompanied by a smaller increase in the level of plasma FSH, the physiologic significance of which is unclear. The plasma progesterone level also begins to rise just prior to midcycle and facilitates the positive feedback action of estradiol on LH secretion.

At the onset of the luteal phase, plasma gonadotropins decrease and plasma progesterone increases. A secondary rise in estrogens causes further gonadotropin suppression. Near the end of the luteal phase, progesterone and estrogen levels fall, andFSHlevels begin to rise to initiate the development of the next follicle (usually in the contralateral ovary) and the next menstrual cycle. Inhibin A levels are low in the follicular phase but reach a peak in the luteal phase. Inhibin B levels, in contrast, are increased in the follicular phase and low in the luteal phase.

The endometrium lining the uterine cavity undergoes marked alterations in response to the changing plasma levels of ovarian hormones (Fig. 336-5). Concurrent with the

decrease in plasma estrogen and progesterone and the decline of corpus luteum function in the late luteal phase, intense vasospasm occurs in the spiral arterioles supplying blood to the endometrium, causing ischemic necrosis, endometrial desquamation, and bleeding. This vasospasm is caused by locally synthesized prostaglandins. The onset of bleeding marks the first day of the menstrual cycle. By the fourth to fifth day of the cycle, the endometrium is thin. During the proliferative phase, glandular growth of the endometrium is mediated by estrogen. After ovulation, increased progesterone levels lead to further thickening of the endometrium, but the rapid growth slows. The endometrium then enters the secretory phase, characterized by tortuosity of the glands, curling of the spiral arterioles, and glandular secretion. As corpus luteum function begins to wane in the absence of conception, the sequence of events leading to menstruation is again set into action.

Biphasic changes in basal body temperature are characteristic of the ovulatory cycle and are mediated by alterations in progesterone levels (Fig. 336-5). An increase in basal body temperature by 0.3 to 0.5°C begins after ovulation, persists during the luteal phase, and returns to the normal baseline (36.2 to 36.4°C) after the onset of the subsequent menses.

Cellular Interactions in the Ovary during the Normal Cycle LHstimulates thecal cells surrounding the follicle to form androgens, and androstenedione diffuses across the basement membrane of the follicle into granulosa cells, where it is aromatized to estrogen (Figs. 336-3 and336-4).

The increase ofFSH late in the preceding menstrual cycle stimulates growth and recruitment of the primary follicles by enhancing granulosa cell proliferation, resulting ultimately in the formation of the dominant follicle. This function of FSH is underscored by the fact that only primary follicles are seen in patients with mutations in FSH or the FSH receptor. In the granulosa cells, FSH also stimulates estrogen synthesis. Enhanced secretion of estradiol causes an increase in the number of estradiol receptors and further proliferation of granulosa cells. In the late follicular phase, FSH, in concert with estradiol, causes induction ofLHreceptors on the granulosa cells. LH acts via these receptors to increase progesterone secretion at midcycle. The amount of progesterone formed by the follicle is believed to be limited by the availability of cholesterol to serve as substrate for steroidogenesis and by the fact that most of the progesterone is converted to androstenedione by thecal cells. Prior to ovulation, the granulosa cells of the follicle are bathed in follicular fluid but have limited access to circulating blood and consequently to plasma low-density lipoprotein (LDL). As depicted in Fig. 336-4, the granulosa cells become vascularized after ovulation, and plasma cholesterol is made available to serve as the major substrate for progesterone synthesis by the corpus luteum. Thus, increased progesterone synthesis by the corpus luteum is the consequence of increased substrate availability. The peak in progesterone secretion by the corpus luteum occurs 8 days after ovulation at the time of maximal vascularization of the granulosa cells.

MENOPAUSE

The *menopause* is defined as the final episode of menstrual bleeding in women. However, the term is used commonly to refer to the time interval that encompasses the

transitional period between the reproductive years up to and after the last episode of menstrual bleeding. During this period, there is a progressive loss of ovarian function and a variety of endocrine, somatic, and psychological changes.

The median age of women at the time of cessation of menstrual bleeding is 50 to 51 years. Since the life expectancy of women is close to 80 years, approximately one-third of life occurs after cessation of reproductive function. Preceding the menopause, the pattern of menstrual cycles is variable, but the interval between menses usually becomes shorter, as follicular recruitment is hastened by increases inFSH. Day 3 FSH and E_2levels are often elevated. Ovulatory cycles continue for some period of time, then anovulation becomes common.

The menopause is the consequence of the exhaustion of ovarian follicles. The decrease in the number of ova begins in intrauterine life; by the time of the menopause, few ova remain, and these appear to be nonfunctional. Only a small number of ova are lost as the result of ovulation during reproductive life; the majority are lost by atresia. The cessation of follicular development results in decreased production of estradiol, inhibin, and other hormones, which causes a loss of negative feedback on the hypothalamic-pituitary centers. In turn, the levels of plasma gonadotropins increase, withFSHlevels rising earlier and higher thanLHlevels (Figs. 336-1 and336-6). The higher concentration of FSH than LH in postmenopausal women may result from the decrease in inhibin secretion by the ovary, from the fact that FSH is cleared from plasma less rapidly than LH, and possibly from the loss of positive feedback on LH production by estradiol.

The ovaries of postmenopausal women are small and wrinkled, and the residual cells are predominantly stromal. Estrogen and androgen levels in plasma are reduced but not absent (Fig. 336-6). Before the menopause, plasma androstenedione is derived almost equally from the adrenals and the ovaries; after menopause the ovarian contribution ceases so that the plasma levels of androstenedione fall by 50% (Fig. 336-6). However, the menopausal ovary continues to secrete testosterone, presumably formed in stromal cells.

Circulating estrogens in the ovulating woman are derived from two sources. Some 60% of mean estrogen formation during the menstrual cycle is in the form of estradiol, formed primarily by ovaries, and the remainder is estrone, formed mainly in extraglandular tissues from androstenedione. After menopause, extraglandular estrogen formation is the major pathway for estrogen synthesis. Because adipose tissue is a major site of extraglandular estrogen production, peripheral estrogen formation may actually be enhanced in obese postmenopausal women, so that total estrogen production rates may be as great or greater than in premenopausal women. The predominant estrogen formed is estrone rather than estradiol.

The most common menopausal symptoms are vasomotor instability (hot flashes), atrophy of the urogenital epithelium and skin, decreased size of the breasts, and osteoporosis. Approximately 40% of menopausal women develop symptoms serious enough to seek medical assistance.

The pathogenesis of the hot flash is uncertain. There is a close temporal relationship

between the onset of the hot flash and pulses ofLHsecretion, which reflect hypothalamic secretion ofGnRH. Alterations in catecholamine, prostaglandin, endorphin, or neurotensin metabolism may play a role in conjunction with low estrogen production. Symptoms associated with the hot flash, including nervousness, anxiety, irritability, and depression, may or may not be caused entirely by estrogen deficiency.

The decrease in size of the tissues of the female reproductive tract and breasts in the menopause is due to estrogen deficiency. The vaginal mucosa and the endometrium usually become thin and atrophic (although endometrial hyperplasia occurs in one-fifth of postmenopausal women).

Osteoporosis is one of the dread afflictions of aging, and there is a close relationship between estrogen deprivation and its development. Approximately one-fourth of aging women and one-tenth of elderly men sustain a vertebral or hip fracture between the ages of 60 and 90, and the incidence is highest in elderly white women. Such fractures are a major cause of loss of independence, death and morbidity, and the fracture-related mortality increases from <10% in the 60- to 64-year age group to >30% in patients over 80 (Chap. 342). Many factors affect the development of osteoporosis, including ethnic origin, diet, activity, smoking, and general health, and estrogen deprivation is of particular importance. White and Asian postmenopausal women are more predisposed to osteoporosis and its consequences because bone mass in this group is lower prior to menopause, so loss in bone density has more severe consequences. Further evidence that osteoporosis is a disease of estrogen deprivation is suggested by the early development of osteoporosis in women with premature menopause due to either natural causes or surgical castration. After the menopause women experience an increase in the incidence of cardiovascular disease as the result of a decrease in the level of high-density lipoprotein (HDL) cholesterol as well as the effects of hypoestrogenism on vascular endothelium and reactivity.

LABORATORY AND CLINICAL ASSESSMENT OF HORMONAL STATUS

The hormonal status of women can usually be assessed by history and physical examination. In general, the presence of secondary sexual characteristics such as normal female breast development indicates adequate estrogen secretion in the past, and the presence of regular, predictable, cyclic menses implies that ovulation and the production of gonadotropins, estrogen, progesterone, and androgens are adequate and that the outflow tract is intact. Such a history may be more valuable than laboratory tests in evaluating ovarian hormone status. However, laboratory tests provide valuable ancillary information in the evaluation of women with endocrine dysfunction or infertility (Chap. 54).

PITUITARY GONADOTROPINS

Plasma gonadotropins are assessed by radioimmunoassay (RIA), fluoroimmunoassay (FIA), or immunoradiometric assay (IRMA). Because bothFSH andLH are secreted in a pulsatile manner, the results obtained from a single serum sample may be difficult to interpret. Consequently, multiple samples taken at 20-min intervals over 2 h may be pooled to obtain a mean value. Serum gonadotropin measurements are of the most use in evaluating women with suspected ovarian failure and in supporting the diagnosis of

polycystic ovarian syndrome (PCOS) and hypogonadotropic hypogonadism. The normal ranges for serum LH and FSH in ovulating women are 0.8 to 57 and 1.4 to 21 IU/L, respectively. FSH levels that are persistently >40 IU/L are diagnostic of ovarian failure, and an LH value <0.8 IU/L suggests hypogonadotropic hypogonadism. In practice, however, gonadotropin values may be equivocal and must be interpreted in light of the remainder of the findings.

OVARIAN HORMONES

The mean plasma levels and production rates of the principal ovarian hormones are presented inTable 336-1.

Estrogen The presence of normal secondary sexual characteristics implies that estrogen production was adequate in the past. The current estrogen status can be estimated by pelvic examination. The presence of a moist, rugated vagina with copious, clear, thin cervical mucus that can be stretched and that exhibits arborization or ferning when spread on a slide is strong evidence of adequate estrogen production. Cytologic demonstration of mature vaginal epithelial cells and abundant cornified squamous epithelial cells with pyknotic nuclei confirms the presence of adequate estrogen levels.

The progesterone-withdrawal test provides a functional assessment of the endometrium, outflow tract, and estrogen status. If menses appear within a week to 10 days after the end of a trial of medroxyprogesterone acetate (10 mg by mouth once or twice a day for 5 days) or after a single intramuscular injection of progesterone (100 mg), then prior estrogen priming was adequate to allow withdrawal bleeding.

Owing to its variable level in plasma during the normal cycle and the difficulty of estimating the day of the cycle in women with abnormal cycles, the measurement of estrogen levels in plasma or urine is of little use in the routine assessment of estrogen status. Measurement of plasma estradiol is useful during attempts to induce ovulation with gonadotropins to prevent the development of the ovarian hyperstimulation syndrome and is used along with ultrasound assessment to monitor follicular growth in women who are to undergo in vitro fertilization.

Progesterone Cyclic, predictable menses also imply that adequate progesterone is secreted during the luteal phase of the menstrual cycle. Assessment of progesterone is useful to detect ovulation and to evaluate the adequacy of the luteal phase in infertile women. Several functional assays of progesterone can be used. The least expensive and most useful is the daily measurement of basal body temperature throughout a cycle. Owing to the thermogenic properties of progesterone, a normal biphasic monthly curve showing a temperature elevation lasting for approximately 2 weeks after ovulation is a valid indication of progesterone secretion during the luteal phase (Fig. 336-5). The presence of viscous cervical mucus that does not stretch or fern and of predominantly intermediate cells on vaginal cytology or demonstration of a secretory epithelium in an endometrial biopsy during the luteal phase on days 20 to 22 of the cycle provides additional assessment of progesterone secretion. In addition, serum progesterone can be measured to assess the function of the corpus luteum.

Androgen Under normal conditions, the ovary secretes androstenedione, testosterone,

and dehydroepiandrosterone. In conditions of androgen excess, hirsutism and/or virilization are common. The evaluation of androgen excess is discussed inChap. 53.

DIAGNOSIS OF PREGNANCY

Pregnancy is usually recognized on the basis of the history and physical examination. That is, a woman with previously cyclic, predictable menses develops amenorrhea accompanied by breast tenderness, malaise, lassitude, and nausea, and on physical examination the uterus is soft and enlarged.

Assays of placental products facilitate the diagnosis of pregnancy. Human chorionic gonadotropin (hCG) is secreted by the trophoblastic cells of the placenta into the maternal plasma and excreted in the urine. Assays of the hCG content of serum or urine use antibodies against hCG and make it possible to detect pregnancies 8 to 10 days after ovulation, before the first missed menstrual period and long before pregnancy can be diagnosed by clinical assessments. Assay of theb subunit of hCG in serum or urine makes it possible to differentiate between excessLH and hCG, an important distinction in evaluating women with trophoblastic disease such as hydatidiform mole or choriocarcinoma. Sensitive and specific hCG-based pregnancy tests are now available for testing by patients at home.

DISORDERS OF OVARIAN FUNCTION

PREPUBERTAL YEARS

Puberty is said to be *precocious* if breast budding begins before age 8 or if menarche occurs before age 9. Those disorders in which the developing sexual characteristics are appropriate for the genetic and gonadal sex -- i.e., feminization in girls or virilization in boys -- are termed *isosexual precocity*, whereas *heterosexual precocity* occurs when sexual characteristics are not in accord with the genetic sex, namely, virilization in girls or feminization in boys. Pubertal disorders of boys are described in Chap. 335.

Isosexual Precocious Puberty Isosexual precocious puberty in girls can be divided into three major categories (Table 336-2).

True Precocious Puberty True precocious puberty is characterized by an early but otherwise normal sequence of pubertal development, including increased secretion of gonadotropins and ovulatory menstrual cycles. Constitutional or idiopathic precocious puberty accounts for 90% of cases. In these individuals, no cause for the premature maturation of the central nervous system-hypothalamic-pituitary axis can be identified, and the diagnosis is confirmed by finding an adult pattern ofLH andFSHrelease on aGnRHstimulation test. As many as half these individuals have abnormal findings on electroencephalograms. Premature appearance of secondary sexual characteristics and of ovulatory cycles with the accompanying risk of fertility may cause significant emotional disturbance. Therefore, prompt initiation of therapy is imperative. GnRH analogues suppress gonadotropins and inhibit estrogen synthesis, thereby blocking precocious puberty; they may also prevent premature closure of the epiphyses and the resulting short stature.

About 10% of cases are due to organic brain diseases, including brain tumors (hypothalamic gliomas, astrocytomas, ependymomas, germinomas, and hamartomas), encephalitis, meningitis, hydrocephalus, head injury, tuberous sclerosis, and neurofibromatosis. It is essential to distinguish this group of patients from those with the idiopathic disorder, and patients whose disorder is designated as idiopathic occasionally prove to have such tumors. Fortunately, most patients with organic lesions serious enough to cause precocious puberty have obvious neurologic signs and symptoms. Evaluation of all patients with precocious puberty should include, at a minimum, skull films and computed tomography (CT) or magnetic resonance imaging (MRI) of the brain. The success of treatment depends on the nature of the lesion, but surgical and radiation treatment of well-localized tumors is occasionally successful.

A rare cause of isosexual precocity is congenital adrenal hyperplasia due to 21-hydroxylase deficiency in girls in whom treatment is delayed until 4 to 8 years of age. After initiation of glucocorticoid replacement, such individuals may undergo isosexual precocious puberty (Chap. 331).

Precocious Pseudopuberty Precocious pseudopuberty occurs when girls undergo feminization as a consequence of enhanced estrogen formation but do not ovulate or develop cyclic menses. Ovarian cysts or tumors that secrete estrogen (granulosa-theca cell tumors) are the most frequent cause of precocious pseudopuberty. Granulosa-theca cell tumors associated with intestinal polyps and pigmentation of the mucous membranes occur in the Peutz-Jeghers syndrome. Other ovarian tumors that secrete estrogens (or androgens that can be converted to estrogens at extraglandular sites) include dysgerminomas, teratomas, cystadenomas, and ovarian carcinomas (Chap. 97). Ovarian tumors can usually be detected by rectoabdominal examination or by sonography,CT,MRI, and/or laparoscopy. Ovarian teratomas and choriocarcinomas and other carcinomas that secretehCG do not cause precocious puberty in girls unless they also secrete estrogen (hCG orLH in the absence ofFSH does not induce ovarian estrogen production). Rarely, feminizing tumors of the adrenal cause isosexual precocious puberty by direct formation of estrogens or by secretion of weak androgens, which are converted to estrogens in extraglandular tissues.

Other causes of precocious pseudopuberty include the following:

1. The McCune-Albright syndrome (polyostotic fibrous dysplasia) is due to an activating mutation in the G-protein, Gsa, that occurs during embryogenesis, leading to a mosaic pattern of expression in various tissues. It is characterized by cafe au lait spots, cystic fibrous dysplasia of bones, and sexual precocity. In the ovary, the Gsa mutation mimics the action ofFSH, leading to autonomous follicle development and estrogen formation. Occasionally, this disorder leads to true precocious puberty (Chap. 343).

2. Primary hypothyroidism is occasionally associated with enhanced secretion ofFSH, inducing ovarian estrogen secretion. High levels of thyroid-stimulating hormone (TSH) caused by hypothyroidism may also stimulate the FSH receptor.

3. The Russell-Silver syndrome, or congenital asymmetry, is associated with short stature and precocious feminization.

4. Estrogen-containing medications, including use of estrogen-containing creams for diaper rash or the ingestion of meat from estrogen-treated animals or poultry or of any estrogen by mouth, can cause this disorder.

Incomplete Isosexual Precocity This term is used to describe the premature development of a single pubertal event and encompasses several entities. Breast budding prior to age 7 (*premature thelarche*) without other evidence of estrogen secretion and without premature bone maturation is believed to be due to a transient increase in estrogen secretion or to a temporary increase in sensitivity to the small amounts of circulating estrogens formed prior to puberty. Usually, the disorder is self-limited and resolves spontaneously. Occasionally, axillary hair and/or pubic hair (*premature adrenarche* and *premature pubarche*) appear without any other secondary sexual development. The phenomenon is associated with adrenal androgen secretion in the range of normal puberty and can be distinguished from syndromes of virilization by the absence of clitoromegaly. It requires no treatment, and patients enter puberty at about the average time.

Heterosexual Precocity Virilization in a prepubertal female is usually due to congenital adrenal hyperplasia or to androgen secretion by an ovarian or adrenal tumor. The manifestations of virilization are described inChaps. 53 and331. Virilization in girls with congenital adrenal hyperplasia usually takes place in a background of variable sexual ambiguity (seeChap. 338).

Evaluation of Sexual Precocity The evaluation of sexual precocity involves a careful history and physical examination, including rectoabdominal examination, abdominal sonography, determination of bone age, andGnRHstimulation test, and measurement of thyroid hormones,TSH, and gonadotropins (and androgen or estrogen levels when appropriate).MRIand/orCT scans should be obtained if a neurologic disorder is suspected and no evidence of ovarian or adrenal tumor is found.

REPRODUCTIVE YEARS

Disorders of the Menstrual Cycle

Abnormal Uterine Bleeding Between menarche and the menopause, almost every woman experiences one or more episodes of abnormal uterine bleeding, here defined as any bleeding pattern that differs in frequency, duration, or amount from the pattern observed during a normal menstrual cycle. A variety of descriptive terms (such as *menorrhagia*, *metrorrhagia*, and *menometrorrhagia*) have been used to characterize patterns of abnormal uterine bleeding. A more logical approach is to divide abnormal uterine bleeding into those patterns associated with ovulatory cycles and those associated with anovulatory cycles.

Ovulatory Cycles Normal menstrual bleeding with ovulatory cycles is spontaneous, regular, cyclic, and predictable and is frequently associated with discomfort (*dysmenorrhea*). Deviations from this pattern associated with cycles that are still regular and predictable are most often due to organic disease of the outflow tract. For example, regular but prolonged and excessive bleeding episodes unassociated with bleeding dyscrasias (hypermenorrhea or menorrhagia) can result from abnormalities of the uterus

such as submucous leiomyomas, adenomyosis, or endometrial polyps. Regular, cyclic, predictable menstruation characterized by spotting or light bleeding is termed *hypomenorrhea* and is due to obstruction of the outflow tract as from intrauterine synechiae or scarring of the cervix. Intermenstrual bleeding between episodes of regular, ovulatory menstruation is also often due to cervical or endometrial lesions. An exception to the association between organic disease and abnormal uterine bleeding is the occurrence of regular menstruation more frequently than 21 days apart (*polymenorrhea*). Such cycles may be a normal variant.

Anovulatory Cycles Uterine bleeding that is unpredictable with respect to amount, onset, and duration and usually painless is described as *dysfunctional uterine bleeding*. This disorder is not due to abnormalities of the uterus but rather to chronic anovulation and occurs when there is interruption of the normal sequence of follicular and luteal phases under the influence of a dominant follicle and its resulting corpus luteum. As discussed above, uterine bleeding in ovulatory cycles is due to progesterone withdrawal and requires that the endometrium first be primed with estrogen. (When castrates or postmenopausal women are given progesterone, withdrawal bleeding usually does not occur.)

Dysfunctional uterine bleeding can occur in women who have a transient disruption of the synchronous hypothalamic-pituitary-ovarian patterns necessary for ovulatory cycles, most often at the extremes of the reproductive life -- in the early menarche and in the perimenopausal period -- but also after temporary stress or intercurrent illness.

Primary dysfunctional uterine bleeding can result from three disorders.

1. *Estrogen withdrawal bleeding* occurs when estrogen is given to a castrated or postmenopausal woman and then withdrawn. As in other types of dysfunctional uterine bleeding, this form of menstrual bleeding is usually painless.

2. *Estrogen breakthrough bleeding* occurs when there is continuous estrogen stimulation of the endometrium not interrupted by cyclic progesterone secretion and withdrawal. This is the most common type of dysfunctional uterine bleeding and is usually due to anovulation associated with chronic acyclic estrogen production, as in women withPCOS. Such women may have histories of irregular, unpredictable menses, oligomenorrhea, or amenorrhea (see below). Alternatively, estrogen breakthrough bleeding can occur in hypogonadal women given estrogens chronically rather than intermittently and in women with estrogen-secreting tumors of the ovary. Estrogen breakthrough bleeding may be profuse and is unpredictable with respect to duration, amount of flow, and time of occurrence. The endometrium is typically thin because its repair between episodes of bleeding is incomplete.

3. *Progesterone breakthrough bleeding* occurs in the presence of abnormally high ratios of progesterone to estrogen, e.g., in women using continuous low-dose oral contraceptives.

The approach to a patient with dysfunctional uterine bleeding begins with a careful history of menstrual patterns and prior hormonal therapy. Since not all urogenital tract bleeding is from the uterus, rectal, bladder, and vaginal or cervical sources must be

excluded by physical examination. If the bleeding is from the uterus, a pregnancy-related disorder such as abortion or ectopic pregnancy must be ruled out.

TREATMENT

Once the diagnosis of dysfunctional uterine bleeding is established, a rational approach to management is as follows: During a first episode of dysfunctional bleeding the patient can simply be observed, provided the bleeding is not copious and no evidence of bleeding dyscrasia is present. If bleeding is moderately severe, control can be achieved with relatively high dose estrogen oral contraceptives for 3 weeks. Alternatively, a regimen of three or four low-dose oral contraceptive pills per day for 1 week followed by tapering to the usual dosage for up to 3 weeks is also effective. If uterine bleeding is more severe, hospitalization, bed rest, and intramuscular injections of estradiol valerate (10 mg) and hydroxyprogesterone caproate (500 mg) or intravenous or intramuscular conjugated estrogens (25 mg) usually control the bleeding. After initial treatment, iron replacement should be instituted, and recurrence can be prevented by cyclic oral contraceptives for 2 to 3 months (or more if pregnancy is not desired). Alternatively, menses can be induced every 2 to 3 months with medroxyprogesterone acetate, 10 mg by mouth once or twice a day for 10 days. If hormone therapy fails to control uterine bleeding, an endometrial biopsy, hysteroscopy, or dilatation and curettage may be required for diagnosis and therapy. Indeed, uterine sampling should be performed prior to hormone therapy in women at risk for endometrial cancer (i.e., in women who are approaching the age of menopause or are massively obese); endometrial cancer is rare in ovulatory women of reproductive age.

Amenorrhea An acceptable definition of amenorrhea is failure of menarche by age 15, irrespective of the presence or absence of secondary sexual characteristics, or the absence of menstruation for 6 months in a woman with previous periodic menses. However, women who do not fulfill these criteria should be evaluated if (1) the patient and/or her family are greatly concerned, (2) no breast development has occurred by age 13, or (3) any sexual ambiguity or virilization is present (Chap. 338). Amenorrhea is commonly categorized as either primary (the woman has never menstruated) or secondary (when menstruation has been present for a variable period of time in the past and has ceased). However, some disorders can cause either primary or secondary amenorrhea. For example, most women with gonadal dysgenesis have primary amenorrhea, but some have a few follicles and ovulate for short periods so that pregnancy occurs rarely. Furthermore, patients with chronic anovulation (PCOS) usually have secondary amenorrhea but on occasion have primary amenorrhea. For these reasons, categorization of amenorrhea into primary and secondary types is less helpful than a classification based on the underlying physiologic derangements: (1) anatomic defects, (2) ovarian failure, and (3) chronic anovulation with or without estrogen present.

ANATOMIC DEFECTS Anatomic or structural defects of the genital tract can preclude menstrual bleeding. Starting from the caudal end of the female genital tract, labial fusion is often associated with disorders of sexual development, particularly female pseudohermaphroditism (congenital adrenal hyperplasia or exposure to maternal androgens in utero; Chap. 338). Congenital defects of the vagina, imperforate hymen, and transverse vaginal septae can also cause amenorrhea. These women frequently have accumulation of menstrual blood behind the obstruction and may have cyclic,

predictable episodes of abdominal pain.

More severe mullerian anomalies include mullerian agenesis (the Mayer-Rokitansky-Kuster-Hauser syndrome;Chap. 338), second in frequency only to gonadal dysgenesis as a cause of primary amenorrhea. It can be caused by mutations in the genes encoding anti-mullerian hormone (AMH) or its receptor (AMHR). Women with this syndrome have a 46,XX karyotype, female secondary sex characteristics, and normal ovarian function, including cyclic ovulation, but have absence or hypoplasia of the vagina. The uterus usually consists of only rudimentary bicornuate cords, but if the uterus contains endometrium, cyclic abdominal pain and accumulation of blood may occur, as in other forms of outlet obstruction. One-third of women with this syndrome have abnormalities of the urogenital tract, and one-tenth have skeletal anomalies, usually involving the spine. The major diagnostic problem is distinguishing mullerian agenesis from complete testicular feminization, in which 46,XY genetic males with testes differentiate as phenotypic women but with a blind vaginal pouch and no uterus. Women with testicular feminization have feminized breasts but a paucity of pubic and axillary hair. The disorder is X-linked and is caused by mutations in the androgen receptor that result in profound resistance to the action of testosterone (Chap. 338). Testicular feminization can be diagnosed by demonstrating a male level of serum testosterone and a 46,XY karyotype, whereas demonstration of a 46,XX karyotype, the biphasic basal body temperature curve characteristic of ovulation, and elevated levels of progesterone during the luteal phase establish the diagnosis of mullerian agenesis.

A rare cause of absence of the uterus in 46,XY phenotypic women who are sexually infantile is the so-called testicular regression syndrome or testicular agenesis (Chap. 338).

Other abnormalities of the uterus that cause amenorrhea include obstruction due to scarring or stenosis of the cervix, often resulting from surgery, electrocautery, laser therapy, or cryosurgery. Such destruction of the endometrium (Asherman's syndrome) usually follows vigorous curettage for postpartum hemorrhage or after therapeutic abortion complicated by infection. This diagnosis is confirmed by hysterosalpingography or by direct visual examination of the endometrial scarring or synechiae using a hysteroscope.

Treatment of disorders of the outflow tract is surgical.

OVARIAN FAILURE Primary ovarian failure is associated with elevated plasma gonadotropin levels and can result from several causes. The most frequent cause is *gonadal dysgenesis*, in which the germ cells are absent and the ovary is replaced by a fibrous streak (Chaps. 65 and338). Women with gonadal dysgenesis can be divided into two broad groups on the basis of chromosomal karyotype. The most common type is due to deletion of genetic material in the X chromosomes and accounts for about two-thirds of cases of gonadal dysgenesis. A 45,X karyotype is found in about half of women with this disorder, and most have somatic defects, including short stature, webbed neck, shield chest, and cardiovascular defects, collectively termed the *Turner phenotype*. The remainder of women with X chromosome abnormalities have chromosomal mosaicism with or without associated structural abnormalities of the X. The most common form of mosaicism is 45,X/46,XX. Gonadal tumors are rare in 45,X

patients, but gonadal malignancies may occur in women with chromosomal mosaicism involving the Y chromosome. Therefore, chromosomal analysis should be performed in all cases of amenorrhea associated with ovarian failure, and the streak gonad should be removed if a Y chromosome is present. One means of identifying the presence of a Y chromosome is to amplify the sex-determining regions of the Y chromosome (SRY) by means of the polymerase chain reaction (Chap. 338). Approximately 90% of women with gonadal dysgenesis due to partial or complete deletion of the X never have menstrual bleeding, and the remaining 10% have sufficient follicles to experience menses and, rarely, fertility; the menstrual and reproductive lives of such individuals are invariably brief.

One-tenth of individuals identified as having bilateral streak gonads have a normal 46,XX or 46,XY karyotype and are said to have *pure gonadal dysgenesis*. These individuals have either normal or above-average stature, owing to failure of estrogen-mediated epiphyseal closure in the presence of a normal chromosomal constitution. Pure gonadal dysgenesis does not constitute a phenotypic or chromosomally homogeneous disorder (Chap. 338). Occasional women with a 46,XY karyotype develop signs of virilization, including clitoromegaly, and have an increased incidence of tumors in the gonadal streaks; as a consequence, gonadal streaks should be removed prophylactically, as discussed above, when a Y chromosome is present. Approximately two-thirds of women with 46,XX gonadal dysgenesis experience no menses, while the remainder have one or more menstrual episodes and are occasionally fertile.

Other causes of ovarian failure and amenorrhea include deficiency of the *CYP17* gene that encodes 17a-hydroxylase and 17,20-lyase activities, premature ovarian failure, the resistant-ovary syndrome, and ovarian failure secondary to chemotherapy or radiation therapy for malignancy. *17a-Hydroxylase deficiency* is characterized by primary amenorrhea, sexual infantilism, and hypertension, the latter due to increased production of desoxycorticosterone (DOC); whereas women with *17,20-lyase deficiency* have primary amenorrhea and sexual infantilism with normal blood pressure (Chaps. 331 and338). The diagnosis of *premature ovarian failure* or *premature menopause* is applied to women who cease menstruating before age 40. The ovaries in such women are similar to the ovaries of postmenopausal women, containing few or no follicles as the result of accelerated follicular atresia. Premature ovarian failure due to ovarian antibodies may be one component of polyglandular failure, together with adrenal insufficiency, hypothyroidism, and other autoimmune disorders (Chap. 339). A rare form of ovarian failure is the *resistant-ovary syndrome*, in which the ovaries contain many follicles that are arrested in development prior to the antral stage, possibly because of resistance to the action ofFSH in the ovary. A subset of these individuals have mutations in FSH or its receptor. To differentiate this disorder from the 46,XX variety of pure gonadal dysgenesis, which is also associated with sexual immaturity, it is necessary to perform ovarian biopsy. However, it is not clinically useful to make this distinction, since the conventional treatment of infertility in both conditions is usually unsuccessful. Women with ovarian failure who desire pregnancy have been treated with hormone replacement and transfer of donor embryos to the uterine cavity or fallopian tubes.

Chronic Anovulation At least 80% or more of gynecologic endocrine disorders result

from chronic anovulation. Women with chronic anovulation fail to ovulate spontaneously but may ovulate with appropriate therapy. The ovaries of such women do not secrete estrogen in a normal cyclic pattern; it is clinically useful to differentiate those women who produce enough estrogen to have withdrawal bleeding after progestogen therapy from those who do not; the latter often have hypothalamic-pituitary dysfunction.

CHRONIC ANOVULATION WITH ESTROGEN PRESENT Women with chronic anovulation who experience withdrawal bleeding after progestogen administration are said to be in a state of "estrus" due to the acyclic production of estrogen, largely estrone, by extraglandular aromatization of circulating androstenedione. This disorder is commonly termed *polycystic ovarian syndrome* (PCOS) and is characterized by infertility, hirsutism, obesity, and amenorrhea or oligomenorrhea. When spontaneous uterine bleeding occurs in women with PCOS, it is unpredictable as to time of onset, duration, and amount; on occasion the bleeding can be severe. The dysfunctional uterine bleeding is usually due to estrogen breakthrough (see above).

The disorder, as originally described by Stein and Leventhal, was characterized by enlarged, polycystic ovaries, but it is now known to be associated with a variety of pathologic findings in the ovaries, only some of which result in enlargement and none of which are pathognomonic. The most common finding is a white, smooth, sclerotic ovary with a thickened capsule, multiple follicular cysts in various stages of atresia, a hyperplastic theca and stroma, and rare or absent corpora albicans. Other ovaries have hyperthecosis in which the ovarian stroma is hyperplastic and may contain lipid-laden luteal cells. Thus, the diagnosis ofPCOS is a clinical one, based on the coexistence of chronic anovulation and varying degrees of androgen excess. The fundamental defect that causes PCOS is unknown, and it is likely to have several distinct causes.

In most women withPCOS, menarche occurs at the expected time, but uterine bleeding is unpredictable in onset, duration, and amount. Amenorrhea ensues after a variable period, although primary amenorrhea occurs in some women. Signs of androgen excess (hirsutism) usually become evident around the time of menarche. One scenario suggests that this disorder originates as an exaggerated adrenarche in obese girls (Fig. 336-7). The combination of elevated levels of adrenal androgens and obesity leads to increased formation of extraglandular estrogen. This estrogen exerts a positive feedback onLHsecretion and negative feedback onFSHsecretion, resulting in a ratio of LH to FSH levels in plasma that is characteristically greater than 2. The increased LH levels can then lead to hyperplasia of the ovarian stroma and theca cells and increased androgen production, which in turn provides more substrate for peripheral aromatization and perpetuates the chronic anovulation. In the advanced stage of the disorder, the ovary is the major site of androgen production, but the adrenal may continue to secrete excess androgen as well. The greater the obesity, the more strongly this sequence would be perpetuated because more androgen is converted to estrogen by adipose tissue stromal cells, which in turn exaggerates inappropriate LH release by positive feedback. Ovarian follicles from women with PCOS have low aromatase activity, but normal aromatase can be induced by treatment with FSH. An association exists between PCOS/hyperthecosis, virilization, acanthosis nigricans, and insulin resistance; in the ovary, insulin may interact via the insulin-like growth factor receptors to enhance androgen synthesis in insulin-resistant states.

TREATMENT

Treatment of PCOSis directed toward interrupting the self-perpetuating cycle and can be accomplished in several ways, such as by decreasing ovarian androgen secretion (by wedge resection or the use of oral contraceptive agents), decreasing peripheral estrogen formation (by weight reduction), or enhancingFSHsecretion [by administration of clomiphene, human menopausal gonadotropin (hMG),GnRH(gonadorelin) by portable infusion pump, or purified FSH (urofollitropin)]. The choice of therapy depends on the clinical findings and the needs of the patient. An attempt at weight reduction is appropriate in all who are obese. If the woman is not hirsute and does not desire pregnancy, periodic withdrawal menses can be induced with medroxyprogesterone acetate 10 days per month; such treatment prevents the development of endometrial hyperplasia. If the woman is hirsute and does not desire pregnancy, the ovarian (and possibly the adrenal) component of androgen production can be suppressed with combined estrogen-progestogen oral contraceptive agents. Combined oral contraceptives are also indicated if prolonged or excessive menstrual bleeding is present. Once androgen excess is controlled, treatment of previously existing hair growth by shaving, depilatories, or electrolysis may be indicated (Chap. 53). If pregnancy is desired, ovulation must be induced. The insulin-sensitizing drugs metformin and troglitazone improve fertility in women with PCOS. Clomiphene promotes ovulation in three-fourths of cases, or ovulation can be induced with hMG, urofollitropin, or gonadorelin (Chap. 54). Pretreatment with GnRH analogues prior to use of hMG, urofollitropin, or gonadorelin may improve the rates of ovulation and pregnancy. Women with PCOS are at increased risk of ovarian hyperstimulation after treatment with gonadotropins. They also experience increased rates of spontaneous abortion. An alternative therapy is ovarian drilling by laser or cautery performed at laparoscopy in women in whom hormonal therapy is not effective; however, the procedure is associated with a high incidence of ovarian adhesions.

Chronic anovulation with estrogen present also may occur with tumors of the ovary. These include granulosa-theca cell tumors, Brenner tumors, cystic teratomas, mucous cystadenomas, and Krukenberg tumors (Chap. 97). Such tumors can either secrete excess estrogen themselves or produce androgens that are aromatized in extraglandular sites. Chronic anovulation and the clinical features ofPCOSresult. Occasionally, areas of the ovary not involved with tumors show the characteristic histologic changes of PCOS. Other causes of chronic anovulation with estrogen present include adrenal production of excess androgen (usually adult-onset adrenal hyperplasia due to partial 21-hydroxylase deficiency) and various thyroid disorders.

CHRONIC ANOVULATION WITH ESTROGEN ABSENT Women with chronic anovulation who have low or absent estrogen production and do not experience withdrawal bleeding after progestogen treatment usually have hypogonadotropic hypogonadism due to disease of either the pituitary or the central nervous system.

Isolated hypogonadotropic hypogonadism associated with defects of smell (olfactory bulb defects) is known as the *Kallmann syndrome* (Chaps. 328 and335). Affected women are sexually infantile and have a defect in the synthesis and/or release ofGnRH. Hypothalamic lesions that impair GnRH production and cause hypogonadotropic hypogonadism include craniopharyngioma, germinoma (pinealoma), glioma,

Hand-Schuller-Christian disease, teratomas, endodermal-sinus tumors, tuberculosis, sarcoidosis, and metastatic tumors that cause suppression or destruction of the hypothalamus. Central nervous system trauma and irradiation can also cause hypothalamic amenorrhea and deficiencies in secretion of growth hormone, adrenocorticotropic hormone (ACTH), vasopressin, and thyroid hormone.

More commonly, gonadotropin deficiency leading to chronic anovulation is believed to arise from functional disorders of the hypothalamus or higher centers. A history of a stressful event in a young woman is frequent. For example, chronic anovulation can begin suddenly in a woman who leaves home for the first time or experiences the death of a loved one. Gonadotropin and estrogen levels are in the low to low-normal range as compared with normal women in the early follicular phase of the cycle. In addition, rigorous exercise, such as jogging or ballet, and diets that result in excessive weight loss may lead to chronic anovulation, particularly in girls with a history of prior menstrual irregularity. The amenorrhea in these women does not appear to be due to weight loss alone but to a combination of a decrease in body fat and chronic stress. An extreme form of weight loss with chronic anovulation occurs in anorexia nervosa. Anorexia nervosa is characterized by the development in a young woman of amenorrhea with associated severe weight loss, distorted attitudes toward eating and weight gain, and distorted body image. In anorexia nervosa amenorrhea can precede, follow, or coincide with weight loss (Chap. 78). During successful therapy, gonadotropin changes recapitulate those observed during normal puberty (Fig. 336-1).

In addition, chronic debilitating diseases such as end-stage kidney disease, malignancy, and malabsorption are believed to lead to development of hypogonadotropic hypogonadism via a hypothalamic mechanism.

Treatment of chronic anovulation due to hypothalamic disorders includes ameliorating the stressful situation, decreasing exercise, and correcting weight loss if appropriate. These women appear to be susceptible to the development of osteoporosis; estrogen replacement therapy is recommended to induce and maintain normal secondary sexual characteristics and prevent bone loss in those who do not desire pregnancy, and gonadotropin or gonadorelin therapy is indicated when pregnancy is desired (see "Treatment," below). When appropriate, therapy is directed at the primary disease of the hypothalamus.

Disorders of the pituitary can lead to the estrogen-deficient form of chronic anovulation by at least two mechanisms -- direct interference with gonadotropin secretion by lesions that either obliterate or interfere with the gonadotropic cells (chromophobe adenomas, Sheehan's syndrome) or inhibition of gonadotropin secretion in association with excess prolactin (prolactinoma). *Pituitary tumors* make up approximately 10% of all intracranial tumors and may secrete no hormone, one hormone, or more than one hormone (Chap. 328). Prolactin levels are elevated in 50 to 70% of patients with pituitary tumors, either because of prolactin secretion by the tumor itself (in the case of prolactinomas) or because the tumor mass interferes with the normal hypothalamic inhibition of prolactin secretion.

Prolactinomas can be divided into microadenomas (<10 mm in diameter) and macroadenomas (>10 mm). Prolactin excess associated with low levels ofLH

andFSHconstitutes a specific subtype of hypogonadotropic hypogonadism. One-tenth or more of amenorrheic women have increased levels of serum prolactin, and more than half of women with both galactorrhea and amenorrhea have elevated prolactin levels. The amenorrhea is most often associated with decreased or absent estrogen production, but prolactin-secreting tumors on occasion are associated with normal ovulatory menses or chronic anovulation with estrogen present. The increased frequency of diagnosis of prolactin-secreting adenomas is probably due to several factors, including increased awareness, improved radiographic detection methods, and availability of radioimmunoassays for prolactin. Since in older autopsy series a 9 to 23% prevalence of pituitary adenomas was observed in asymptomatic women, the clinical and prognostic significance of small microadenomas in asymptomatic individuals is unclear. However, when tumors of any size are associated with symptoms of amenorrhea or galactorrhea, particularly when visual field defects or severe headaches are present, bromocriptine therapy or neurosurgical evaluation is indicated. In the latter half of pregnancy, prolactin-secreting pituitary tumors may expand, leading to headaches, compression of the optic chiasm, bitemporal hemianopsia, and blindness. Therefore, before inducing ovulation for the purposes of achieving pregnancy, it is mandatory to exclude the presence of a pituitary tumor.**The evaluation, differential diagnosis, and management of hyperprolactinemia are described in Chap. 328.*

Large pituitary tumors such as null cell adenomas -- whether or not hyperprolactinemia is present -- are likely to be associated with deficiency of hormones in addition to gonadotropins (Chap. 328).

Craniopharyngiomas, which are thought to arise from remnants of Rathke's pouch, account for 3% of intracranial neoplasms, occur most frequently in the second decade of life, and may extend into the suprasellar region. Many of these tumors calcify and can be diagnosed by conventional skull films. Patients often present with sexual infantilism, delayed puberty, and amenorrhea due to gonadotropin deficiency; secretion ofTSH,ACTH, growth hormone, and vasopressin may also be impaired.

Panhypopituitarism can occur spontaneously, be caused by mutations in transcription factors (Pit1; Prop1) involved in pituitary gland development, result from surgical or radiation treatment of pituitary adenomas, or develop after postpartum hemorrhage (Sheehan's syndrome). Patients with the latter disorder characteristically have failure to lactate or ovulate, loss of genital and axillary hair, hypothyroidism, and adrenal insufficiency (Chap. 328).

Evaluation of Amenorrhea A general scheme for the evaluation of women with amenorrhea is given in Fig. 336-8. On physical examination, attention should be given to three features: (1) the degree of maturation of the breasts, pubic and axillary hair, and external genitalia; (2) the current estrogen status; and (3) the presence or absence of a uterus. Pregnancy should be excluded in all women with amenorrhea; it is prudent to perform a suitable pregnancy screening test even when the history and physical examination are not suggestive. Once that is done, the cause of amenorrhea can frequently be diagnosed clinically. For example, Asherman's syndrome is suggested by a history of curettage in a woman who previously menstruated; in women with primary amenorrhea and sexual infantilism, the essential differential diagnosis is between gonadal dysgenesis and hypopituitarism, and the diagnosis of gonadal dysgenesis

(Turner's syndrome) or of anatomic defects of the outflow tract (mullerian agenesis, testicular feminization, and cervical stenosis) is frequently suggested on the basis of physical findings. When a specific cause is suspected, it is appropriate to proceed directly to confirm the diagnosis (obtaining a chromosomal karyotype or measurement of plasma gonadotropins). It is also useful to measure serum prolactin and FSH levels during the initial evaluation.

Estrogen status is evaluated by determining if the vaginal mucosa is moist and rugated and if the cervical mucus can be stretched and shown to fern upon drying. If these criteria are indeterminate, a progestational challenge is indicated, most often the administration of 10 mg medroxyprogesterone acetate by mouth once or twice daily for 5 days or 100 mg progesterone in oil intramuscularly. (It should be emphasized that progestogen should never be administered until pregnancy is excluded.) If estrogen levels are adequate (and the outflow tract is intact), menstrual bleeding should occur within 1 week of ending the progestogen treatment. If withdrawal bleeding occurs, the diagnosis is chronic anovulation with estrogen present, usually caused by PCOS.

If no withdrawal bleeding or only minimal vaginal spotting occurs, the nature of the subsequent workup depends on the results of the initial prolactin assay. If plasma prolactin is elevated, or if galactorrhea is present, radiography of the pituitary should be undertaken. When the plasma prolactin level is normal in an anovulatory woman with estrogen absent and with elevated FSH levels, the diagnosis is ovarian failure. If the gonadotropins are in the low or normal range, the diagnosis is either hypothalamic-pituitary disorder or an anatomic defect of the outflow tract. As indicated previously, the diagnosis of outflow tract disorder is usually suspected or established on the basis of the history and physical findings. When the physical findings are not clear-cut, it is useful to administer cyclic estrogen plus progestogen (1.25 mg oral conjugated estrogens per day for 3 weeks, with 10 mg medroxyprogesterone acetate added for the last 7 to 10 days of estrogen treatment), followed by 10 days of observation. If no bleeding occurs, the diagnosis of Asherman's syndrome or another anatomic defect of the outflow tract is confirmed by hysterosalpingography or hysteroscopy. If withdrawal bleeding occurs following the estrogen-progestogen combination, the diagnosis of chronic anovulation with estrogen absent (functional hypothalamic amenorrhea) is suggested. Radiologic evaluations of the pituitary-hypothalamic areas may be indicated in the latter cases -- irrespective of the prolactin level -- because of the danger of overlooking a pituitary-hypothalamic tumor and because the diagnosis of functional hypothalamic amenorrhea is one of exclusion (Chap. 328).

Infertility Infertility, the failure to become pregnant after 1 year of unprotected intercourse, affects approximately 10 to 15% of couples and is a common reason for seeking gynecologic assistance (Chap. 54). Male factors account for 40% of infertility problems (Chap. 335). In women, failure of ovulation accounts for 30% of cases; pelvic factors, such as tubal disease or endometriosis, account for half; and a cervical factor is implicated in about one-tenth. In 10 to 20% of infertile women no etiology is found.

Medical Aspects of Pregnancy (See also Chap. 7) The possibility of pregnancy should be considered in all women of reproductive age who are evaluated for medical illness or considered for surgery. Procedures such as x-ray exposure, drugs, and

anesthetics may be harmful to the developing fetus, and a variety of medical problems may worsen during pregnancy, including hypertension; diseases of the heart, lungs, kidney, and liver; and metabolic and endocrine disorders. Abnormal vaginal bleeding or amenorrhea during the reproductive years should prompt consideration of a complication of pregnancy, such as incomplete abortion, ectopic pregnancy, or trophoblastic disease (hydatidiform mole or choriocarcinoma). Women who present with these complications of pregnancy often have histories of abdominal pain and vaginal bleeding and may have evidence of intraabdominal hemorrhage.

Choriocarcinoma is a particular problem because of its protean manifestations. Half these malignancies follow pregnancies complicated by hydatidiform mole, and the remainder occur after spontaneous abortion, ectopic pregnancy, or normal deliveries. Patients may present with intraabdominal bleeding due to rupture of the uterus, liver, or ovary, with pulmonary manifestations (cough, hemoptysis, pleuritic pain, dyspnea, and respiratory failure) or gastrointestinal symptoms, usually chronic blood loss or melena. In addition, patients can present with cerebral metastases or renal involvement. The diagnosis can be established by demonstrating an elevated level of the b subunit ofhCG in plasma. Treatment and cure are possible with chemotherapeutic agents (dactinomycin and/or methotrexate).**The manifestations of choriocarcinoma in men are discussed in Chap. 96.*

Ovarian Tumors SeeChap. 97

TREATMENT

Progestogens The major use of progestogens is in conjunction with estrogen to ensure the full maturation of the endometrium, both in combination birth control pills and in the therapy of hypogonadal states. In certain circumstances, however, progestogen therapy is appropriate by itself -- to induce a progestational effect on the estrogen-primed endometrium (in diagnostic tests for the evaluation of amenorrhea), to inhibit pituitary gonadotropins for contraception (the progestogen-only birth control pill or progestogen-containing implants), for prophylaxis to prevent hyperplasia inPCOS, for palliation in cases of endometrial and breast carcinoma, and for treatment of endometriosis. Even when a direct progestational effect is desired, the available oral drugs substitute a synthetic derivative for the naturally occurring hormone. Oral progestogens include medroxyprogesterone acetate, megestrol acetate, norethindrone, norgestrel, and micronized progesterone. Parenteral agents include progesterone in oil, medroxyprogesterone acetate suspension, and 17-hydroxyprogesterone caproate. Vaginal progesterone suppositories are used for treatment of luteal-phase defects, and progestogen implants are available for long-term contraception.

The most common undesirable side effect is breakthrough bleeding, which occurs when progestogens are used continuously. Other complications include nausea, vomiting, and hirsutism. Abnormal liver function is a side effect of those derivatives with alkyl substitution in the 17a position. Synthetic progestogens are contraindicated if pregnancy is known or suspected, because of the risk of birth defects.

Estrogens Estrogens are used for the treatment of gonadal failure, the control of fertility, and the management of dysfunctional uterine bleeding. However, none of the

available oral or parenteral hormones replaces the pattern of circulating estradiol levels characteristic of the normally cycling, premenopausal woman (Fig. 336-5). Estrogens that can be given by mouth are either nonsteroidal agents (such as diethylstilbestrol) that mimic the action of estradiol, estrogen conjugates that must be hydrolyzed before they become active (usually estrone sulfate from pregnant mare's urine), or estrogen analogues that cannot be metabolized to estradiol (mestranol, quinestrol;Fig. 336-9). Even when micronized estradiol is given orally, it is rapidly converted in the body to estrone. Because oral therapy neither replaces nor mimics the daily secretory pattern of the deficient hormone, such therapy must be viewed as a pharmacologic substitution rather than a physiologic replacement. Likewise, the use of parenteral estrogens rarely mimics the physiologic situation. Parenteral preparations of conjugated estrogens, like the oral derivatives, are poor precursors of estradiol, and estradiol esters (estradiol benzoate and valerate) rarely result in plasma estradiol levels that mimic the normal monthly secretory cycle of the hormone. Transdermal estradiol results in constant levels of blood estradiol and is effective in the treatment of menopausal symptoms. Estrogen vaginal rings and creams can be used for local treatment of vaginal atrophy, but systemic absorption is variable. The side effects of estrogen substitution differ at various times of life.

Hypoestrogenism In women with decreased estrogen production, whether due to disease of the ovaries (gonadal dysgenesis) or to hypogonadotropic hypogonadism, treatment with cyclic estrogens should be instituted at the time of expected puberty to induce the development and maintenance of female secondary sexual characteristics and to prevent osteoporosis. The most commonly used medications are conjugated estrogens (0.625 to 1.25 mg/d by mouth) together with medroxyprogesterone acetate (2.5 mg/d or 5 to 10 mg during the last several days of monthly estrogen treatment to prevent development of endometrial hyperplasia). Alternatively, oral contraceptives may be given (Chap. 54). Abnormal bleeding in women receiving estrogen replacement mandates histologic evaluation of the endometrium. Such substitution therapy or the use of oral contraceptives may also be used for the purpose of suppressing pituitary gonadotropins, as in women withPCOS, in whom the major therapeutic aim is suppression of ovarian androgen production.

Temporary administration of estrogens in larger quantities (up to two times the usual adult maintenance dose) may be necessary to induce the full development of secondary sexual characteristics in girls and for the control of menopausal symptoms. Even larger doses of parenteral estrogens (10 mg estradiol valerate or 25 mg conjugated estrogen) in conjunction with progestogen may be required in some instances of dysfunctional uterine bleeding. In addition to the potential long-term side effects of all estrogens (see below), high doses may cause nausea, vomiting, and edema.

Contraceptives SeeChap. 54

Estrogen Treatment of the Menopause The use of estrogens in postmenopausal women is based on evidence that they may relieve some of the complications of the postmenopausal state, including osteoporosis, and some manifestations of aging itself. In some parts of the United States, as many as half of women in the menopausal age group used one or more forms of estrogen replacement for a median period of 5 years.

The menopause is not, however, a state of simple estrogen deprivation, as some estrogens continue to be produced. It is instead a state of altered estrogen metabolism; the predominant estrogen becomes estrone, which is formed by extraglandular conversion of prehormone, rather than estradiol secreted by the ovary. As is true for all estrogen therapy, the estrogen treatment of the menopause is actually a pharmacologic substitution of one or another estrogen analogue for estradiol rather than a physiologic replacement of the missing steroid. The estrogens available for replacement therapy include conjugated estrogens, estrogen substitutes (diethylstilbestrol), synthetic estrogen (ethinyl estradiol or derivatives), micronized estradiol, estrogen-containing vaginal creams, and estrogen-containing dermal patches. SelectiveERmodulators (e.g., raloxifene) have estrogenic activity in the bone and the cardiovascular system but are antiestrogenic in breast and uterus. Raloxifene binds to the ER, with a conformational change in the domain of the receptor involved in transcription. Regimens associated with a low risk of complications include the following: (1) cyclic estrogen therapy in the lowest effective dose for 25 days per month or continuous estrogens given each day of the month, (2) estrogens plus the addition of progestogen during the last 10 to 14 days of estrogen therapy, (3) low-dose continuous progestogen plus estrogen given daily, and (4) daily selective ER modulators (SERM).

The most clear-cut early benefit of estrogen therapy in the menopause is the relief of vasomotor instability (hot flashes) and of atrophy of the urogenital epithelium and skin. Estrogen therapy ameliorates these symptoms in most cases. When estrogen therapy is intended to treat hot flashes alone, it should be continued for only a few years, since hot flashes tend to diminish after 3 to 4 years in untreated women. SelectiveERmodulators have no effect on hot flashes.

Several lines of evidence indicate that routine estrogen therapy is beneficial in preventing the complications of menopausal osteoporosis, especially in high-risk women (i.e., thin white women;Chap. 342). First, in women undergoing premature menopause, the incidence and complication rates of osteoporosis are increased, and long-term estrogen replacement appears to be beneficial. Second, estrogen therapy has short-term positive effects on calcium balance and long-term beneficial effects on bone density. Third, in women given estrogen therapy, the incidence of fractures is decreased.

Of the potential side effects, the possibility of an increased risk of endometrial carcinoma is perhaps most worrisome. The relative risk of developing endometrial adenocarcinoma in estrogen users is between six and eight times the risk in nonusers. This risk increases with increasing duration and dosage of estrogen but is largely negated in women given combination estrogen-progestogen therapy. Despite the large body of evidence linking endometrial carcinoma and estrogen use, the increased incidence primarily involves low-grade malignancies that may be difficult to distinguish histologically from hyperplasia. These forms of malignancy have little effect on life expectancy.

Apprehension concerning worsening of hypertension and thromboembolic disease appears to be due to reports of the effects of estrogen-progestogen oral contraceptives during the reproductive years and not to estrogen use in postmenopausal women. There is no conclusive evidence that low-dose estrogen therapy after menopause

increases the incidence or the severity of breast cancer or hypertension, but the risk for venous thromboembolism is slightly increased. Low-dose estrogen treatment after menopause does not appear to influence the development of atherosclerosis, myocardial infarction, or stroke. Strong evidence suggests that, in fact, estrogens may decrease the incidence of death from myocardial infarction. There is a slightly increased risk for the development of gallbladder disease with postmenopausal estrogen use.

A reasonable approach to the postmenopausal use of estrogens is as follows: (1) For long-term use, estrogens should be given in the minimal effective doses (0.625 mg conjugated estrogen orally or 1.0 mg micronized estradiol or transdermal estradiol 0.05 to 1.0 mg in a formulation that is changed every 3.5 days or every week). For women with an intact uterus, it is the practice in some clinics to give estrogens alone for 15 days and estrogen plus a daily progestogen dose for the remainder of the month. The most common regimens involve continuous estrogen plus low-dose continuous progestogen. (2) Such replacement therapy is indicated routinely in women undergoing premature menopause (surgically induced or spontaneous). (3) Estrogen therapy is also indicated routinely in women of all ages who have severe hot flashes or symptomatic atrophy of the urogenital epithelium. Hot flashes rarely persist for longer than 7 years, so, if therapy is given for this purpose, its duration can be limited. (4) In women who have had a hysterectomy, the potential benefits of treatment appear to outweigh the dangers, and in such women cyclic or continuous estrogen without progestogen is recommended. Whether estrogens should be given routinely to all women with intact uteri is an unsettled question, but the authors prescribe it in the absence of contraindications in hopes of ameliorating osteoporosis and reducing the risk of cardiovascular disease. (5) Raloxifene is given as a 60-mg tablet daily when the goal is to provide protection against bone loss without incurring additional risk of estrogen-dependent breast cancer. Each woman receiving estrogens must be monitored indefinitely at yearly intervals.

Induction of Ovulation SeeChap. 54

OTHER DISORDERS OF THE FEMALE REPRODUCTIVE TRACT

VULVA

Most disorders of the vulva are due to venereal disease, most commonly syphilis (painless chancre), condylomata acuminata (venereal warts), and herpes vulvitis (painful ulcers; Chap. 132). All other lesions of the vulva, particularly in older women, must be biopsied. Early biopsy of cancer of the vulva is mandatory, because when it becomes symptomatic (pruritus and bleeding), it has often progressed to an advanced stage.

VAGINA

Infections of the vagina usually present as vaginal discharge and pruritus. The most frequent organisms are *Trichomonas*, *Candida albicans*, and *bacterial vaginalis* (Chap. 132). The diagnosis is made by microscopic examination of the discharge, and appropriate therapy can be instituted using vaginal or oral antibiotics.

Abnormalities of the vagina and cervix in female offspring of women given

diethylstilbestrol during pregnancy include adenosis of the vagina and structural abnormalities of the vagina, cervix, and uterus; the risk of developing a rare vaginal cancer (adenocarcinoma, clear cell type) is increased (2 per 10,000 exposed women). Periodic examination of women at risk should begin at age 12 to 14, and reexamination should be done after any episode of abnormal bleeding.

CERVIX

Preinvasive lesions of the cervix (also known as *cervical intraepithelial neoplasia*) and invasive carcinoma of the cervix can be detected reliably by obtaining a Papanicolaou (Pap) smear.

Evaluation of the Pap Smear The incidence of invasive cervical cancer has declined as a result of Pap smear screening. In the United States, approximately 2 to 3 million abnormal Pap smears are found each year. Most represent low-grade lesions but require appropriate follow-up. The follow-up of abnormal Pap smears requires an understanding of the Bethesda system for evaluating such smears (see below) and of the limitations of cytologic screening systems. Further evaluation may require repeat cytologic examination, colposcopy, or both.

Current Screening Recommendations Risk factors for cervical neoplasia include a history of multiple sexual partners, coitus beginning at an early age, a history of infection with human papilloma virus (HPV), infection with HIV or another immunosuppressed state, and a history of cancer of the lower genital tract. Cervical cancer screening is recommended annually beginning at 18 years of age or when the woman becomes sexually active, if earlier than age 18. "Less frequent" screening is performed when three consecutive, negative, satisfactory annual Pap smears have been obtained or if the woman is in a low-risk category. There is no upper age limit for screening, because the prevalence of invasive cancer shows a linear increase with age, most of these cancers being diagnosed after age 50. Even after hysterectomy, annual screening should be performed if there is a history of abnormal Pap smears or other lower genital tract neoplasia.

The Bethesda System of Cytologic Examination Pap smears are evaluated in regard to the adequacy of the specimen (satisfactory for evaluation, satisfactory but limited, or unsatisfactory for evaluation because of a stated reason), the general diagnosis (normal or abnormal), and a descriptive diagnosis if the smear is abnormal. The descriptive diagnoses include benign cellular changes, reactive cellular changes, and epithelial cell abnormalities, the latter including (1) atypical squamous cells of undetermined significance (ASCUS); (2) low-grade squamous intraepithelial lesion (LSIL), which is further categorized to include HPV infection, cervical intraepithelial neoplasia (CIN 1), and high-grade squamous intraepithelial lesion (HSIL, which is itself subdivided into CIN 2 and CIN 3); and (3) squamous cell carcinoma.

Guidelines for the Management of Women with Abnormal Pap Smears For ASCUS smears that are unqualified or suggest a reactive process, a repeat smear should be obtained every 4 to 6 months for 2 years until three consecutive negative smears have been obtained. For ASCUS smears that are unqualified but have severe inflammation, any specific cause should be treated, and the smear should be repeated in 2 to 3

months; because invasive carcinoma can be obscured by severe inflammation, clinical evaluation is mandatory. For postmenopausal women not using hormone replacement, a course of topical estrogen should be given before the test is repeated. For LSIL smears, the Pap test is repeated every 4 to 6 months for 2 years until three consecutive negative smears have been obtained; treatment ofHPV is of no established benefit, and there is a high rate of regression of LSIL, so that in compliant, low-risk individuals, the outcome is usually favorable. If LSIL is persistent, colposcopy with directed biopsy is performed, and endocervical curettage is undertaken if a specific diagnosis is made by biopsy. Cervical cone biopsy or loop electrosurgical excision procedures are performed for higher-grade lesions such as HSIL. If cervical cancer is diagnosed by biopsy, clinical staging is performed, and the patient is treated with radiation therapy or surgery.

UTERUS

Only 40% of cases of endometrial adenocarcinoma are detected by Pap smear. In women at high risk for endometrial carcinoma (because of obesity, a history of chronic anovulatory cycles, diabetes mellitus, hypertension, or estrogen treatment), yearly endometrial sampling should be performed. Measurement of endometrial thickness by sonography can indicate which patients are at risk for endometrial pathology. Endometrial thickness <5 mm is rarely associated with either hyperplasia or cancer. Low-dose oral estrogen therapy rarely causes breakthrough or withdrawal bleeding in postmenopausal women. Therefore, irrespective of whether the patient is using estrogen therapy, the occurrence of postmenopausal bleeding makes it mandatory to obtain a tissue diagnosis by either endometrial sampling or curettage to exclude endometrial cancer.

One of the most common disorders of the uterus and the most frequent tumor of women (one of four women affected) is the uterine leiomyoma, or fibroid tumor. Three-fourths of women with leiomyoma are asymptomatic, and the diagnosis is made on routine pelvic examination. When the tumor is associated with excessive menstrual blood loss, is large or fast-growing, or causes significant pelvic pain (Chap. 52), the preferred treatment is hysterectomy if there is no desire for further childbearing. In young women, myomectomy is sometimes indicated when infertility or repeated fetal wastage is a manifestation or where future childbearing is desired.

FALLOPIAN TUBES AND OVARIES

Infectious pelvic inflammatory disease is a common disorder of the fallopian tubes and usually becomes symptomatic after a menstrual period; the symptoms include fever, chills, abdominal pain, and vaginal discharge, and pelvic tenderness on physical examination is common. The initiating organism most often is *Chlamydia trachomatis* or *Neisseria gonorrhoeae*, but tuboovarian abscess and sterility are probably caused by mixed aerobic and anaerobic superinfections and require wide-spectrum antibiotic treatment (Chap. 133).

Endometriosis is a benign disorder characterized by the presence and proliferation of endometrial tissue (stroma and glands) outside the endometrial cavity. The clinical manifestations are variable. Endometriosis occurs most commonly between the ages of 30 and 40 and is found incidentally at the time of surgery in approximately one-fifth of all

gynecologic operations. The fertility rate is reduced in affected women. The disorder usually involves the posterior cul-de-sac or the ovaries and can give rise to ovarian enlargement (endometriomas), although it may involve distant sites (lung, umbilicus). The major symptom is pelvic pain, characteristically dysmenorrhea (Chap. 52). However, the frequency and severity of symptoms correlate poorly with the extent of disease. Other manifestations include dyspareunia, pain with defecation, and infertility. The characteristic physical findings are multiple tender nodules palpable along the uterosacral ligament at the time of rectal-vaginal examination, a posteriorly fixed uterus, or enlarged, cystic ovaries. The diagnosis can only be confirmed by direct visualization, usually at diagnostic laparoscopy. Treatment depends on the degree of involvement and the desires of the patient and includes observation for mild disease with no associated infertility or pain, hormonal suppressive therapy, conservative surgery by laparoscopy or laparotomy if fertility is desired, or removal of the uterus, tubes, and ovaries in severe disease. Endometriosis is rare after the menopause.

Any adnexal mass that persists for more than 6 weeks or is larger than 6 cm must be evaluated. Although ovarian cysts and neoplasms are the most common pelvic adnexal masses (see above), tumors of the fallopian tubes, uterus, gastrointestinal tract, or urinary tract should also be considered. Sonography or radiographic evaluation is often helpful in identifying the nature of the adnexal mass prior to surgical exploration.

337. ENDOCRINE DISORDERS OF THE BREAST - *Jean D. Wilson*

The breasts are the site of fatal and preventable cancer in women and provide clues to underlying systemic illness in both men and women. Consequently, examination of the breasts is an important part of the physical examination. It is the duty of every physician to distinguish the abnormal from the normal at the earliest possible stage and to seek referral if there is any doubt.**For discussion of cancer of the breast, see Chap. 89.*

ENDOCRINE CONTROL OF THE BREAST

There is no histologic or functional difference in the breasts of prepubertal boys and girls, but a profound sexual dimorphism in breast development ensues at the time of puberty. The endocrine control of female breast development is illustrated inFig. 337-1. Growth of the female breast at puberty is mediated primarily by estradiol, which induces the enlargement, division, and elongation of the tubular duct system and maturation of the nipples. Administration of estrogen to men is equally effective in this regard. To produce true alveolar development at the ends of the ducts, however, the synergistic action of progesterone is required. Within the gland a variety of mediators influence epithelial cell division and differentiation, including stimulatory factors such as the insulin-like growth factors, transforming growth factor a, and epidermal growth factor and inhibitory factors such as transforming growth factor b. Once the anatomic development of the ducts and alveoli is complete, the continued action of estrogen and progesterone is not required for lactation itself.

The endocrine control of milk formation is complex, requiring, in addition to appropriate priming by estrogen and progesterone, lactogenic hormones and the permissive action of glucocorticoid, insulin, thyroxine, and, in some species, growth hormone. There are two lactogenic hormones: (1) human placental lactogen (hPL, or chorionic somatomammotropin) and (2) prolactin. hPL is secreted in large amounts by the placenta during the latter part of gestation and prepares the breast for milk production. It disappears from the maternal (and fetal) circulation shortly after termination of pregnancy. The secretion of pituitary prolactin (Chap. 328) rises during pregnancy and plays the critical role in the initiation and maintenance of lactation in the puerperium. During late pregnancy and lactation, 60 to 80% of the anterior pituitary may consist of prolactin-secreting lactotrope cells, reflecting the stimulatory effects of estrogen on these cells.

Unlike most pituitary hormones, prolactin secretion is controlled predominantly by tonic inhibition. Under basal conditions inhibitory hypothalamic hormones, the most important being dopamine, are delivered from the central nervous system to the pituitary via the hypothalamic portal system and inhibit the release of prolactin into the blood (Chap. 328). Most factors that influence prolactin secretion do so by affecting the synthesis or release of dopamine. Basal prolactin levels in the mother fall after delivery, but prolactin secretion is enhanced by stimulation of the breasts, such as the act of nursing (the so-called sucking reflex), a phenomenon that is probably mediated by the reflex release of oxytocin, which acts as a prolactin-releasing factor. Prolactin binds to specific receptors on the cell surface of the breast acinar cells and activates the JAK-STAT signal transduction cascade to stimulate the synthesis ofb-casein, whey acidic protein, and other milk constituents. In the postgestational state, the normal lactating woman

forms about a liter of milk per day containing 38 g fat, 70 g lactose, and 12 g protein. Lactation can be suppressed by the administration of estrogens or diethylstilbestrol, which inhibit milk production by direct effects on the breast, or dopamine agonists such as bromocriptine, which inhibit prolactin secretion by the pituitary. Alternatively, if a woman does not nurse or use breast pumps postpartum, lactation usually ceases in 1 to 2 weeks.

GALACTORRHEA

Galactorrhea refers to the nonpuerperal discharge of milk-containing fluid from the breast. The definition of exactly what constitutes galactorrhea is not always clearly defined in the literature. According to the studies of Friedman and Goldfein, breast secretions are absent in normal, regularly menstruating nulligravid women. However, breast secretions can be demonstrated in a fourth of normal women who have been pregnant in the past; thus breast secretions in small amounts may be of no clinical significance in these instances. Spontaneous leakage of milk from the breasts is usually of more significance than milk that must be expressed. When the secretion is milky or white, it is safe to assume that it contains fat, casein, and lactose and is in fact milk; the concentration of milk constituents may increase after repeated sampling. When the secretion is brown or greenish, it rarely contains normal milk constituents and consequently may not result from an underlying endocrinopathy. Bloody discharges may be due to neoplasms of the breast. With these issues in mind, galactorrhea can be defined as inappropriate production of milk that is persistent or worrisome to the patient, recognizing that in some instances no underlying pathology may be demonstrated.

Since the action of a lactogenic hormone is necessary for the initiation of milk production, it is logical to consider galactorrhea as a consequence of deranged prolactin physiology. However, as indicated above, a complex hormonal milieu is necessary for lactation. Milk production does not take place in many instances in which prolactin is elevated, both in men and in women who have not been exposed to the necessary hormonal environment. As a consequence, hyperprolactinemia is more common than galactorrhea. Furthermore, while enhanced prolactin secretion is necessary for the initiation of lactation, continued production can be maintained in the presence of minimally or intermittently elevated prolactin levels so that basal plasma prolactin levels are not always elevated in patients with galactorrhea. In some such women prolactin levels may be elevated during sleep or with stimulation of the nipple; in others, hyperprolactinemia may have been present transiently. Perhaps the strongest evidence for a critical role for prolactin in galactorrhea is the fact that administration of dopaminergic agents that suppress plasma prolactin levels corrects galactorrhea even when the basal plasma prolactin levels are normal.

Differential Diagnosis Galactorrhea can be due to failure of the normal hypothalamic inhibition of prolactin release, to increased prolactin-releasing factor(s), or to autonomous prolactin secretion by tumors (Table 337-1). Pituitary stalk section, whether traumatic or secondary to the mass effects of sellar tumors, results in increases in prolactin secretion due to interruption in the delivery of dopamine to the pituitary. Likewise, many drugs that influence the central nervous system (CNS) (including virtually all psychotropic agents, methyldopa, reserpine, and antiemetics) enhance prolactin release, presumably by inhibiting synthesis, release, or action of dopamine.

Estrogens increase prolactin secretion, but estrogen withdrawal (as in the discontinuation of oral contraceptives) may also trigger the onset of galactorrhea. CNS diseases outside the pituitary can cause galactorrhea presumably by interfering with the production or delivery of dopamine to the pituitary (CNS sarcoidosis, craniopharyngioma, pinealoma, encephalitis, meningitis, hydrocephalus, hypothalamic tumors).

In primary hypothyroidism, galactorrhea results from the enhanced production of thyrotropin-releasing hormone (TRH), which also stimulates prolactin release; thyroid hormone replacement corrects the galactorrhea. A similar mechanism, involving enhanced secretion of oxytocin, may cause the galactorrhea that follows breast surgery or breast trauma.

Enhanced prolactin release can also occur from pituitary or nonpituitary tumors. Three types of pituitary tumors (Chap. 328) can cause galactorrhea: (1) pure prolactin-secreting micro- or macroadenomas, (2) mixed tumors that secrete both growth hormone and prolactin and cause acromegaly with galactorrhea, and (3) large null cell adenomas. The latter may interfere with the delivery of dopamine to the pituitary, either by mass effects on the hypothalamus or by compressing the pituitary stalk. Excess growth hormone secretion, in the absence of hyperprolactinemia, on occasion causes galactorrhea. Rarely, prolactin is secreted by bronchogenic carcinomas, and hydatidiform moles and choriocarcinomas may secrete placental lactogen.

In series involving several hundred patients with galactorrhea, a pituitary tumor was identified in about one-fourth, other known causes were identified in another fourth or fifth, and the remaining half fell into the idiopathic category. Many of the latter group ultimately developed prolactin-secreting pituitary tumors, some probably had subtle disorders of hypothalamic function, and in others a drug-related cause may have been missed. The fact remains that no satisfactory diagnosis is reached in many patients. When menses are normal, the likelihood of establishing a cause for galactorrhea is poor.

Galactorrhea is unusual in men, even in the presence of profound elevations of plasma prolactin; when it does occur, it is usually upon the background of a feminizing state (see below).

Diagnostic Evaluation If hyperprolactinemia is present, the evaluation is fundamentally that of a pituitary tumor once drug causes and hypothyroidism are excluded (Chap. 328). Even when a specific cause cannot be identified and the diagnosis of idiopathic galactorrhea is made by exclusion, it is necessary to remember that pituitary tumors may subsequently become manifest. The higher the prolactin values and the more persistent the galactorrhea, the greater is the likelihood of such a development.

TREATMENT

Breast binders can be effective in patients with mild galactorrhea of unknown etiology, presumably by preventing stimulation of the nipple and the consequent perpetuation of lactation. The aim of treatment in other instances is to correct the elevated prolactin

level, and treatment of a pituitary tumor, cessation of causative drugs, or correction of hypothyroidism is often followed by the disappearance of galactorrhea. Dopamine agonists that suppress plasma prolactin have been used to treat idiopathic hyperprolactinemia, prolactin-secreting tumors of the pituitary (Chap. 328), and even normoprolactinemic galactorrhea. These drugs suppress lactation and may cause resumption of menstrual cycles (and even fertility) in women with amenorrhea and galactorrhea.

GYNECOMASTIA

Enlargement of the male breast, or *gynecomastia*, can be a normal physiologic phenomenon at certain times of life or the result of several pathologic states (Table 337-2). A central issue in the evaluation of breast tissue in adult men is the separation of the normal from the abnormal, as gynecomastia can be an important indicator of underlying disease. It is sometimes difficult to distinguish true breast tissue enlargement from adipose tissue (*lipomastia*). True glandular tissue is often palpable, especially around the areolae, as it is firmer and contains cordlike features that are distinct from the texture of adipose tissue. In difficult cases, true gynecomastia can be identified by mammography or ultrasonography. In this discussion, we shall assume that any palpable breast tissue in men (except for the three physiologic states see below) can be due to an underlying endocrinopathy and deserves, at a minimum, a limited evaluation.

Early gynecomastia is characterized by proliferation in the breast of both the fibroblastic stroma and the duct system, which elongates, buds, and duplicates. As gynecomastia persists, progressive fibrosis and hyalinization are associated with regression of epithelial proliferation and, eventually, a decrease in the number of ducts. When the cause of the gynecomastia is corrected early in the course, resolution occurs by reduction in size and epithelial content with gradual disappearance of the ducts, leaving hyaline bands that eventually disappear.

Growth of the breast in men, as in women, is mediated by estrogen and results from an decrease in the ratio of active androgen to estrogen. As described inChap. 335, estradiol formation in normal men occurs principally by the conversion of circulating androgen to estrogen in extraglandular tissues; the normal ratio of the two hormones in plasma is about 300:1. Growth of the breast ensues in men when the normal ratio decreases as the result of diminished testosterone production or action, enhanced estrogen formation, or both processes occurring simultaneously.

Physiologic Gynecomastia In the *newborn* transient enlargement of the breast is due to the action of maternal and/or placental estrogens. The enlargement usually disappears in a few weeks but may persist longer. *Adolescent* gynecomastia is common at some time during puberty. The median age of onset is 14; it is often asymmetric or transiently unilateral, frequently tender, and it regresses so that by age 20 only a small number of men have palpable vestiges of glandular tissue in one or both breasts. Although the origin of the excess estrogen has not been identified, the onset of gynecomastia correlates with the increase in adrenal androgens at adrenarche. In addition, the luteinizing hormone (LH) stimulation of androgen synthesis by the Leydig cell in early puberty may be associated with transient elevations of plasma estradiol so that the ratio of potent androgen to estrogen is low prior to the completion of puberty.

Gynecomastia of aging also occurs in 40% or more of otherwise healthy elderly men. A likely explanation is the increase with age in the conversion of androgens to estrogens in extraglandular tissues. Abnormal liver function or drug therapy may be contributing causes in such men.

Pathologic Gynecomastia Pathologic gynecomastia can result from one of three basic mechanisms: deficiency in testosterone production or action (with or without a secondary increase in estrogen production), increase in estrogen production, or drugs (Table 337-2). Most of the disorders that cause primary and secondary testicular failure are discussed inChap. 335. The fact that deficient testosterone production can cause gynecomastia is illustrated by the syndrome of congenital anorchia in which normal (or slightly low) estradiol levels, in the presence of profoundly decreased testosterone production, results in florid gynecomastia. Decreased testosterone production is also responsible for gynecomastia in some men with Klinefelter syndrome or testicular failure of other causes. In the disorders of androgen resistance, such as testicular feminization, deficient androgen action and increased testicular estrogen production are both present.

A primary increase in estrogen production can result from a variety of causes. Increased secretion of testicular estrogen may result from elevations in plasma gonadotropins, as in cases of aberrant production of chorionic gonadotropin by testicular tumors or by bronchogenic carcinomas, from the ovarian elements in the gonads of men with true hermaphroditism, or as the result of formation by testicular tumors (particularly Leydig and Sertoli cell tumors). Increased conversion of androgen to estrogens in extraglandular tissues can be due either to increased availability of substrate (androstenedione) for extraglandular estrogen formation (congenital adrenal hyperplasia, hyperthyroidism, and most feminizing adrenal tumors), or to diminished catabolism of androstenedione (liver disease) so that estrogen precursors are shunted to aromatase in peripheral sites. Extraglandular aromatase can be increased in tumors of the liver or adrenal gland and rarely as a result of an inherited disorder manifested by gynecomastia in affected males and macromastia in females.

Drugs can cause gynecomastia by several mechanisms. Many drugs either act directly as estrogens or cause an increase in plasma estrogen activity (e.g., in men receiving diethylstilbestrol for prostatic carcinoma and in transsexuals in preparation for sex-change operations). Boys and young men are particularly sensitive to estrogen and can develop gynecomastia after the use of dermal ointments containing estrogen or after the ingestion of milk or meat from estrogen-treated animals. The gynecomastia of digitalis ingestion is usually attributed to an estrogen-like side effect of the drug, but it occurs most commonly in men with abnormal liver function. A second mechanism of drug-induced gynecomastia is illustrated by clomiphene and human chorionic gonadotropin (hCG), which cause enhanced testicular secretion of estrogen. Other drugs cause gynecomastia by interfering with testosterone synthesis (ketoconazole and alkylating agents) and/or testosterone action, for instance, by blocking the binding of androgen to its receptor protein in target tissues (spironolactone and cimetidine). Finally, drugs that cause gynecomastia by mechanisms that have not been defined include busulfan, ethionamide, isoniazid, methyldopa, tricyclic antidepressants, penicillamine, omeprazole, calcium channel blocking agents, angiotensin-converting enzyme inhibitors, metoclopramide, antiretroviral agents, diazepam, marijuana, and heroin. In some instances, the feminization is due to effects of drugs on liver function.

Treatment with growth hormone can cause gynecomastia even in prepubertal boys, suggesting that growth hormone itself or one of the insulin-like growth factors has a direct effect on the breast.

Diagnostic Evaluation The evaluation of patients with gynecomastia should include: (1) a careful drug history; (2) measurement and examination of the testes (if both are small, a chromosomal karyotype should be obtained; if the testes are asymmetric, a workup for testicular tumor should be instituted); (3) evaluation of liver function; and (4) endocrine workup to include measurement of serum androstenedione or 24-h urinary 17-ketosteroids (usually elevated in feminizing adrenal states), measurement of plasma estradiol andhCG(helpful if elevated but usually normal), and measurement of plasmaLH and testosterone. If LH is high and testosterone is low, the diagnosis is usually testicular failure; if LH and testosterone are both low, the diagnosis is most likely increased primary estrogen production (e.g., a Sertoli cell tumor of the testis), provided hypogonadotropic hypogonadism has been excluded; and if both LH and testosterone are elevated, the diagnosis is either an androgen-resistance state or a gonadotropin-secreting tumor.

A satisfactory diagnosis can be made in only half or fewer of patients referred for gynecomastia. This implies either that the diagnostic techniques are not sufficiently refined to recognize mild disturbances, that many causes of gynecomastia are as yet undefined, that the causes may be transient and difficult to diagnose, or that gynecomastia may in some instances be normal rather than due to a pathologic state. Because of the problem of separating the normal from the abnormal, gynecomastia should probably be worked up routinely only if the drug history is negative, the breast is tender (indicating rapid growth), or the breast mass is >4 cm in diameter. However, the decision to perform an endocrine evaluation depends on the clinical context. For example, gynecomastia associated with signs of underandrogenization should always be evaluated. A firm or hard breast mass should raise suspicion of male breast cancer (Chap. 89).

TREATMENT

When the primary cause can be identified and corrected, the breast enlargement usually subsides promptly and eventually disappears. For example, androgen replacement therapy may produce dramatic improvement in men with testicular insufficiency. However, if the gynecomastia is of long duration (and fibrosis has replaced the original ductal hyperplasia), correction of the primary defect may not be followed by resolution. In such instances and when the primary cause cannot be corrected, surgery is the only effective therapy. Indications for surgery include several psychological and/or cosmetic problems, continued growth or tenderness, or suspected malignancy. Although the relative risk of carcinoma of the breast is increased in men with gynecomastia, it is rare nevertheless. Prophylactic radiation of the breasts prior to the institution of diethylstilbestrol or estrogen therapy is effective in preventing gynecomastia and has a low complication rate. In patients who have painful gynecomastia and who are not candidates for other therapy, treatment with antiestrogens such as tamoxifen may be indicated.

338. DISORDERS OF SEXUAL DIFFERENTIATION - *Jean D. Wilson*, *James E. Griffin*

Sexual differentiation is a sequential and ordered process. *Chromosomal sex*, established at the moment of fertilization, determines *gonadal sex*, and gonadal sex, in turn, causes the development of *phenotypic sex*, in which the male or female urogenital tract is formed (Fig. 338-1). A disturbance of any step in this process during embryogenesis may impair sexual differentiation (Table 338-1). Known causes of such disorders include environmental insults as in the ingestion of a virilizing drug during pregnancy, nonfamilial aberrations of the sex chromosomes as in 45,X gonadal dysgenesis, birth defects of multifactorial etiology as in most cases of hypospadias, and disorders due to single gene mutations as in the testicular feminization syndrome.

Limitations of knowledge make it necessary to make empirical assignments as to the type of derangement in some disorders, but specific diagnoses can usually be made as the result of genetic, endocrine, phenotypic, and chromosomal assessment. As a consequence, gender assignment in the newborn is usually appropriate, even in extreme instances of ambiguous genitalia.

NORMAL SEXUAL DIFFERENTIATION

The first event in sexual differentiation is the establishment of chromosomal sex, the heterogametic sex (XY) being male and the homogametic sex (XX) female. The embryos of both sexes then develop in an identical fashion until approximately 40 days of gestation.

The second phase of sexual differentiation is the conversion of the indifferent gonad into a testis or an ovary. No matter how many X chromosomes are present (as in 47,XXY, 48,XXXY, etc.), a testis will develop as long as a normal Y chromosome is present. Differentiation of the indifferent gonad into a testis is initiated by the actions of a single gene on the short arm of the Y chromosome (*SRY*); expression of an *SRY* transgene into female mice causes them to develop as males. The gene encodes a DNA-binding protein, but the mechanism by which *SRY* promotes testicular development remains poorly defined. At least four additional genes are also necessary for normal testicular development: (1) the Wilms' tumor-related gene (*WT1*), (2) steroidogenic factor 1 (*SF1*), (3) *SRY*-related HMG-box 9 (*SOX9*), and (4) *d*osage-sensitive sex reversal-*a*drenal hypoplasia congenita critical region on the *X* chromosome gene *1* (*DAX1*). These genes each encode putative transcription factors that regulate the expression of genes necessary for gonadal survival; mutations in *SRY* or any of the four downstream genes impair testicular development. It remains unclear if there are analogous "ovarian-determining genes," or if ovarian development is a default pathway in the absence of testicular determination genes. Mutations in some of the genes noted above (e.g., *SF1*) also prevent normal ovarian development.

The final process in sexual differentiation, the translation of gonadal sex into phenotypic sex (formation of the male or female urogenital tracts), is the consequence of the type of gonad formed and the endocrine secretions of the fetal gonads. The internal urogenital tract is derived from the wolffian and mullerian ducts that exist side by side in early embryos of both sexes (Fig. 338-1*A*). In the male the wolffian ducts give rise to the

epididymides, vasa deferentia, and seminal vesicles, and the mullerian ducts disappear. In the female the mullerian ducts are converted into the fallopian tubes, uterus, and upper vagina, and the wolffian ducts regress. The external genitalia and urethra in the two sexes develop from common anlage -- the urogenital sinus and the genital tubercle, folds, and swellings (Fig. 338-1*B*). The urogenital sinus gives rise to the prostate and prostatic urethra in the male and to the urethra and lower portion of the vagina in the female. The genital tubercle gives rise to the glans penis in the male and the clitoris in the female. The urogenital swellings become the scrotum or the labia majora, and the urethral folds form the labia minora or fuse to form the shaft of the penis and the male urethra.

In the absence of the testes, as in the normal female or in the male embryo castrated prior to the onset of gonadal differentiation, phenotypic sex develops along female lines. Thus, masculinization of the fetus is induced by hormones from the fetal testes, whereas female development does not require the presence of the ovary. Phenotypic sex normally conforms to chromosomal sex. That is, chromosomal sex determines gonadal sex, and gonadal sex, in turn, controls phenotypic sex.

Formation of the male phenotype is vested in the action of three hormones. Two -- antimullerian hormone (AMH) and testosterone -- are secreted by the fetal testis. AMH [also termed *mullerian-inhibiting substance* (MIS)] is a protein that suppresses the mullerian ducts and prevents development of the uterus and fallopian tubes in the male. Testosterone acts directly to virilize the wolffian duct and is the precursor for the third embryonic male hormone, dihydrotestosterone (Chap. 335), which promotes development of the male urethra and prostate and formation of the penis and scrotum. Testosterone and dihydrotestosterone induce formation of the male urogenital tract during fetal life by acting through the same nuclear androgen receptor by which they act in postembryonic life (Chap. 335).

The secretion of testosterone by the fetal testes approaches a maximum by the tenth week of gestation, and formation of the sexual phenotypes is largely completed by the end of the first trimester. During the latter phases of gestation, the ovarian follicles develop and the vagina matures in the female, and testicular descent and phallic growth take place in the male.

DISORDERS OF CHROMOSOMAL SEX

Disorders of chromosomal sex (Table 338-2) occur when the number or structure of the X or Y chromosomes is abnormal (Chap. 66).

KLINEFELTER SYNDROME

Clinical Features Klinefelter syndrome is characterized by small, firm testes, azoospermia, gynecomastia, and elevated levels of plasma gonadotropins in men with two or more X chromosomes. The common karyotype is either a 47,XXY chromosomal pattern (the classic form) or 46,XY/47,XXY mosaicism. It is the most frequent major abnormality of sexual differentiation, the incidence being around 1 in 500 men.

Prepubertally, the testes are small but otherwise appear normal. After puberty, the

disorder is manifest as infertility, gynecomastia, or occasionally underandrogenization (Table 338-3). Hyalinization of the seminiferous tubules and azoospermia are consistent features of the 47,XXY variety. The small, firm testes are usually <2 cm and always<3.5 cm in length (corresponding to 2- and 12-mL volume, respectively). Longer legs cause increased mean height. Gynecomastia is common and ordinarily develops during adolescence, is generally bilateral and painless, and may become disfiguring (Chap. 337). Obesity and varicose veins occur in one-third to one-half, and leg ulcers are associated with deficiency of plasminogen activator inhibitor-1. The diagnosis is made most frequently in boys with developmental delay and/or learning disabilities and social maladjustment; abnormalities of thyroid function, diabetes mellitus, and pulmonary disease are also common. The risk of breast cancer is 20 times that of normal men (but only about a fifth that in women). Most have male psychosexual orientation and function sexually as normal men.

About 10% of the patients have the mosaic form, as estimated by chromosomal karyotypes on peripheral blood leukocytes. The frequency of this variant may be underestimated, since chromosomal mosaicism can be present in the testes when the peripheral leukocyte karyotype is normal. The mosaic form is usually not as severe as the 47,XXY variety, and the testes may be normal (Table 338-3). The endocrine abnormalities are less severe, and gynecomastia and azoospermia are less common, and occasional mosaic individuals are fertile. In some the diagnosis may not be suspected because the manifestations are so mild.

Approximately 30 additional variants of Klinefelter syndrome have been described, including those with uniform cell lines (such as 48,XXYY, 48,XXXY, and 49,XXXXY) and a variety of mosaicisms of the X chromosome with or without associated structural abnormalities of the X. In general, the greater the chromosomal abnormality the more severe the manifestations.

Pathophysiology The classic form is due to meiotic nondisjunction of the chromosomes during gametogenesis (Fig. 338-2). About 40% of the responsible meiotic nondisjunctions occur during spermatogenesis, and 60% occur during oogenesis. Advanced maternal age is a predisposing factor. The mosaic form is thought to result from chromosomal mitotic nondisjunction after fertilization of the zygote and can take place in either a 46,XY zygote (Fig. 338-2) or a 47,XXY zygote. The latter situation, double nondisjunction (meiotic and mitotic), may be the usual cause and thus explain why the mosaic form is less frequent than the classic disorder.

Levels of plasma follicle stimulating hormone (FSH) and luteinizing hormone (LH) are usually high; FSH shows the best discrimination because of the consistent damage to the seminiferous tubules. The plasma testosterone level averages half normal but may overlap the normal range. Mean plasma estradiol levels are elevated; early, estradiol secretion by the testes may increase in response to the elevated plasma LH level, but the testicular secretion of estradiol and testosterone eventually declines. Elevated plasma estradiol late in the course is probably due both to decreased metabolic clearance and increased conversion of testosterone to estradiol in extragonadal tissues. The net result both early and late is a variable degree of feminization and virilization. Feminization, including gynecomastia, depends on the ratio of circulating estrogen to androgen (relative or absolute), and individuals with low plasma testosterone and high

plasma estradiol levels are more likely to develop gynecomastia (Chap. 337). Men with untreated Klinefelter syndrome may have enlarged pituitary glands, presumably due to hyperplasia of the gonadotrophs due to inadequate testosterone feedback.

TREATMENT

In men with some sperm production, or in whom spermatids can be recovered from testicular biopsy, fertility is possible with in vitro fertilization (Chap. 335). Gynecomastia should be treated surgically. Some underandrogenized men benefit from supplemental androgen, particularly in those with decreased bone density, but such treatment may worsen the gynecomastia, presumably by providing increased substrate for estrogen formation in peripheral tissues. Testosterone should be injected in the form of testosterone cypionate or testosterone enanthate or administered via the transdermal route (Chap. 335). Following the administration of testosterone, the plasmaLH level returns to normal only after several months, if at all.

XX MALE SYNDROME

A 46,XX karyotype is found in approximately 1 in 20,000 phenotypic males. The findings resemble those in Klinefelter syndrome: the testes are small and firm (generally<2 cm), gynecomastia is frequent, the penis is normal to small in size, azoospermia and hyalinization of the seminiferous tubules are usual, no female urogenital structures are present, psychosexual identification is male, mean plasma testosterone level is low, plasma estradiol level is elevated, and plasma gonadotropin levels are high. Affected individuals differ from typical Klinefelter patients only in that average height is less than in normal men, the incidence of cognitive problems is not increased, and the incidence of hypospadias is increased.

The majority of XX males have Y-related DNA (e.g., detected by polymerase chain reaction of the *SRY* gene); thus an X-Y or Y-autosome translocation appears to be the common cause. Some 46,XX males are negative for all Y-specific DNA, suggesting that their disorder is due to mutation in a downstream, autosomal or X-linked gene involved in development of the testes. The management is similar to that of Klinefelter syndrome.

GONADAL DYSGENESIS (TURNER SYNDROME)

Clinical Features Gonadal dysgenesis is characterized by primary amenorrhea, sexual infantilism, short stature, multiple congenital anomalies, and bilateral streak gonads in phenotypic women with any of several defects of the X chromosome. This condition should be distinguished from (1) mixed gonadal dysgenesis in which a unilateral testis and a contralateral streak gonad may be present; (2) pure gonadal dysgenesis in which bilateral streak gonads are associated with a normal 46,XX or 46,XY karyotype, normal stature, and primary amenorrhea; and (3) the Noonan syndrome, an autosomal dominant disorder in both sexes characterized by webbed neck, short stature, congenital heart disease, cubitus valgus, and other congenital defects despite normal karyotypes and normal gonads.

The incidence is estimated at 1 in 3000 newborn females; the prenatal incidence may be as high as 2% of all human conceptuses, only a small fraction of whom survive to

term. The diagnosis is made either at birth because of the associated anomalies or at puberty when amenorrhea and failure of sexual development are noted in conjunction with the associated anomalies. Gonadal dysgenesis is the most common cause of primary amenorrhea, accounting for a third of such patients. The external genitalia are unambiguously female but remain immature, and there is no breast development unless exogenous estrogen is given. The fallopian tubes and uterus are immature, and bilateral streak gonads are present in the broad ligaments. Primordial germ cells are present transiently during embryogenesis but disappear because of an accelerated rate of atresia (Chap. 336). After the age of expected puberty, these streaks lack identifiable follicles and ova and consist of fibrous tissue that is indistinguishable from normal ovarian stroma.

The somatic abnormalities primarily involve the skeleton and connective tissue. Lymphedema of the hands and feet, webbing of the neck, low hairline, redundant skin folds on the back of the neck, a shieldlike chest with widely spaced nipples, and growth retardation are features that suggest the diagnosis in infancy. Micrognathia, epicanthal folds, prominent low-set or deformed ears, a fishlike mouth, and ptosis may be present. Short fourth metacarpals are present in half, and 10 to 20% have coarctation of the aorta. In adults, the average height rarely exceeds 150 cm. Associated conditions include renal malformations, pigmented nevi, hypoplastic nails, tendency to keloid formation, perceptive hearing loss, unexplained hypertension, glucose intolerance, and autoimmune thyroid disease.

Pathophysiology About half have a 45,X karyotype, approximately one-fourth have mosaicism with no structural abnormality (46,XX/45,X), and the remainder have a structurally abnormal X chromosome with or without mosaicism (Chap. 66). The mechanism of chromosome loss is unknown and may occur during gametogenesis in either parent or as a mitotic error during one of the early cleavage divisions of the fertilized zygote (Fig. 338-2). Short stature and other somatic features result from haploinsufficiency of one or more genes encoded on the short arm of the X chromosome. Streak gonads result when genetic material is missing from either the long or short arm of the X. In individuals with mosaicism or structural abnormalities of the X, the phenotype on average is less severe than in the 45,X variety. In some patients with hypertrophy of the clitoris, an unidentified fragment of a chromosome is present and is assumed to be an abnormal Y; gonadoblastoma may develop in the streak gonads in this subset of patients. The Y-linked genes that predispose to gonadoblastoma are distinct from *SRY* because XY women with *SRY* deletions or mutations are also at risk for such tumors. Rarely, familial transmission of gonadal dysgenesis can be the result of a balanced X-autosome translocation (Chap. 66). Analysis of chromosomal karyotype is necessary to establish the diagnosis and to identify the group with Y chromosomal elements and hence a chance of developing malignancy in the streak gonads.

After the time of expected puberty, pubic and axillary hair remain sparse, the breasts are infantile, and no menses occur. SerumFSH is elevated in infancy, falls during midchildhood to the normal range, and increases to castrate levels at the age of 9 or 10. At this time, the serumLH level is also elevated, and plasma estradiol levels are low [<40 pmol/L (<10 pg/mL)]. Approximately 2% of 45,X and 12% of mosaic women have sufficient residual follicles to allow some menstruation, and occasionally minimally

affected women become pregnant; the reproductive life in such individuals is brief.

TREATMENT

At the anticipated time of puberty, replacement therapy with estrogen should be instituted to induce maturation of the breasts, labia, vagina, uterus, and fallopian tubes (Chap. 336). Linear growth and bone maturation rates usually double during the first year of treatment with estradiol, but the eventual height rarely approaches the predicted height. Combination therapy with oxandrolone and/or growth hormone accelerates growth and increases final height. Streak gonads should be removed in all women who are virilized or have Y-chromosome sequences.

MIXED GONADAL DYSGENESIS

Clinical Features Mosaicism for a Y-bearing cell line, usually the 45,X/46,XY karyotype, is responsible for most instances of mixed gonadal dysgenesis. Affected individuals usually have a testis on one side and a streak gonad on the other, but bilateral dysgenetic testes or bilateral streak gonads may be present. The incidence is unknown, but in most hospitals the disorder is the second most common cause of ambiguous genitalia in the neonate after congenital adrenal hyperplasia.
