Atopic dermatitis (AD) is the cutaneous expression of the atopic state, characterized by a family history of asthma, hay fever, or dermatitis in up to 70% of patients. The criteria for the diagnosis of atopic eczema are shown inTable 56-1. The prevalence of atopic dermatitis is increasing worldwide, with a point prevalence in Norwegian school children as high as 23%.

The etiology ofAD is only partially defined. There is a clear genetic predisposition. When both parents are affected by AD, over 80% of their children manifest the disease. When only one parent is affected, the prevalence drops to slightly over 50%. A number of genes have been tentatively linked to AD including genes coding for IgE, the high-affinity IgE receptor, mast cell tryptase, and interleukin (IL) 4. Patients with AD may display a variety of immunoregulatory abnormalities including increased IgE synthesis; increased specific IgE to foods, aeroallergens, bacteria, and bacterial products; increased expression of CD23 (low-affinity IgE receptor) on monocytes and B cells; impaired delayed type hypersensitivity reactions; and increased type II and decreased type I cytokine responses.

The clinical presentation often varies with age. Half of patients withADpresent within the first year of life, and 80% present by 5 years of age. Some 80% ultimately coexpress allergic rhinitis or asthma later in life. The infantile pattern is characterized by weeping inflammatory patches and crusted plaques that occur on the face, neck, extensor surfaces, and groin. The childhood and adolescent pattern is marked by dermatitis of flexural skin, particularly in the antecubital and popliteal fossae (seePlate IIA-4). AD may resolve spontaneously in adults, but the dermatitis will persist into adult life in over half of individuals affected as children. The distribution of lesions may be similar to those seen in childhood. However, adults affected with AD frequently have localized disease, manifesting as hand eczema or lichen simplex chronicus (see below).

Pruritus is a prominent characteristic of AD, and many of the cutaneous findings in affected patients are secondary to rubbing and scratching. Other cutaneous stigmata of AD are perioral pallor, an extra fold of skin beneath the lower eyelid (Dennie's line), increased palmar markings, and increased incidence of cutaneous infections,

particularly with *Staphylococcus aureus*. Atopic individuals often have dry itchy skin, abnormalities in cutaneous vascular responses, and, in some instances, elevations in serum IgE.

Histologic examinaton of the skin affected byAD may demonstrate features of acute or chronic dermatitis. Immunopathology shows activated, memory T helper cells, which express the cutaneous lymphocyte antigen, the ligand for the inducible endothelial cell adhesion molecule E-selectin. AD skin lesions may also demonstrate IgE-bearing CD1a+ positive Langerhans cells, and these cells have been implicated in AD disease pathophysiology through mediation of hypersensitivity responses to environmental antigens.

TREATMENT

Therapy of ADshould be based on avoidance of cutaneous irritants, adequate cutaneous hydration, judicious use of low- or midpotency topical glucocorticoids, and prompt treatment of secondarily infected skin lesions. Patients should be instructed to bathe using warm, but not hot, water and to limit their use of soap. Immediately after bathing while the skin is still moist, the skin should be lubricated with a low- or midpotency topical glucocorticoid in a cream or ointment base. Potent fluorinated topical glucocorticoids should not be used on the face or intertriginous areas. It takes a minimum of 30 g of glucocorticoid ointment to cover the entire body surface of an average adult.

Crusted and weeping skin lesions should be treated with systemic antibiotics with activity against *S. aureus* since secondary infection often exacerbates eczema. The frequency of macrolide-resistant organisms makes the use of penicillinase-resistant penicillins or cephalosporins preferable. Dicloxacillin or cephalexin (250 mg four times daily for 7 to 10 days) is generally adequate to decrease heavy colonization. As an adjunct, the use of triclosan-containing antibacterial washes and intermittent nasal mupirocin may be useful as prophylactic measures. The role of dietary allergens in atopic dermatitis is controversial, and there is little evidence that they play any role outside of infancy.

Control of pruritus is essential for treatment, sinceAD often represents "an itch that rashes." Antihistamines are useful to control the pruritus, but sedation may limit their usefulness. Unlike their effects in urticaria, nonsedating antihistamines are of little use since the effectiveness of antihistamines in the treatment of pruritus associated with AD is primarily related to their sedative effects as opposed to any specific action on histamine-mediated pathways.

Treatment with systemic glucocorticoids should be limited to severe exacerbations unresponsive to conservative topical therapy. In the patient with chronicAD, therapy with systemic glucocorticoids will generally clear the skin only briefly, but cessation of the systemic therapy will invariably be accompanied by return, if not worsening, of the dermatitis. Patients who do not respond to conventional therapies should be considered for patch testing to rule out allergic contact dermatitis. Immunotherapy with aeroallergens has not proven useful in AD, unlike its effect in allergic rhinitis and extrinsic asthma.

CONTACT DERMATITIS

Contact dermatitis is an inflammatory process in skin caused by an exogenous agent or agents that directly or indirectly injure the skin. This injury may be caused by an inherent characteristic of a compound -- irritant contact dermatitis (ICD). An example of ICD would be dermatitis induced by a concentrated acid or base. Agents that cause allergic contact dermatitis (ACD) induce an antigen-specific immune response. The clinical lesions of contact dermatitis may be acute (wet and edematous) or chronic (dry, thickened, and scaly), depending on the persistence of the insult (see Plate IIA-8). The most common presentation of contact dermatitis is hand eczema, and it is frequently related to occupational exposures. Occupation-related contact dermatitis represents a significant proportion of occupation-induced injury, affecting over 60,000 persons annually.

ICDis generally strictly demarcated and often localized to areas of thin skin (eyelids, intertriginous areas) or to areas where the irritant was occluded. Lesions may range from minimal skin erythema to areas of marked edema, vesicles, and ulcers. Chronic low-grade irritant dermatitis is the most common type of ICD and the most common area of involvement is the hands (see below). The most common irritants encountered are chronic wet work, soaps, and detergents. Treatment should be directed to avoidance of irritants and use of protective gloves or clothing.

ACDis a manifestation of delayed type hypersensitivity mediated by memory T lymphocytes in the skin. The most common cause of ACD is exposure to plants, specifically to members of the family Anacardiaceae; including the genera *Toxicodendrun*, *Anacardium*, *Gluta*, *Mangifera*, and *Semecarpus*. Poison ivy, poison oak, and poison sumac are members of the genus *Toxicodendron* and cause an allergic reaction marked by erythema, vesiculation, and severe pruritus. The eruption is often linear, corresponding to areas where plants have touched the skin. However, other allergens may be more difficult to identify, especially if the exposure is chronic and the skin becomes thickened and scaly. The sensitizing antigen common to these plants is urushiol, an oleoresin containing the active ingredient pentadecylcatechol. The oleoresin may adhere to skin, clothing, tools, and pets, and contaminated articles may cause dermatitis even after prolonged storage. Blister fluid does not contain urushiol and is not capable of inducing skin eruption in exposed subjects.

TREATMENT

IfACD is suspected and an offending agent is identified and removed, the eruption will resolve. Usually, treatment with high-potency fluorinated topical glucocorticoids is enough to relieve symptoms while the ACD runs its course. For those patients who require systemic therapy, a tapering course over 2 to 3 weeks given as single morning doses is the preferred method.

Identification of a contact allergen can be a difficult and time-consuming task. Patients with dermatitis unresponsive to conventional therapy or with an unusual and patterned distribution should be suspected of havingACD. They should be questioned carefully regarding occupational exposures, topical medicaments, and oral medications.

Common sensitizers include preservatives in topical preparations, nickel sulfate, potassium dichromate, thimerosal in ocular preparations, neomycin sulfate, fragrances, formaldehyde, and rubber-curing agents. Patch testing is helpful in identifying these agents, but should not be attempted on patients with widespread active dermatitis or on those taking systemic glucocorticoids.

HAND ECZEMA

Hand eczema is a very common, chronic skin disorder. It represents a large proportion of occupation-associated skin disease. It may be associated with other cutaneous disorders such as atopic dermatitis or may occur by itself. Similar to other forms of dermatitis, both exogenous and endogenous factors play important roles in the expression of hand dermatitis. Chronic, excessive exposure to water and detergents may initiate or aggravate this disorder. It may present with dryness and cracking of the skin of the hands as well as with variable amounts of erythema and edema. Often, the dermatitis will begin under rings where water and irritants are trapped. A variant of hand dermatitis, dyshidrotic eczema, presents with multiple, intensely pruritic, small papules and vesicles occurring on the thenar and hypothenar eminences and the sides of the fingers (see Plate IA-5). Lesions tend to occur in crops that slowly form crusts and heal.

The evaluation of a patient with hand eczema should include an assessment of potential occupation-associated exposures. Predominant involvement of the dorsal surface of the hands with sparing of the palmar surface suggests a possible contact dermatitis. The history should be directed to identifying possible irritant or allergen exposures. The use of rubber gloves to protect dermatitic skin is sometimes associated with the development of delayed type hypersensitivity reactions to agents used for cross-linking rubber. Such reactions can be detected by patch testing. Less commonly, patients may manifest hand dermatitis as a consequence of developing immediate type hypersensitivity reactions to latex. These are of particular concern since these patients are at risk for anaphylactic reactions. The most sensitive method of detection is the use of scratch testing with latex extract. However, this should be done with extreme caution only in a setting where an anaphylactic reaction can be treated. A latex radioallergosorbent test is available but is only about 60%sensitive.

TREATMENT

Therapy of hand dermatitis is directed toward avoidance of irritants, identification of possible contact allergens, treatment of coexistent infection, and application of topical glucocorticoids. Whenever possible, the hands should be protected by gloves, preferably vinyl. Most patients can be treated with cool moist compresses (dressings) to dry and debride acute inflammatory lesions and to decrease swelling, followed by application of a mid- to high-potency topical glucocorticoid in a cream or ointment base. As with atopic dermatitis, treatment of secondary infection by staphylococci or streptococci is essential for good control. Additionally, patients with hand dermatitis should be examined for dermatophyte infection by KOH preparation and culture (see below).

NUMMULAR ECZEMA

Nummular eczema is characterized by circular or oval "coinlike" lesions. Initially, this eruption consists of small edematous papules that become crusted and scaly. The most common locations are on the trunk or the extensor surfaces of the extremities, particularly on the pretibial areas or dorsum of the hands. It occurs more frequently in men and is most commonly seen in middle age. The etiology of nummular eczema is unknown. Whether nummular eczema represents a variant of atopic eczema is controversial. The treatment of nummular eczema is similar to that for other forms of dermatitis.

LICHEN SIMPLEX CHRONICUS

Lichen simplex chronicus may represent the end stage of a variety of pruritic and eczematous disorders. It consists of a well-circumscribed plaque or plaques with lichenified or thickened skin due to chronic scratching or rubbing. Common areas involved include the posterior nuchal region, dorsum of the feet, or ankles. Treatment of lichen simplex chronicus centers around breaking the cycle of chronic itching and scratching, which often occur during sleep. High-potency topical glucocorticoids are helpful in alleviating pruritus in most cases, but in recalcitrant cases, application of topical glucocorticoids under occlusion or intralesional injection of glucocorticoids may be required. Oral antihistamines such as hydroxyzine (10 to 50 mg every 6 h) or tricyclic antidepressants with antihistaminic activity such as doxepin (10 to 25 mg at bedtime) are useful as antipruritics primarily due to their sedating action, and are particularly useful at bedtime (see above). Patients need to be counseled regarding driving or operating heavy equipment after taking these medications due to their potentially potent sedative activity.

ASTEATOTIC ECZEMA

Asteatotic eczema, also known as xerotic eczema or "winter itch," is a mildly inflammatory variant of dermatitis that develops most commonly on the lower legs of elderly individuals during dry times of year. Fine cracks, with or without erythema, characteristically develop on the anterior surface of the lower extremities. Pruritus is variable. Asteatotic eczema responds well to avoidance of irritants, rehydration of the skin, and application of topical emollients.

STASIS DERMATITIS AND STASIS ULCERATION

Stasis dermatitis develops on the lower extremities secondary to venous incompetence and chronic edema. Early findings in stasis dermatitis consist of mild erythema and scaling associated with pruritus. The typical initial site of involvement is the medial aspect of the ankle, often over a distended vein (seePlate IIA-7). As the disorder progresses, the dermatitis becomes progressively pigmented, due to chronic erythrocyte extravasation leading to cutaneous hemosiderin deposition. As with other forms of dermatitis, stasis dermatitis may become acutely inflamed, with crusting and exudate. Chronic stasis dermatitis is often associated with dermal fibrosis that is recognized clinically as brawny edema of the skin. Stasis dermatitis is often complicated by secondary infection and contact dermatitis. Severe stasis dermatitis may precede the development of stasis ulcers.

TREATMENT

Avoidance of irritants and use of emollients and/or midpotency topical glucocorticoids are the cornerstones of therapy for stasis dermatitis. Control of chronic edema is important to prevent leg ulcers. Patients should be encouraged to elevate the affected extremity when sitting. A compression stocking with a gradient of at least 30 to 40 mmHg is most effective for edema control and is much more effective for preventing chronic edema than is antiembolism hose.

Stasis ulcers are difficult to treat, and resolution of these lesions is slow even under the best of circumstances. It is extremely important to elevate the affected limb as much as possible. The ulcer should be kept clear of necrotic material by gentle debridement and covered with a semipermeable dressing under pressure. Glucocorticoids should not be applied to ulcers, since they may retard healing. Secondarily infected lesions should be treated with appropriate oral antibiotics, but it should be noted that all ulcers will become colonized with bacteria, and the purpose of antibiotic therapy should not be to clear all bacterial growth. Some ulcers may take months to heal or require skin grafting.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a common, chronic disorder, characterized by greasy scales overlying erythematous patches or plaques. The most common location is in the scalp where it may be recognized as severe dandruff. On the face, seborrheic dermatitis affects the eyebrows, eyelids, glabella, nasolabial fold, or ears (seePlate IIA-6). Scaling within the external ear is often mistaken for a chronic fungal infection (otomycosis), and postauricular dermatitis often becomes macerated and tender. Additionally, seborrheic dermatitis may develop in the central chest, axilla, groin, submammary folds, and gluteal cleft. Rarely, it may cause a widespread generalized dermatitis. Seborrheic dermatitis is usually symptomatic, with patients complaining of itching or burning.

Seborrheic dermatitis may be evident within the first few weeks of life, and within this context it occurs in the scalp ("cradle cap"), face, or groin. It is rarely seen in children beyond infancy but becomes evident again during adult life. Although it is frequently seen in patients with Parkinson's disease, in those who have had cerebrovascular accidents, and in those with human immunodeficiency virus (HIV) infection, the overwhelming majority of individuals with seborrheic dermatitis have no underlying disorder.

TREATMENT

Treatment with low-potency topical glucocorticoids in conjunction with shampoos containing coal tar and/or salicylic acid is generally sufficient to control activity of this disorder. High-potency topical glucocorticoid solutions (betamethasone or fluocinonide) are effective for control of scalp involvement. Fluorinated topical glucocorticoids should not be used on the face since this is often associated with the development of rebound worsening and steroid-induced rosacea or atrophy.

PAPULOSQUAMOUS DISORDERS (Table 56-2)

PSORIASIS

Psoriasis is one of the most common dermatologic diseases, affecting up to 1 to 2% of the world's population. It is a chronic inflammatory skin disorder clinically characterized by erythematous, sharply demarcated papules and rounded plaques, covered by silvery micaceous scale. The skin lesions of psoriasis are variably pruritic. Traumatized areas often develop lesions of psoriasis (Koebner or isomorphic phenomenon). Additionally, other external factors may exacerbate psoriasis including infections, stress, and medications (lithium, beta blockers, and antimalarials).

The most common variety of psoriasis is called *plaque type*. Patients with plaque-type psoriasis will have stable, slowly growing plaques, which remain basically unchanged for long periods of time. The most common areas for plaque psoriasis to occur are the elbows, knees, gluteal cleft, and the scalp. Involvement tends to be symmetric. *Inverse psoriasis* affects the intertriginous regions including the axilla, groin, submammary region, and navel, it also tends to affect the scalp, palms, and soles. The individual lesions are sharply demarcated plaques (seePlate IIA-3) but may be moist due to their location. Plaque psoriasis generally develops slowly and runs an indolent course. It rarely remits spontaneously.

Eruptive psoriasis (guttate psoriasis) is most common in children and young adults. It develops acutely in individuals without psoriasis or in those with chronic plaque psoriasis. Patients present with many small erythematous, scaling papules, frequently after upper respiratory tract infection withb-hemolytic streptococci. The differential diagnosis should include pityriasis rosea and secondary syphilis. Patients with psoriasis may also develop pustular lesions. These may be localized to the palms and soles or may be generalized and associated with fever, malaise, diarrhea, and arthralgias.

About half of all patients with psoriasis have fingernail involvement, appearing as punctate pitting, nail thickening, or subungual hyperkeratosis. About 5 to 10% of patients with psoriasis have associated joint complaints, and these are most often found in patients with fingernail involvement. Although some have the coincident occurrence of classic rheumatoid arthritis (Chap. 312), many have joint disease that falls into one of three types associated with psoriasis: (1) asymmetric inflammatory arthritis most commonly involving the distal and proximal interphalangeal joints and less commonly the knees, hips, ankles, and wrists; (2) a seronegative rheumatoid arthritis-like disease; a significant portion of these patients go on to develop a severe destructive arthritis; or (3) disease limited to the spine (psoriatic spondylitis).

The etiology of psoriasis is still poorly understood. There is clearly a genetic component to psoriasis. Over 50% of patients with psoriasis report a positive family history, and a 65 to 72% concordance among monozygotic twins has been reported in twin studies. Psoriasis has been linked to HLA-Cw6 and, to a lesser extent, to HLA-DR7. Evidence has accumulated clearly indicating a role for T cells in the pathophysiology of psoriasis. Stimulation of immune function with cytokines such asIL-2 has been associated with abrupt worsening of preexisting psoriasis, and bone marrow transplantation has resulted in clearance of disease. Psoriatic lesions are characterized by infiltration of skin with activated memory T cells, with CD8+ cells predominating in the epidermis. Agents that inhibit activated T cell function are often effective for the treatment of severe psoriasis.

Presumably, cytokines from activated T cells elaborate growth factors that stimulate keratinocyte hyperproliferation.

TREATMENT

Treatment of psoriasis depends on the type, location, and extent of disease. All patients should be instructed to avoid excess drying or irritation of their skin and to maintain adequate cutaneous hydration. Most patients with localized plaque-type psoriasis can be managed with midpotency topical glucocorticoids, although their long-term use is often accompanied by loss of effectiveness (tachyphylaxis). Crude coal tar (1 to 5% in an ointment base) is an old but useful method of treatment in conjunction with ultraviolet light therapy. A topical vitamin D analogue (calcipitriol) is also efficacious in the treatment of psoriasis.

Ultraviolet light is an effective therapy for patients with widespread psoriasis. The ultraviolet B (UV-B) spectrum is effective alone, or may be combined with coal tar (Goeckerman regimen) or anthralin (Ingram regimen). Natural sunlight or an artificial light source can be used. The combination of the ultraviolet A (UV-A) spectrum with either oral or topical psoralens (PUVA) is also extremely effective for the treatment of psoriasis, but long-term use may be associated with an increased incidence of squamous cell cancer and melanoma of the skin.

Various other agents can be used for widespread psoriatic disease. Methotrexate is an effective agent, especially in patients with associated psoriatic arthritis. Liver toxicity from long-term use limits its use to patients with widespread disease not responsive to less aggressive modalities. The synthetic retinoid, acetretin, has been shown to be effective in some patients with severe psoriasis but is a potent teratogen, thus limiting its use in women with childbearing potential. The evidence implicating psoriasis as a T cell-mediated disorder has created a new perspective relating to the treatment of psoriasis. Based on this presumed disease mechanism, immunomodulatory therapy utilizing cyclosporine has proven to be highly effective in selected patients with severe, crippling, and potentially life-threatening disease.

LICHEN PLANUS

Lichen planus (LP) is a papulosquamous disorder in which the primary lesions are pruritic, polygonal, flat-topped, violaceous papules. Close examination of the surface of these papules often reveals a network of gray lines (Wickham's striae). The skin lesions may occur anywhere but have a predilection for the wrists, shins, lower back, and genitalia (see Plate IIA-9). Involvement of the scalp may lead to hair loss. LP commonly involves mucous membranes, particularly the buccal mucosa, where it can present as a white netlike eruption. Its etiology is unknown, but cutaneous eruptions clinically resembling LP have been observed after administration of numerous drugs, including diuretics, gold, antimalarials, penicillamine, and phenothiazines, and in patients with skin lesions of chronic graft-versus-host disease. Additionally, LP associated with abnormal liver function has been correlated with viral hepatitis, particularly hepatitis C infection. The course of LP is variable, but most patients have spontaneous remissions 6 months to 2 years after the onset of disease. Topical glucocorticoids are the mainstay of therapy.

PITYRIASIS ROSEA

Pityriasis rosea (PR) is a papulosquamous eruption of unknown etiology that occurs more commonly in the spring and fall. Its first manifestation is the development of a 2- to 6-cm annular lesion (the herald patch). This is followed in a few days to a few weeks by the appearance of many smaller annular or papular lesions with a predilection to occur on the trunk (see Plate IIA-13). The lesions are generally oval, with their long axis parallel to the skin-fold lines. Individual lesions may range in color from red to brown and have a trailing scale. PR shares many clinical features with the eruption of secondary syphilis, but palm and sole lesions are extremely rare in PR and common in secondary syphilis. The eruption tends to be moderately pruritic and lasts 3 to 8 weeks. Treatment is generally directed at alleviating pruritus and consists of oral antihistamines, midpotency topical glucocorticoids, and, in some cases, the use ofUV-Bphototherapy.

CUTANEOUS INFECTIONS (Table 56-3)

IMPETIGO AND ECTHYMA

Impetigo is a common superficial bacterial infection of skin caused by group Ab-hemolytic streptococci (Chap. 140) or *S. aureus* (Chap. 139). The primary lesion is a superficial pustule that ruptures and forms a characteristic yellow-brown honey-colored crust (seePlate IID-38). Lesions caused by staphylococci may be tense, clear bullae, and this less common form of the disease is called *bullous impetigo*. Lesions may occur on normal skin or in areas already affected by another skin disease. Ecthyma is a variant of impetigo that generally occurs on the lower extremities and causes punched-out ulcerative lesions. Treatment of both ecthyma and impetigo involves gentle debridement of adherent crusts, which is facilitated by the use of soaks and topical antibiotics, in conjunction with appropriate oral antibiotics.

ERYSIPELAS AND CELLULITIS

SeeChap. 128

DERMATOPHYTOSIS

Dermatophytes are fungi that infect skin, hair, and nails and include members of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*. Infection of the foot (tinea pedis) is most common and is often chronic; it is characterized by variable erythema and edema, scaling, pruritus, and occasionally vesiculation. Involvement may be widespread or localized, but almost invariably the web space between the fourth and fifth toes is affected. Infection of the nails (tinea unguium) occurs in many patients with tinea pedis and is characterized by opacified, thickened nails and subungual debris. The groin is the next most commonly involved area (tinea cruris), with males affected much more often than females. It presents as a scaling erythematous eruption that spares the scrotum. Microscopic examination of either untreated tinea pedis or tinea cruris scale after digestion with KOH preparation will generally demonstrate hyphae.

Dermatophyte infection of the scalp (tinea capitis) has returned in epidemic proportions,

particularly affecting inner city children. The predominant organism is *T. tonsurans*. This organism can produce an inflammatory or relatively noninflammatory infection that may present with either well-defined or irregular, diffuse areas of mild scaling and hair loss. Tinea corporis, or infection on non-hair-bearing skin, may have a variable appearance, depending on the extent of the associated inflammatory reaction (see Plate IID-51). It may have the typical annular appearance of "ringworm" or appear as deep inflammatory nodules (on the scalp known as a *kerion*) or granulomas. KOH examination of scale or hair from patients with tinea capitis or inflammatory tinea corporis often does not reveal hyphae, and diagnosis may require culture or biopsy.

TREATMENT

Both topical and systemic therapies may be used to treat dermatophyte infection. Treatment depends on the site involved and the type of infection. Topical therapy is generally effective for uncomplicated tinea corporis, tinea cruris, and limited tinea pedis. It is not effective as monotherapy for tinea capitis or tinea unguium. Topical imidazoles (miconazole, ketoconazole, econazole, clotrimazole, oxiconazole, and sulconazole), triazoles (terconazole), and allylamines (terbinafine and naftifine) may all be effective topical therapies for dermatophyte infections. Haloprogin, undecylic acid, ciclopirox-olamine, and tolnaftate are also effective, but nystatin is not active against dermatophytes. Treatment should continue until the patient is clear of infection by clinical examination and culture. Tinea pedis often requires longer treatment courses and is associated with a high relapse rate.

Griseofulvin is the drug of choice for dermatophyte infections requiring systemic therapy. A daily dose of 500 mg of microsized or 350 mg of ultramicrosized griseofulvin administered with a fatty meal is an adequate dose for most dermatophyte infections. The duration of therapy may be as short as 2 weeks for uncomplicated tinea corporis but may be as long as 6 to 12 months for nail infections. The most common side effects of griseofulvin are gastrointestinal distress and headache. Dermatophyte infection of hair-bearing areas (e.g., tinea capitis) requires systemic antifungal therapy. The usual adult dose of griseofulvin is 1 g of microsized or 0.5 g of ultramicrosized given daily, and treatment should be continued for 6 to 8 weeks. Children should be treated with 15 to 20 mg/kg as a single daily dose given with a fatty meal. The adjunctive use of topical antifungal agents in addition to systemic therapy may be useful, but topical therapy alone is not adequate. Markedly inflammatory tinea capitis may result in scarring and hair loss, and systemic or topical glucocorticoids may be helpful in preventing this sequela. Recent studies in children have also suggested that both itraconazole (3 to 5 mg/kg for 6 to 10 weeks) and terbinafine (125 mg/d for 6 weeks) may be effective treatments for tinea capitis.

Until recently, griseofulvin was the recommended therapy for dermatophyte infection of the nails. However, despite prolonged treatment, cure rates were poor. Itraconazole given as either continuous daily therapy (200 mg/d for 3 months) or pulses (200 mg twice daily for 1 week per month for 3 consecutive months) has been shown to be a safe and effective therapy. Itraconazole has the potential for interactions with other drugs requiring the P450 enzyme system for metabolism. Similarly, terbinafine (250 mg/d for 3 months) has shown similar cure rates. Only limited data are available on the dosing and effectiveness of the newer antifungal agents in tinea corporis, tinea cruris,

and uncomplicated tinea pedis.

TINEA VERSICOLOR

Tinea versicolor is caused by a nondermatophyte dimorphic fungus that is a normal inhabitant of the skin. As the yeast form *Pityrosporum orbiculare*, it generally does not cause disease (except for folliculitis in certain individuals). However, in some individuals, it converts to the hyphal form and causes characteristic lesions. The expression of infection is promoted by heat and humidity. The typical lesions consist of oval scaly macules, papules, and patches concentrated on the chest, shoulders, and back but only rarely on the face or distal extremities. On dark skin, they often appear as hypopigmented areas, while on light skin, they are slightly hyperpigmented. In some darkly pigmented individuals, they may only appear as scaling patches. A KOH preparation from scaling lesions will demonstrate a confluence of short hyphae and round spores (so-called spaghetti and meatballs). Solutions containing sulfur, salicylic acid, or selenium sulfide will clear the infection if used daily for a week and then intermittently thereafter. Treatment with a single 400-mg dose of ketaconazole is also effective.

CANDIDIASIS

Candidiasis is a fungal infection caused by a related group of yeasts, whose manifestations may be localized to the skin, or rarely, may be systemic and life-threatening. The causative organism is usually *Candida albicans*, but may also be *C. tropicalis*, *C. parapsilosis*, or *C. krusei*. These organisms are normal saprophytic inhabitants of the gastrointestinal tract but may overgrow (usually due to broad-spectrum antibiotic therapy) and cause disease at a number of cutaneous sites. Other predisposing factors include diabetes mellitus, chronic intertrigo, oral contraceptive use, and cellular immune deficiency. Candidiasis is a very common infection in HIV-infected individuals (Chap. 309). The oral cavity is commonly involved. Lesions may occur on the tongue or buccal mucosa (thrush) and appear as white plaques (see Plate IID-43). Microscopic examination of scrapings demonstrate both pseudohyphae and yeast forms. Fissured, macerated lesions at the corners of the mouth (perleche) are often seen in individuals with poorly fitting dentures and may also be associated with candidal infection. Additionally, candidal infections have an affinity for sites that are chronically wet and macerated and may occur around nails (onycholysis and paronychia) and in intertriginous areas. Intertriginous lesions are characteristically edematous, erythematous, and scaly, with scattered "satellite pustules." In males, there is often involvement of the penis and scrotum as well as the inner aspect of the thighs. In contrast to dermatophyte infections, candidal infections are frequently accompanied by a marked inflammatory response. Diagnosis of candidal infection is based upon the clinical pattern and demonstration of yeast on KOH preparation, or culture.

TREATMENT

Treatment routinely involves removing any predisposing factors such as antibiotic therapy or chronic wetness and the use of appropriate topical or systemic antifungal therapy. Effective topical agents include nystatin or topical azoles (miconazole,

clotrimazole, econazole, or ketoconazole). These agents are generally effective in clearing mucous membrane or glabrous skin involvement in nonimmunosuppressed patients. The associated inflammatory response that often accompanies candidal infection on glabrous skin should be treated with a mild glucocorticoid lotion or cream (2.5% hydrocortisone). Systemic therapy is generally reserved for immunosuppressed patients or individuals with chronic or recurrent disease who fail to respond to or tolerate appropriate topical therapy. Vulvovaginal candidiasis may respond to treatment with a single dose of fluconazole (150 mg). Chronic recurrent oral or vaginal candidiasis may be treated with weekly to monthly oral fluconazole (150 to 200 mg) in conjunction with topical therapy.

WARTS

Warts are cutaneous neoplasms that are caused by papilloma viruses. Over 50 different human papilloma viruses (HPV) have been described, and this number will almost certainly continue to grow. Typical verruca vulgaris lesions are sessile, dome-shaped, usually about a centimeter in diameter, and their surface is made up of many small filamentous projections. The HPV that cause typical verruca vulgaris also cause typical plantar warts, flat warts (or verruca plana), and filiform warts in intertriginous areas. Plantar warts are endophytic and are covered by thick keratin. Paring of the wart will generally demonstrate a central core of keratinized debris and punctate bleeding points. Filiform warts are most commonly seen on the face, neck, and skin folds and present as papillomatous lesions on a narrow base. Flat warts are only slightly elevated and have a velvety, nonverrucous surface. They have a propensity for the face, arms, and legs and are often spread by shaving.

MultipleHPVtypes have been associated with genital tract lesions. They generally begin as small papillomas that may grow to form large fungating lesions. In women, they may involve either the labia, perineum, or perianal skin. Additionally, the mucosa of the vagina, urethra, and anus can be involved, as well as the cervical epithelium. In men, the lesions often occur initially in the coronal sulcus, but may be seen on the shaft of the penis, the scrotum, perianal skin, or in the urethra.

Within the past decade, appreciable evidence has accumulated that suggestsHPVplays a role in the development of neoplasia of the uterine cervix and external genitalia (Chap. 97). HPV types 16 and 18 have been most intensely studied, while recent evidence also implicates other types. Lesions may initially appear as small, flat, velvety, hyperpigmented papules occurring on the genitalia or perianal skin. Histologic examination of biopsies from affected sites may reveal changes associated with typical warts and/or features typical of intraepidermal carcinoma (Bowen's disease). Squamous cell carcinomas associated with HPV infections have also been observed in extragenital skin (Chap. 86). This is most commonly seen in patients immunosuppressed after organ transplantation.

TREATMENT

There are many modalities available to treat warts, but no single therapy is universally effective. Factors that influence the choice of therapy include the location of the wart, extent of disease, the age and immunologic status of the patient, and the patient's

desire for therapy. Perhaps the most useful and convenient method for treating warts in almost any location is cryotherapy with liquid nitrogen. Equally effective, but requiring much more patient compliance, is the use of keratolytic agents such as salicylic acid plasters or combinations of lactic acid and salicylic acid. For genital warts, application of podophyllin solution is moderately effective but may be associated with marked local reactions in certain individuals. Dilute preparations of purified podophyllin permit physician-directed by patient-applied use, facilitating treatment of mucosal warts. Topical imiquimod, a potent inducer of local cytokine release, has also been approved for use in genital warts. Other topical agents that are used include trichloracetic acid or cantharidin. Electrodessication and curettage or CO_2laser excision are also effective therapies but require local anesthesia. Recurrence of warts appears to be common to all these modalities because viral genomic material is present in normal-appearing skin adjacent to the clinical lesions.

Treatment of warts should be tempered by the observation that an overwhelming majority of warts in normal individuals resolve spontaneously within 1 to 2 years. Also, only an extremely small proportion of warts is associated with neoplasia, and those are almost exclusively located on the genitalia or perianal skin.

HERPES SIMPLEX

HERPES ZOSTER

*See Chap. 183

ACNE

ACNE VULGARIS

Acne vulgaris is a self-limited disorder primarily of teenagers and young adults, although perhaps 10 to 20% of adults may continue to experience some form of the disorder. The permissive factor for the expression of the disease in adolescence is the increase in sebum release by sebaceous glands after puberty. Small cysts, called *comedones*, form in hair follicles due to blockage of the follicular orifice by retention of sebum and keratinous material. The activity of lipophilic yeast (*Pityrosporum orbiculare*) and bacteria (*Proprionobacterium acnes*) within the comedones releases free fatty acids from sebum, causes inflammation within the cyst, and results in rupture of the cyst wall. An inflammatory foreign-body reaction develops as a result of extrusion of oily and keratinous debris from the cyst.

The clinical hallmark of acne vulgaris is the comedone, which may be closed (whitehead) or open (blackhead). Closed comedones appear as 1- to 2-mm pebbly white papules, which are accentuated when the skin is stretched. They are the precursors of inflammatory lesions of acne vulgaris. The contents of closed comedones are not easily expressed. Open comedones, which rarely result in inflammatory acne lesions, have a large dilated follicular orifice and are filled with easily expressible oxidized, darkened, oily debris. Comedones are usually accompanied by inflammatory

lesions: papules, pustules, or nodules.

The earliest lesions seen in early adolescence are generally mildly inflamed or noninflammatory comedones on the forehead. Subsequently, more typical inflammatory lesions develop on the cheeks, nose, and chin (seePlate IIA-1). The most common location for acne is the face, but involvement of the chest and back is not uncommon. Most disease remains mild and does not lead to scarring. However, a small number of patients develop large inflammatory cysts and nodules, which may drain and result in significant scarring.

Exogenous and endogenous factors can alter the expression of acne vulgaris. Friction and trauma may rupture preexisting microcomedones and elicit inflammatory acne lesions. This is commonly seen with headbands or chin straps of athletic helmets. Application of comedogenic topical agents in cosmetics or hair preparations or chronic topical exposure to certain industrial compounds that are comedogenic may elicit or aggravate acne. Glucocorticoids, applied topically or administered systemically in high doses, may also elicit acne. Other systemic medications such as lithium, isoniazid, halogens, phenytoin, and phenobarbital may produce acneiform eruptions, or aggravate preexisting acne.

TREATMENT

Treatment of acne vulgaris is directed toward elimination of comedones by normalization of follicular keratinization, decreasing sebaceous gland activity, decreasing the population of lipophilic bacteria and yeast, and decreasing inflammation. Acne vulgaris may be treated with either local or systemic medications. Minimal to moderate, pauci-inflammatory disease may respond adequately to local therapy alone. Although areas affected with acne should be kept clean, there is little evidence to suggest that removal of surface oils plays an important role in therapy. Overly vigorous scrubbing may aggravate acne due to mechanical rupture of comedones. Topical agents such as retinoic acid, benzoyl peroxide, or salicylic acid may alter the pattern of epidermal desquamation, preventing the formation of comedones and aiding in the resolution of preexisting cysts. Topical antibacterial agents such as benzoyl peroxide, azelaic acid, topical erythromycin (with or without zinc), clindamycin, or tetracycline are also useful adjuncts to therapy.

Patients with moderate to severe acne with a prominent inflammatory component will benefit from the addition of systemic therapy. Oral tetracyclines or erythromycin in doses of 250 to 1000 mg/d will decrease follicular colonization with some of the lipophilic organisms. They also appear to have an anti-inflammatory effect independent of their antibacterial effect. Female patients who do not respond to oral antibiotics may benefit from hormonal therapy. Women placed on oral contraceptives containing ethinyl estradiol and norgestimate have demonstrated improvement in their acne when compared to a placebo control.

Severe nodulocystic acne not responsive to oral antibiotics, hormonal therapy, or topical therapy may be treated with the synthetic retinoid isotretinoin. It is used at doses of 0.5 to 2.0 mg/kg as a single daily dose for 15 to 20 weeks. The use of this drug is limited by its teratogenicity, and female patients must be screened for pregnancy prior to initiating

therapy, maintain a method of birth control during therapy, and be screened for pregnancy during treatment. Patients receiving this medication develop extremely dry skin and cheilitis and must be followed for development of hypertriglyceridemia.

ACNE ROSACEA

Acne rosacea is an inflammatory disorder predominantly affecting the central face. It is seen almost exclusively in adults, only rarely affecting patients under 30 years of age. Rosacea is seen more often in women, but those most severely affected are men. It is characterized by the presence of erythema, telangiectases, and superficial pustules (see Plate IIA-2), but is not associated with the presence of comedones. Rosacea only rarely involves the chest or back.

There is a relationship between the tendency for pronounced facial flushing and the subsequent development of acne rosacea. Often, individuals with rosacea initially demonstrate a pronounced flushing reaction. This may be in response to heat, emotional stimuli, alcohol, hot drinks, or spicy foods. As the disease progresses, the flush persists longer and longer and may eventually become permanent. Papules, pustules, and telangiectases can become superimposed on the persistent flush. Rosacea of very long standing may lead to connective tissue overgrowth, particularly of the nose (rhinophyma). Rosacea may also be complicated by various inflammatory disorders of the eye, including keratitis, blepharitis, iritis, and recurrent chalazion. These ocular problems are potentially sight-threatening and warrant ophthalmologic evaluation.

TREATMENT

Acne rosacea can generally be treated effectively with oral tetracycline in doses ranging from 250 to 1000 mg/d. Topical metronidazole or sodium sulfacetamide has also been shown to be effective. In addition, the use of low-potency, nonfluorinated topical glucocorticoids, particularly after cool soaks, is helpful in alleviating facial erythema. Fluorinated topical glucocorticoids should be avoided since chronic use of these preparations may actually elicit rosacea. Topical therapy is not effective treatment for ocular disease.

57. SKIN MANIFESTATIONS OF INTERNAL DISEASE - *Jean L. Bolognia*, *Irwin M. Braverman*

It is now a generally accepted concept in medicine that the skin can show signs of internal disease. Therefore, in textbooks of medicine one finds a chapter describing in detail the major systemic disorders that can be identified by cutaneous signs. The underlying assumption of such a chapter is that the clinician has been able to identify the disorder in the patient and needs only to read about it in the textbook. In reality, concise differential diagnoses and the identification of these disorders are actually difficult for the nondermatologist because he or she is not well versed in the recognition of cutaneous lesions or their spectrum of presentations. Therefore, the authors of this chapter have decided to cover this particular topic of cutaneous medicine not by discussing individual disorders but by describing and discussing the various presenting clinical signs and symptoms that indicate the presence of these disorders. Concise differential diagnoses will be generated in which the significant diseases will be briefly discussed and distinguished from the more common disorders that have no significance for internal diseases. The latter disorders are reviewed in table form and always need to be excluded when considering the former. For a detailed description of individual diseases, the reader should consult a dermatologic text.

PAPULOSQUAMOUS SKIN LESIONS (Table 57-1)

When an eruption is characterized by elevated lesions, papules (<1 cm) or plaques (>1 cm), in association with scale, it is referred to as *papulosquamous*. The most common papulosquamous diseases -- *psoriasis*, *tinea*, *pityriasis rosea*, and *lichen planus* -- are primary cutaneous disorders (Chap. 56). When psoriatic lesions are accompanied by arthritis, the possibility of psoriatic arthritis or *Reiter's disease* should be considered. A history of oral ulcers, conjunctivitis, uveitis, and/or urethritis points to the latter diagnosis. In *guttate psoriasis* there is an acute onset of small, widely scattered, uniform lesions, often in association with a streptococcal infection. Lithium, beta blockers, HIV infection, and a rapid taper of systemic glucocorticoids are also known to exacerbate psoriasis.

Whenever the diagnosis of pityriasis rosea or lichen planus is made, it is important to review the patient's medications because the eruption can be treated by simply discontinuing the offending agent. Pityriasis rosea-like drug eruptions are seen most commonly with beta blockers, angiotensin-converting enzyme (ACE) inhibitors, gold, and metronidazole, while the drugs that can produce a lichenoid eruption include gold, antimalarials, thiazides, quinidine, phenothiazines, sulfonylureas, and ACE inhibitors. Lichen planus-like lesions are also observed in chronic graft-versus-host disease.

Parapsoriasis is an intermediate disease, for it can remain solely as a primary cutaneous disease or it can progress to cutaneous T cell lymphoma (CTCL) after a latency period of as long as 40 years. There are several forms of parapsoriasis, including small plaque (0.5 to 5 cm), large plaque (>6 cm), and retiform. The lesions of both small plaque and large plaque parapsoriasis are thin and salmon-pink in color with fine white scale. In small plaque forms, the lesions are commonly on the trunk but can be widely scattered. In large plaque forms, the most common location is the "girdle" area, and fine wrinkling secondary to epidermal atrophy is often seen. Retiform

parapsoriasis forms a netlike pattern, and the individual papules are red-brown and flat-topped. The latter two forms of parapsoriasis, large plaque and retiform, can progress to CTCL.

A clue to the development of*CTCL*within lesions of large plaque or retiform parapsoriasis is an increase in the palpable component of the plaque (increased infiltration). In its early stages, CTCL may be confused with ezcema or psoriasis, but it often fails to respond to the appropriate therapy for those inflammatory diseases. The diagnosis of CTCL is established by skin biopsy in which collections of atypical T lymphocytes are found in the epidermis and dermis. As the disease progresses, cutaneous tumors and lymph node involvement may appear.

In *secondary syphilis* there are scattered red-brown papules with thin scale. The eruption often involves the palms and soles and can resemble pityriasis rosea. Associated findings are helpful in making the diagnosis and include annular plaques on the face, nonscarring alopecia, condyloma lata (broad-based and moist), and mucous patches as well as lymphadenopathy, malaise, fever, headache, and myalgias. The interval between the primary chancre and the secondary stage is usually 4 to 8 weeks, and spontaneous resolution without appropriate therapy is seen.

ERYTHRODERMA (Table 57-2)

Erythroderma is the term used when the majority of the skin surface is erythematous (red in color). There may be associated scale, erosions, or pustules as well as shedding of the hair and nails. Potential systemic manifestations include fever, chills, hypothermia, reactive lymphadenopathy, peripheral edema, hypoalbuminemia, and high-output cardiac failure. The major etiologies of erythroderma are (1) *cutaneous diseases* such as psoriasis and dermatitis (Table 57-3); (2) *drugs*; (3) *systemic diseases*, most commonlyCTCL; and (4) *idiopathic*. In the first three groups, the location and description of the initial lesions, prior to the development of the erythroderma, aid in the diagnosis. For example, a history of red scaly plaques on the elbows and knees would point to psoriasis. It is also important to examine the skin carefully for a migration of the erythema and associated secondary changes such as pustules or erosions. Migratory waves of erythema studded with superficial pustules are seen in *pustular psoriasis*.

Drug-induced erythroderma (exfoliative dermatitis) may begin as a morbilliform eruption (Chap. 59) or may arise as diffuse erythema. Fever and peripheral eosinophilia often accompany the eruption, and occasionally there is an associated allergic interstitial nephritis. A number of drugs can produce an erythroderma, including penicillins, sulfonamides, carbamazepine, phenytoin, gold, allopurinol, and captopril. While reactions to anticonvulsants can lead to a pseudolymphoma syndrome, reactions to allopurinol may be accompanied by hepatitis, gastrointestinal bleeding, and nephropathy.

The most common malignancy that is associated with erythroderma isCTCL; in some series, up to 25% of the cases of erythroderma were due to CTCL. The patient may progress from isolated plaques and tumors, but more commonly the erythroderma is present throughout the course of the disease (Sezary syndrome). In the Sezary

syndrome, there are circulating atypical T lymphocytes, pruritus, and lymphadenopathy. In cases of erythroderma where there is no apparent cause (idiopathic), longitudinal follow-up is mandatory to monitor for the possible development of CTCL. There have been isolated case reports of erythroderma secondary to some solid tumors -- lung, liver, prostate, thyroid, and colon -- but it is usually in a late stage of the disease.

ALOPECIA (Table 57-4)

The two major forms of alopecia are scarring and nonscarring. In *scarring alopecia* there is associated fibrosis, inflammation, and loss of hair follicles. A smooth scalp with a decreased number of follicular openings is usually observed clinically, but in some cases the changes are seen only in biopsy specimens from the affected areas. In *nonscarring alopecia* the hair shafts are gone, but the hair follicles are preserved, explaining the reversible nature of nonscarring alopecia.

Primary cutaneous disorders are the most common causes of nonscarring alopecia and they include *telogen effluvium*, *androgenetic alopecia*, *alopecia areata*, *tinea capitis*, and *traumatic alopecia* (Table 57-5). In women with androgenetic alopecia, an elevation in circulating levels of androgens may be seen as a result of ovarian or adrenal gland dysfunction. When there are signs of virilization, such as a deepened voice and enlarged clitoris, the possibility of an ovarian or adrenal gland tumor should be considered.

Exposure to various *drugs* can also cause diffuse hair loss, usually by inducing a telogen effluvium. An exception is the anagen effluvium observed with antimitotic agents such as daunorubicin. Alopecia is a side effect of the following drugs: warfarin, heparin, propylthiouracil, carbimazole, vitamin A, isotretinoin, acetretin, lithium, beta blockers, colchicine, and amphetamines. Fortunately, spontaneous regrowth usually follows discontinuation of the offending agent.

Less commonly, nonscarring alopecia is associated with *lupus erythematosus* and *secondary syphilis.* In systemic lupus there are two forms of alopecia -- one is scarring secondary to discoid lesions (see below) and the other is nonscarring. The latter form may be diffuse and involve the entire scalp, or it may localized to the frontal scalp and result in multiple short hairs ("lupus hairs"). Scattered, poorly circumscribed patches of alopecia with a "moth-eaten" appearance are a manifestation of the secondary stage of syphilis. Diffuse thinning of the hair is also associated with hypothyroidism, hyperthyroidism, and HIV infection (Table 57-4).

Scarring alopecia is more frequently the result of a primary cutaneous disorder such as *lichen planus*, *folliculitis decalvans*, *cutaneous lupus*, or *linear scleroderma* (*morphea*) than it is a sign of systemic disease. Although the scarring lesions of *discoid lupus* can be seen in patients with systemic lupus, in the majority of cases the disease process is limited to the skin. Less common causes of scarring alopecia include *sarcoidosis* (see "Papulonodular Skin Lesions") and cutaneous *metastases*.

In the early phases of discoid lupus, lichen planus, and folliculitis decalvans, there are circumscribed areas of alopecia. Fibrosis and subsequent loss of follicles are observed primarily in the center of the individual lesions, while the inflammatory process is most

prominent at the periphery. The areas of active inflammation in discoid lupus are erythematous with scale, whereas the areas of previous inflammation are often hypopigmented with a rim of hyperpigmentation. In lichen planus the peripheral perifollicular macules are usually violet-colored. Complete examination of the skin and oral mucosa combined with a biopsy and direct immunofluorescence microscopy will aid in distinguishing these two entities. The peripheral active lesions in folliculitis decalvans are perifollicular pustules; these patients can develop a reactive arthritis.

FIGURATE SKIN LESIONS (Table 57-6)

In *figurate* eruptions, the lesions form rings and arcs that are usually erythematous but can be flesh-colored to brown. Most commonly, they are due to primary cutaneous diseases such as *tinea*, *urticaria*, *erythema annulare centrifugum*, and *granuloma annulare* (Chaps. 56 and58). An underlying systemic illness is found in a second, less common group of migratory annular erythemas. It includes *erythema gyratum repens*, *erythema migrans*, *erythema marginatum*, and *necrolytic migratory erythema*.

In erythema gyratum repens, one sees hundreds of mobile concentric arcs and wavefronts that resemble the grain in wood. A search for an underlying malignancy is mandatory in a patient with this eruption. Erythema migrans is the cutaneous manifestation of Lyme disease, which is caused by the spirochete *Borrelia burgdorferi*. In the initial stage (3 to 30 days after tick bite), a single annular lesion is usually seen, which can expand to ³10 cm in diameter. Within several days, approximately half the patients develop multiple smaller erythematous lesions at sites distant from the bite. Associated symptoms include fever, headache, photophobia, myalgias, arthralgias, and malar rash. Erythema marginatum is seen in patients with rheumatic fever, primarily on the trunk. Lesions are pink-red in color, flat to mildly elevated, and transient.

There are additional cutaneous diseases that present as annular eruptions but lack an obvious migratory component. Examples include*CTCL*, *annular cutaneous lupus*, also referred to as *subacute lupus*, *secondary syphilis*, and *sarcoidosis* (see "Papulonodular Skin Lesions").

ACNE (Table 57-7)

Acne vulgaris and *acne rosacea* are the two major forms of acne (Chap. 56). Estrogens decrease sebaceous gland activity, whereas androgens enhance sebum production. Therefore, acne vulgaris in an adult, especially if it is of recent onset, may be a reflection of increased levels of circulating *androgens*. Dysfunction of the ovary or adrenal gland, e.g., polycystic ovary disease or Cushing's syndrome, can lead to the hormonal imbalance. Examination of the patient for signs such as hirsutism, androgenetic alopecia, hypertension, and redistribution of subcutaneous fat will aid in the diagnosis.

Exacerbations of acne vulgaris follow the ingestion of several *drugs*, such as anabolic steroids, glucocorticoids, lithium, and iodides as well as the application of oil-containing compounds. Acne-like lesions can be seen in patients with Behcet's disease (see "Ulcers"), and in immunocompromised hosts, disseminated fungal infections (e.g., cryptococcosis) may present as an acneiform eruption.

Patients with the carcinoid syndrome have episodes of flushing of the head, neck, and sometimes the trunk. Resultant skin changes of the face, in particular telangiectasias, may mimic the clinical appearance of acne rosacea.

PUSTULAR LESIONS

Acneiform eruptions (see "Acne") and *folliculitis* represent the most common pustular dermatoses. An important consideration in the evaluation of perifollicular pustules is a determination of the associated pathogen, e.g., normal flora, *Staphylococcus aureus*, *Pityrosporum*. Noninfectious forms of folliculitis include HIV-associated eosinophilic folliculitis and folliculitis secondary to drugs such as glucocorticoids and lithium. Administration of high-dose oral glucocorticoids can result in a widespread eruption of perifollicular pustules on the trunk, characterized by lesions in the same stage of development. With regard to underlying systemic diseases, pustules are a characteristic component of pustular psoriasis and can be seen in septic emboli of bacterial or fungal origin (see "Purpura").

TELANGIECTASIAS (Table 57-8)

In order to distinguish the various types of telangiectasias, it is important to examine the shape and configuration of the dilated blood vessels. *Linear telangiectasias* are seen on the face of patients with *actinically damaged skin* and *acne rosacea* and they are found on the legs of patients with *venous hypertension* and *essential telangiectasia*. Patients with an unusual form of *mastocytosis* (telangiectasia macularis eruptiva perstans), the *carcinoid* syndrome (see "Acne"), and *ataxia-telangiectasia* also have linear telangiectasias. In ataxia-telangiectasia, linear telangiectasias appear on the bulbar conjunctiva during childhood. Eventually, there is involvement of the ears, eyelids, cheeks, and/or flexural areas such as the antecubital and popliteal fossae. Lastly, linear telangiectasias are found in areas of cutaneous inflammation. For example, lesions of discoid lupus frequently have telangiectasias within them.

Poikiloderma is a term used to describe a patch of skin with (1) reticulated hypo- and hyperpigmentation, (2) wrinkling secondary to epidermal atrophy, and (3) telangiectasias. Poikiloderma does not imply a single disease entity -- it is seen in skin damaged by *ionizing radiation*, in the disorders *poikiloderma vasculare atrophicans* (PVA) and *xeroderma pigmentosum*, as well as in patients with connective-tissue diseases, primarily *dermatomyositis* (DM).PVA is a precursor lesion ofCTCL, and the areas of poikiloderma usually begin in the flexural areas of the axillae and groin.

In *scleroderma*, the dilated blood vessels have a unique configuration and are known as *mat telangiectasias*. The lesions are broad macules that usually measure 2 to 7 mm in diameter but occasionally are larger. Mats have a polygonal or oval shape, and their erythematous color may be uniform or the result of delicate telangiectasias. The most common locations for mat telangiectasias are the face, oral mucosa, and hands -- peripheral sites that are prone to intermittent ischemia. The CREST (*c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) variant of scleroderma (Chap. 313) is associated with a chronic course and anticentromere antibodies. Mat telangiectasias are an important clue to the diagnosis of

the CREST syndrome as well as systemic scleroderma, for they may be the only cutaneous finding.

Periungual telangiectasias are pathognomonic signs of the three major connective tissue diseases -- *lupus erythematosus*, *scleroderma*, and*DM*. They are easily visualized by the naked eye and occur in at least two-thirds of these patients. In both DM and lupus there is associated nailfold erythema, and in DM the erythema is often accompanied by "ragged" cuticles and fingertip tenderness. Under 10´ magnification, the blood vessels in the nailfolds of lupus patients are tortuous and resemble "glomeruli," whereas in scleroderma and DM there is a loss of capillary loops and those that remain are markedly dilated.

In *hereditary hemorrhagic telangiectasia* (Osler-Rendu-Weber disease), the lesions usually appear during adulthood and are most commonly seen on the mucous membranes, face, and distal extremities, including under the nails. They represent arteriovenous (AV) malformations of the dermal microvasculature, are dark red in color, and are usually slightly elevated. When the skin is stretched over an individual lesion, an eccentric punctum with radiating legs is seen. Although the degree of systemic involvement varies in this autosomal dominant disease (due to mutations in either the endoglin or activin receptor-like kinase gene), the major symptoms are recurrent epistaxis and gastrointestinal bleeding. The fact that these mucosal telangiectasias are actually AV communications helps to explain their tendency to bleed.

HYPOPIGMENTATION (Table 57-9)

Disorders of hypopigmentation are classified as either diffuse or localized. The classic example of *diffuse hypopigmentation* is *oculocutaneous albinism* (OCA). The most common forms are due to mutations in the tyrosinase gene (type I) or the *P* gene (type II); patients with type IA OCA have a total lack of enzyme activity. At birth, different forms of OCA can appear similar -- white hair, gray-blue eyes, and pink-white skin. However, the patients with no tyrosinase activity maintain this phenotype, whereas those with decreased activity or *P* gene mutations will acquire some pigmentation of the eyes, hair, and skin as they age. The degree of pigment formation is also a function of racial background, and the pigmentary dilution is readily apparent when patients are compared to their first-degree relatives.

The ocular findings inOCAcorrelate with the degree of hypopigmentation and include decreased visual acuity, nystagmus, photophobia, and monocular vision. Generalized vitiligo, phenylketonuria, and homocystinuria are other unusual causes of diffuse pigmentary dilution. In generalized vitiligo, melanocytes are not found in affected skin, whereas in OCA they are present but have decreased activity. Appropriate laboratory tests exclude the other disorders of metabolism.

The differential diagnosis of *localized hypomelanosis* includes the following primary cutaneous disorders: *idiopathic guttate hypomelanosis*, *postinflammatory hypopigmentation*, *tinea (pityriasis) versicolor*, *vitiligo*, *chemical leukoderma*, *nevus depigmentosus* (see below), and *piebaldism* (Table 57-9). In this group of diseases, the areas of involvement are macules or patches with a decrease or absence of pigmentation. Patients with vitiligo also have an increased incidence of several

autoimmune disorders, including hypothyroidism, Graves' disease, pernicious anemia, Addison's disease, uveitis, alopecia areata, chronic mucocutaneous candidiasis, and the polyglandular autoimmune syndromes (types I and II). Diseases of the thyroid gland are the most frequently associated disorders, occurring in up to 30% of patients with vitiligo. Circulating autoantibodies are often found, and the most common ones are antithyroglobulin, antimicrosomal, and antiparietal cell antibodies.

There are three systemic diseases that should be considered in a patient with skin findings suggestive of vitiligo -- *Vogt-Koyanagi-Harada syndrome*, *scleroderma*, and *melanoma-associated leukoderma*. A history of aseptic meningitis, nontraumatic uveitis, tinnitus, hearing loss, and/or dysacousis points to the diagnosis of the Vogt-Koyanagi-Harada syndrome. In these patients, the face and scalp are the most common locations of pigment loss. The vitiligo-like leukoderma seen in patients with scleroderma has a clinical resemblance to idiopathic vitiligo that has begun to repigment as a result of treatment; that is, perifollicular macules of normal pigmentation are seen within areas of depigmentation. The basis of this leukoderma is unknown; there is no evidence of inflammation in areas of involvement, but it can resolve if the underlying connective tissue disease becomes inactive. In contrast to idiopathic vitiligo, melanoma-associated leukoderma often begins on the trunk, and its appearance should prompt a search for metastatic disease. The possibility exists that the destruction of normal melanocytes is the result of an immune response against malignant melanocytes.

There are two systemic disorders that may have the cutaneous findings of piebaldism (Table 57-10). They are *Hirschsprung's disease* and *Waardenburg's syndrome*. A possible explanation for both disorders is an abnormal embryonic migration or survival of two neural crest-derived elements, one of them being melanocytes and the other myenteric ganglion cells (Hirschsprung's disease) or auditory nerve cells (Waardenburg's syndrome). The latter syndrome is characterized by congenital sensorineural hearing loss, dystopia canthorum (lateral displacement of the inner canthi but normal interpupillary distance), heterochromic irises, and a broad nasal root, in addition to the piebaldism. Patients with Waardenburg's syndrome have been shown to have mutations in two genes that encode DNA-binding proteins, *PAX-3* and *MITF*, while patients with Hirschsprung's disease and white spotting have mutations in one of three genes -- endothelin 3, endothelin B receptor, and *SOX-10*.

In *tuberous sclerosis*, the earliest cutaneous sign is an ash leaf spot. These lesions are often present at birth and are usually multiple; however, detection may require Wood's lamp examination, especially in fair-skinned individuals. The pigment within them is reduced but not absent. The average size is 1 to 3 cm, and the common shapes are polygonal and lance-ovate. Examination of the patient for additional cutaneous signs such as adenoma sebaceum (multiple angiofibromas of the face), ungual and gingival fibromas, fibrous plaques of the forehead, and connective tissue nevi (shagreen patches) is recommended. It is important to remember that an ash leaf spot on the scalp will result in *poliosis*, which is a circumscribed patch of gray-white hair. Internal manifestations include seizures, mental retardation, central nervous system (CNS) and retinal hamartomas, renal angiomyolipomas, and cardiac rhabdomyomas. The latter can be detected in up to 60% of children (<18 years) with tuberous sclerosis by echocardiography.

Nevus depigmentosus is a stable, well-circumscribed hypomelanosis that is present at birth. There is usually a single circular or rectangular lesion, but occasionally the nevus has a dermatomal or whorled pattern. It is important to distinguish this more common entity from ash leaf spots especially when there are multiple lesions. In *hypomelanosis of Ito*, swirls and streaks of hypopigmentation run parallel to one another in a pattern that resembles a marble cake. Lesions may progress or regress with time, and in up to a third of patients, associated abnormalities are found including in the musculoskeletal system (asymmetry), theCNS(seizures and mental retardation), and the eyes (strabismus and hypertelorism). Chromosomal mosaicism has been detected in these patients; this lends support to the hypothesis that the pattern is the result of the migration of two clones of primordial melanocytes, each with a different pigment potential.

Localized areas of decreased pigmentation are commonly seen as a result of cutaneous inflammation (Table 57-10) and have been observed in the skin overlying active lesions of sarcoidosis (see "Papulonodular Skin Lesions") as well as inCTCL. Cutaneous infections also present as disorders of hypopigmentation, and in *tuberculoid leprosy* there are a few asymmetric patches of hypomelanosis that have associated anesthesia, anhidrosis, and alopecia. Biopsy specimens of the palpable border show dermal granulomas that lack *Mycobacterium leprae* organisms.

HYPERPIGMENTATION (Table 57-11)

Disorders of hyperpigmentation are also divided into two groups -- localized and diffuse. The *localized* forms are due to an epidermal alteration, a proliferation of melanocytes, or an increase in pigment production. Both seborrheic keratoses and acanthosis nigricans belong to the first group. *Seborrheic keratoses* are common lesions, but in one clinical setting they are a sign of systemic disease, and that setting is the sudden appearance of multiple lesions, often with an inflammatory base and in association with acrochordons (skin tags) and acanthosis nigricans. This is termed the *sign of Leser-Trelat* and signifies an internal malignancy. *Acanthosis nigricans* can also be a reflection of an internal malignancy, most commonly of the gastrointestinal tract, and it appears as velvety hyperpigmentation, primarily in flexural areas. In the majority of patients, acanthosis nigricans is associated with obesity, but it may be a reflection of an endocrinopathy such as acromegaly, Cushing's syndrome, the Stein-Leventhal syndrome, or insulin-resistant diabetes mellitus (type A, type B, and lipoatrophic forms).

A proliferation of melanocytes results in the following pigmented lesions: *lentigo*, *melanocytic nevus*, and *melanoma* (Chap. 86). In an adult, the majority of lentigines are related to sun exposure, which explains their distribution. However, in the Peutz-Jeghers and LEOPARD [*l*entigines; *E*CG abnormalities, primarily conduction defects, *o*cular hypertelorism; *p*ulmonary stenosis and subaortic valvular stenosis; *a*bnormal genitalia (cryptorchidism, hypospadias); *r*etardation of growth; and *d*eafness (sensorineural)] syndromes, lentigines do serve as a clue to systemic disease. In the multiple lentigines or *LEOPARD syndrome*, hundreds of lentigines develop during childhood and are scattered over the entire surface of the body. The lentigines in patients with *Peutz-Jeghers syndrome* are located primarily around the nose and mouth, on the hands and feet, and within the oral cavity. While the pigmented macules on the

face may fade with age, the oral lesions persist. However, similar intraoral lesions are also seen in Addison's disease and as a normal finding in darkly pigmented individuals. Patients with this autosomal dominant syndrome (due to mutations in a novel serine threonine kinase gene) have multiple benign polyps of the gastrointestinal tract, testicular tumors, and an increased risk of developing gastrointestinal (primarily colon), breast, and gynecologic cancers.

Lentigines are also seen in association with cardiac myxomas and have been described in two syndromes whose findings overlap: *LAMB* (*l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi) *syndrome* and *NAME* [*n*evus, *a*trial myxoma, *m*yxoid neurofibroma, and *e*phelides (freckles)] *syndrome*. These patients can also have evidence of endocrine overactivity in the form of Cushing's syndrome, acromegaly, or sexual precocity.

The third type of localized hyperpigmentation is due to a local increase in pigment production, and it includes *ephelides* and cafe au lait macules (CALM). The latter are most commonly associated with two disorders -- neurofibromatosis (NF) and McCune-Albright syndrome. *CALM* are flat, uniformly light brown in color, and can vary in size from 0.5 to 12 cm. Approximately 80% of adult patients with *type I NF* will have six or more CALM measuring 1.5 cm or greater in diameter. Additional findings are discussed in the section on neurofibromas (see "Papulonodular Skin Lesions"). In comparison with NF, the CALM in patients with *McCune-Albright syndrome* [polyostotic fibrous dysplasia with precocious puberty in females due to mosaicism for an activating mutation in a G protein ($G_s a$) gene] are usually larger, more irregular in outline, and tend to respect the midline. CALM have also been associated with pulmonary stenosis (Watson syndrome), tuberous sclerosis, theLEOPARDsyndrome, and ataxia telangiectasia, but a few such lesions can be found in normal individuals.

In incontinentia pigmenti, dyskeratosis congenita, and bleomycin pigmentation, the areas of localized hyperpigmentation form a pattern -- swirled in the first, reticulated in the second, and flagellate in the third. Patients with the X-linked dominant disorder *incontinentia pigmenti* can have linear blisters and verrucous papules during infancy. During childhood, parallel swirls and streaks of hyperpigmentation appear on the trunk, and occasionally streaks of hypopigmentation appear on the extremities. Associated findings include seizures, mental retardation, retinal vascular abnormalities, and delayed or impaired dentition. Biopsy specimens of the streaks will show pigment within dermal macrophages ("incontinent pigment"). In *dyskeratosis congenita*, atrophic reticulated hyperpigmentation is seen on the neck, thighs, and trunk and is accompanied by nail dystrophy, pancytopenia, and leukoplakia of the oral and anal mucosa. The latter often develops into squamous cell carcinoma. In addition to the flagellate pigmentation (linear streaks) on the trunk, patients receiving bleomycin often have hyperpigmentation on the elbows, knees, and small joints of the hand.

Localized hyperpigmentation is seen as a side effect of several other *systemic medications*, including those that produce fixed drug reactions [phenolphthalein, nonsteroidal anti-inflammatory drugs (NSAIDs), sulfonamides, and barbiturates] and those that can complex with melanin (antimalarials). Fixed drug eruptions recur in the same location as circular areas of erythema that can become bullous and then resolve as brown macules. The eruption usually appears within hours of administration of the

offending agent, and common locations include the genitalia, extremities, and perioral region. Chloroquine and hydroxychloroquine produce gray-brown to blue-black discoloration of the shins, hard palate, and face, while blue macules can be seen on the lower extremities and in sites of inflammation with prolonged minocycline administration. Estrogen in oral contraceptives can induce melasma -- symmetric brown patches on the face, especially the cheeks, upper lip, and forehead. Similar changes are seen in pregnancy, in patients receiving hydantoin, and in the adult form of Gaucher's disease. In the latter group there is also hyperpigmentation of the distal lower extremities.

In the *diffuse* forms of hyperpigmentation, the darkening of the skin may be of equal intensity over the entire body or may be accentuated in sun-exposed areas. The causes of diffuse hyperpigmentation can be divided into four groups -- endocrine, metabolic, autoimmune, and drugs. The endocrinopathies that frequently have associated hyperpigmentation include *Addison's disease*, *Nelson syndrome*, and *ectopic ACTH syndrome*. In these diseases, the increased pigmentation is diffuse but is accentuated in the palmar creases, sites of friction, scars, and the oral mucosa. An overproduction of the pituitary hormonesa-MSH (melanocyte-stimulating hormone) and ACTH can lead to an increase in melanocyte activity. These peptides are products of the proopiomelanocortin gene and exhibit homology; e.g.,a-MSHand ACTH share 13 amino acids. A minority of the patients with Cushing's disease or hyperthyroidism have generalized hyperpigmentation.

The metabolic causes of hyperpigmentation include *porphyria cutanea tarda* (PCT), *hemochromatosis*, *vitamin B_{12}deficiency*, *folic acid deficiency*, *pellagra*, *malabsorption*, and *Whipple's disease*. In patients with PCT (see "Vesicles/Bullae"), the skin darkening is seen in sun-exposed areas and is a reflection of the photoreactive properties of porphyrins. The increased level of iron in the skin of patients with hemochromatosis stimulates melanin pigment production and leads to the classic bronze color. Patients with pellagra have a brown discoloration of the skin, especially in sun-exposed areas, as a result of nicotinic acid (niacin) deficiency. In the areas of increased pigmentation, there is a thin varnish-like scale. These changes are also seen in patients who are vitamin B_6deficient, have functioning carcinoid tumors (increased consumption of niacin), or take isoniazid. Approximately 50% of the patients with Whipple's disease have an associated generalized hyperpigmentation in association with diarrhea, weight loss, arthritis, and lymphadenopathy. A diffuse slate-blue color is seen in patients with melanosis secondary to metastatic melanoma. Although there is a debate as to whether the color is due to single-cell metastases in the dermis or to a widespread deposition of melanin resulting from the high concentration of circulating melanin precursors, there is more evidence to support the latter.

Of the autoimmune diseases associated with diffuse hyperpigmentation, *biliary cirrhosis* and *scleroderma* are the most common, and occasionally, both disorders are seen in the same patient. The skin is dark brown in color, especially in sun-exposed areas. In biliary cirrhosis the hyperpigmentation is accompanied by pruritus, jaundice, and xanthomas, whereas in scleroderma it is accompanied by sclerosis of the extremities, face, and, less commonly, the trunk. Additional clues to the diagnosis of scleroderma are telangiectasias, calcinosis cutis, Raynaud's phenomenon, and distal ulcerations (see "Telangiectasias"). The differential diagnosis of cutaneous sclerosis with hyperpigmentation includes the POEMS [*p*olyneuropathy; *o*rganomegaly (liver, spleen,

lymph nodes); *e*ndocrinopathies (impotence, gynecomastia); *M*-protein; and *s*kin changes] syndrome. The skin changes include hyperpigmentation, skin thickening, hypertrichosis, and angiomas.

In the late 1980s, an epidemic of the eosinophilia-myalgia syndrome was described that was presumably due to contaminated L-tryptophan preparations. In addition to maculopapular eruptions and alopecia, large areas of scleroderma-like induration were observed with overlying hyperpigmentation.

Diffuse hyperpigmentation that is due to *drugs* or *metals* can result from one of several mechanisms -- induction of melanin pigment formation, complexing of the drug or its metabolites to melanin, and deposits of the drug in the dermis. Busulfan, cyclophosphamide, long-term, high-dose ACTH, and inorganic arsenic induce pigment production. Complexes containing melanin or hemosiderin plus the drug or its metabolites are seen in patients receiving chlorpromazine and minocycline. The sun-exposed skin as well as the conjunctivae of patients on long-term, high-dose chlorpromazine can become blue-gray in color. Patients taking minocycline may develop a diffuse blue-gray, muddy appearance in sun-exposed areas in addition to pigmentation of the mucous membranes, teeth, nails, bones, and thyroid. Administration of amiodarone can result in both a phototoxic eruption (exaggerated sunburn) and/or a brown or blue-gray discoloration of sun-exposed skin. Biopsy specimens of the latter show yellow-brown granules in dermal macrophages, which represent intralysosomal accumulations of lipids, amiodarone, and its metabolites. Actual deposits of a particular drug or metal in the skin are seen with silver (argyria), where the skin appears blue-gray in color; gold (chrysiasis), where the skin has a brown to blue-gray color; and clofazimine, where the skin appears reddish brown. The associated hyperpigmentation is accentuated in sun-exposed areas, and discoloration of the eye is seen with gold (sclerae) and clofazimine (conjunctivae).

VESICLES/BULLAE (Table 57-12)

Depending on their size, cutaneous blisters are referred to as *vesicles* (<0.5 cm) or *bullae* (>0.5 cm). The primary blistering disorders include *pemphigus vulgaris*, *pemphigus foliaceus*, *pemphigus erythematosus*, *paraneoplastic pemphigus*, *bullous pemphigoid*, *herpes gestationis*, *cicatricial pemphigoid*, *epidermolysis bullosa acquisita*, *linear IgA disease*, and *dermatitis herpetiformis* (Chap. 58).

Vesicles and bullae are also seen in *contact dermatitis*, both allergic and irritant forms (Chap. 56). When there is a linear arrangement of vesicular lesions, an exogenous cause should be suspected. Bullous disease secondary to the ingestion of drugs can take one of several forms, including phototoxic eruptions, isolated bullae, toxic epidermal necrolysis, and erythema multiforme (Chap. 59). Clinically, phototoxic eruptions resemble an exaggerated sunburn with diffuse erythema and bullae in sun-exposed areas. The most commonly associated drugs are thiazides, doxycycline, sulfonamides,NSAIDs, and psoralens. The development of a phototoxic eruption is dependent on the doses of both the drug and UV-A irradiation.

Toxic epidermal necrolysis (TEN) is characterized by bullae that arise on widespread areas of erythema and then slough. This results in large areas of denuded skin. The

associated morbidity, such as sepsis, and mortality are relatively high and are a function of the extent of epidermal necrosis. In addition, these patients may also have involvement of the mucous membranes and intestinal tract. Drugs are the primary cause of TEN, and the most common offenders are phenytoin, barbiturates, sulfonamides, penicillins, andNSAIDs. Severe acute graft-versus-host disease (grade 4) also can resemble TEN.

In *erythema multiforme* (EM), the primary lesions are pink-red macules and edematous papules, the centers of which may become vesicular. The clue to the diagnosis of EM, as opposed to a drug-induced morbilliform exanthem, is the development of a "dusky" violet color or petechiae in the center of the lesions. Target or iris lesions are also characteristic of EM and arise as a result of active centers and borders in combination with centrifugal spread. However, iris lesions need not be present to make the diagnosis of EM. Preferred sites of involvement include the distal extremities and mucous membranes (oral, nasal, ocular, and genital). Hemorrhagic crusts of the lips are characteristic of EM as well as herpes simplex, pemphigus vulgaris, and paraneoplastic pemphigus. Fever, malaise, myalgias, sore throat, and cough may precede or accompany the eruption. The lesions of EM usually resolve over 3 to 6 weeks but may be recurrent.

Drugs can induceEM, in particular sulfonamides, phenytoin, barbiturates, penicillins, and carbamazepine, but they do not cause the majority of cases, especially in young adults. Infections with herpes simplex are the most common cause of EM in this age group, and the lesions appear 7 to 12 days after the viral eruption. Other infectious agents associated with EM include *Mycoplasma pneumoniae*, dimorphic fungi, and several viruses (echovirus, coxsackievirus, Epstein-Barr, and influenza). EM can also follow vaccinations with BCG, poliomyelitis, or vaccinia viruses; radiation therapy; and exposure to environmental toxins.

In addition to primary blistering disorders and hypersensitivity reactions, bacterial and viral infections can lead to vesicles and bullae. The most common infectious agents are herpes simplex (Chap. 182), herpes varicella-zoster (Chap. 183), and staphylococci (Chap. 139).

Staphylococcal scalded-skin syndrome (SSSS) and *bullous impetigo* are two blistering disorders associated with staphylococcal (phage group II) infection. In SSSS, the initial findings are redness and tenderness of the central face, neck, trunk, and intertriginous zones. This is followed by short-lived flaccid bullae and a slough or exfoliation of the superficial epidermis. Crusted areas then develop, characteristically around the mouth. SSSS is distinguished fromTEN by the following features: younger age group, more superficial site of blister formation, no oral lesions, shorter course, less morbidity and mortality, and an association with staphylococcal exfoliative toxin ("exfoliatin"), not drugs. A rapid diagnosis of SSSS versus TEN can be made by a frozen section of the blister roof or exfoliative cytology of the blister contents. In SSSS the site of staphylococcal infection is usually extracutaneous (conjunctivitis, rhinorrhea, otitis media, pharyngitis, tonsillitis), and the cutaneous lesions are sterile, whereas in bullous impetigo the skin lesions are the site of infection. Impetigo is more localized than SSSS and usually presents with honey-colored crusts. Occasionally, superficial purulent blisters also form. *Cutaneous emboli* from gram-negative infections may present as

isolated bullae, but the base of the lesion is purpuric or necrotic, and it may develop into an ulcer (see "Purpura").

Several metabolic disorders are associated with blister formation, including diabetes mellitus, renal failure, and porphyria. Local hypoxia secondary to decreased cutaneous blood flow can also produce blisters, which explains the presence of bullae over pressure points in comatose patients (coma bullae). In *diabetes mellitus*, tense bullae with clear viscous fluid arise on normal skin. The lesions can be as large as 6 cm in diameter and are located on the distal extremities. There are several types of porphyria, but the most common form with cutaneous findings is*PCT*. In sun-exposed areas (primarily the face and hands), the skin is very fragile, and trauma leads to erosions and tense vesicles. These lesions then heal with scarring and formation of milia; the latter are firm, 2- to 3-mm white or yellow papules that represent epidermoid inclusion cysts. Associated findings can include hypertrichosis of the lateral malar region (males) or face (females) and, in sun-exposed areas, hyperpigmentation and firm sclerotic plaques. An elevated level of urinary uroporphyrins confirms the diagnosis and is due to a decrease in uroporphyrinogen decarboxylase activity. Precipitating agents include alcohol, iron, chlorinated hydrocarbons, and hepatitis C infection.

The differential diagnosis ofPCTincludes (1) *porphyria variegata* -- the skin signs of PCT plus the systemic findings of acute intermittent porphyria; it has a diagnostic plasma porphyrin fluorescence emission at 626 nm; (2) *drug-induced bullous photosensitivity* (pseudoporphyria) -- the clinical and histologic findings are similar to PCT, but porphyrins are normal; etiologic agents include naproxen, furosemide, tetracycline, and nalidixic acid; (3) *bullous dermatosis of hemodialysis* -- the same appearance as PCT, but porphyrins are usually normal or occasionally borderline elevated; patients have chronic renal failure and are on hemodialysis; (4) PCT associated with hepatomas, hepatic carcinomas, and hemodialysis; and (5) *epidermolysis bullosa acquisita* (Chap. 58).

EXANTHEMS (Table 57-13)

Exanthems are characterized by an acute generalized eruption. The two most common presentations are erythematous macules and papules (morbilliform) and confluent blanching erythema (scarlatiniform). *Morbilliform* eruptions are usually due to either *drugs* or *viral infections*. For example, up to 5% of the patients receiving penicillins, sulfonamides, phenytoin, or gold will develop a maculopapular eruption. Accompanying signs may include pruritus, fever, eosinophilia, and transient lymphadenopathy. Similar maculopapular eruptions are seen in the classic childhood viral exanthems, including (1) *rubeola* (measles) -- a prodrome of coryza, cough, and conjunctivitis followed by Koplik's spots on the buccal mucosa; the eruption begins behind the ears, at the hairline, and on the forehead and then spreads down the body, often becoming confluent; (2) *rubella* -- it begins on the forehead and face and then spreads down the body; it resolves in the same order and is associated with retroauricular and suboccipital lymphadenopathy; and (3) *erythema infectiosum* (fifth disease) -- erythema of the cheeks is followed by a reticulated pattern on extremities; it is secondary to a parvovirus B19 infection, and an associated arthritis is seen in adults.

Both measles and rubella are seen in unvaccinated young adults, and an atypical form

of measles is seen in adults immunized with either killed measles vaccine or killed vaccine followed in time by live vaccine. In contrast to classic measles, the eruption of atypical measles begins on the palms, soles, wrists, and knuckles, and the lesions may become purpuric. The patient with atypical measles can have pulmonary involvement and be quite ill. Rubelliform and roseoliform eruptions are also associated with *Epstein-Barr virus* (5 to 15% of patients), *echovirus*, *coxsackievirus*, and *adenovirus* infections. Detection of specific IgM antibodies or fourfold elevations in IgG antibodies allows the proper diagnosis. Occasionally, a maculopapular eruption is the result of a drug-viral interaction. For example, about 95% of the patients with infectious mononucleosis who are given ampicillin will develop a rash.

Of note, early in the course of infections with *Rickettsia* and *meningococcus*, prior to the development of purpura, the lesions may be erythematous macules and papules. This is also the case in chickenpox prior to the development of vesicles. Maculopapular eruptions are associated with early *HIV infection*, early secondary *syphilis*, *typhoid fever*, and *acute graft-versus-host disease*. In the last, lesions frequently begin on the palms and soles; the macular rose spots of typhoid fever involve primarily the anterior trunk.

The prototypic *scarlatiniform* eruption is seen in *scarlet fever* and is due to an erythrotoxin produced by group A b-hemolytic streptococcal infections, most commonly pharyngitis. This eruption is characterized by diffuse erythema, which begins on the neck and upper trunk, and red perifollicular puncta. Additional findings include a white strawberry tongue (white coating with red papillae) followed by a red strawberry tongue (red tongue with red papillae); petechiae of the palate; a facial flush with circumoral pallor; linear petechiae in the antecubital fossae; and desquamation of the involved skin, palms, and soles 5 to 20 days after onset of the eruption. A similar desquamation of the palms and soles is seen in toxic shock syndrome, Kawasaki's disease, and after severe febrile illnesses. Certain strains of staphylococci also produce an erythrotoxin that leads to the same clinical findings as in streptococcal scarlet fever, except that the antistreptolysin O titers are not elevated.

In *toxic shock syndrome* (TSS), staphylococcal (phage group I) infections produce an exotoxin (TSST-1) that causes the fever and rash, as well as enterotoxins. Initially, the majority of cases were reported in menstruating women who were using tampons. However, other sites of infection, including wounds and vaginitis, may produce TSS. The diagnosis of TSS is based on clinical criteria (Chap. 139), and three of these involve mucocutaneous sites. The clinical criteria are (1) fever; (2) diffuse erythema of the skin; (3) desquamation of the palms and soles 1 to 2 weeks after onset of illness; (4) hypotension; and (5) involvement of three or more organ systems, including the gastrointestinal tract, muscles, kidney, liver,CNS, hematologic (thrombocytopenia), and mucous membranes. The latter is characterized as hyperemia of the vagina, oropharynx, or conjunctivae. Similar systemic findings have been described in *streptococcal toxic shock-like syndrome* (Chap. 140), and although an exanthem is seen less often than in TSS due to a staphylococcal infection, the underlying infection is often in the soft tissue.

The cutaneous eruption in *Kawasaki's disease* (mucocutaneous lymph node syndrome) (Chap. 317) is polymorphous, but the two most common forms are morbilliform and

scarlatiniform. The majority of cases are seen in children less than 5 years of age, but adult cases have been reported. The diagnosis is based on a fever lasting more than 5 days plus four of the five following criteria: (1) bilateral conjunctival injection; (2) exanthem; (3) cervical lymphadenopathy, usually unilateral; (4) erythema and edema of the hands and feet followed by desquamation; and (5) diffuse erythema of the oropharynx, red strawberry tongue, and erosions with crusting on the lips. This clinical picture can resembleTSS and scarlet fever, but clues to the diagnosis of Kawasaki's disease are the cervical lymphadenopathy, lip erosions, and increased platelets. The most serious associated systemic finding in this disease is coronary aneurysm secondary to arteritis. Aneurysms may lead to sudden death, primarily within the first 30 days of the illness. Scarlatiniform eruptions are also seen in the early phase of SSSS(see "Vesicles/Bullae") and as reactions to drugs.

URTICARIA (Table 57-14)

Urticaria (hives) are transient lesions that are composed of a central wheal surrounded by an erythematous halo. Individual lesions are round, oval, or figurate and are often pruritic. *Acute* and *chronic* urticaria have a wide variety of allergic etiologies. Less common systemic causes of urticaria are mastocytosis (urticaria pigmentosa), hyperthyroidism, malignancy, and juvenile rheumatoid arthritis (JRA). In JRA, the lesions coincide with the fever spike and are transient but not migratory as in erythema marginatum.

The common *physical urticarias* include dermographism, solar urticaria, cold urticaria, and cholinergic urticaria. Patients with *dermographism* exhibit linear wheals following minor pressure or scratching of the skin. It is a common disorder, affecting approximately 5% of the population. *Solar urticaria* characteristically occur within minutes of sun exposure and are a skin sign of one systemic disease -- erythropoietic protoporphyria. In addition to the urticaria, these patients have subtle pitted scarring of the nose and hands. *Cold urticaria* are precipitated by exposure to the cold, and therefore exposed areas are usually affected. In some cases, the disease is associated with abnormal circulating proteins -- more commonly cryoglobulins and less commonly cryofibrinogens and cold agglutinins. Additional systemic symptoms include wheezing and syncope, thus explaining the need for these patients to avoid swimming in cold water. *Cholinergic urticaria* are precipitated by heat, exercise, or emotion and are characterized by small wheals with relatively large flares. They are occasionally associated with wheezing.

Whereas urticaria are the result of dermal edema, subcutaneous edema leads to the clinical picture of *angioedema.* Sites of involvement include the eyelids, lips, tongue, larynx, and gastrointestinal tract as well as the subcutaneous tissue. Angioedema occurs alone or in combination with urticaria, including urticarial vasculitis and the physical urticarias. Both acquired and hereditary (autosomal dominant) forms of angioedema occur (Chap. 310), and in the latter, urticaria is rarely seen.

Urticarial vasculitis is an immune complex disease that may be confused with simple urticaria. In contrast to simple urticaria, individual lesions tend to last longer than 24 h and usually develop central petechiae that can be observed even after the urticarial phase has resolved. The patient may also complain of burning rather than pruritus. On

biopsy, there is a leukocytoclastic vasculitis of the small blood vessels. Although many cases of urticarial vasculitis are idiopathic in origin, it can be a reflection of an underlying systemic illness such as lupus erythematosus, Sjogren's syndrome, or hereditary complement deficiency. There is a spectrum of urticarial vasculitis that ranges from purely cutaneous to multisystem involvement. The most common systemic signs and symptoms are arthralgias and/or arthritis, nephritis, and crampy abdominal pain, with asthma and chronic obstructive lung disease seen less often. Hypocomplementemia occurs in one- to two-thirds of patients, even in the idiopathic cases. Urticarial vasculitis can also be seen in patients with *hepatitis B* and *hepatitis C* infections, *serum sickness*, and *serum sickness-like illnesses*.

PAPULONODULAR SKIN LESIONS (Table 57-15)

In the *papulonodular diseases*, the lesions are elevated above the surface of the skin and may coalesce to form plaques. The location, consistency, and color of the lesions are the keys to their diagnosis; this section is organized on the basis of color.

White Lesions In *calcinosis cutis* there are firm white to white-yellow papules with an irregular surface. When the contents are discharged, a chalky white material is seen. *Dystrophic* calcification is seen at sites of previous inflammation or damage to the skin. It develops in acne scars as well as on the distal extremities of patients with scleroderma and in the subcutaneous tissue and intermuscular fascial planes inDM. The latter is more extensive and is more commonly seen in children. An elevated calcium phosphate product, as in secondary hyperparathyroidism, can lead to nodules of *metastatic* calcinosis cutis, which tend to be subcutaneous and periarticular. This form is often accompanied by calcification of muscular arteries and subsequent ischemic necrosis (calciphylaxis).

Skin-Colored Lesions There are several types of skin-colored lesions, including epidermoid inclusion cysts, lipomas, rheumatoid nodules, neurofibromas, angiofibromas, neuromas, and adnexal tumors such as tricholemmomas. Both *epidermoid inclusion cysts* and *lipomas* are very common mobile subcutaneous nodules -- the former are rubbery and compressible and drain cheeselike material (sebum and keratin) if incised. Lipomas are firm and somewhat lobulated on palpation. When extensive facial epidermoid inclusion cysts develop in childhood or there is a family history of such lesions, the patient should be examined for other signs of Gardner syndrome, including osteomas and desmoid tumors. *Rheumatoid nodules* are firm, 0.5- to 4-cm nodules that tend to localize around pressure points, especially the elbows. They are seen in approximately 20% of patients with rheumatoid arthritis and 6% of patients with Still's disease. Biopsies of the nodules show palisading granulomas. Similar lesions that are smaller and shorter-lived are seen in rheumatic fever.

Neurofibromas (benign Schwann cell tumors) are soft papules or nodules that exhibit the "button-hole" sign, that is, they invaginate into the skin with pressure in a manner similar to a hernia. Single lesions are seen in normal individuals, but multiple neurofibromas, usually in combination with six or moreCALMmeasuring >1.5 cm (see "Hyperpigmentation") and multiple Lisch nodules, are seen in von Recklinghausen's disease (NF type I). Lisch nodules are 1-mm yellow-brown spots within the iris that are best observed with slit-lamp examination. Additional manifestations include axillary

freckling and peripheral andCNStumors (Chap. 370). In some patients the neurofibromas are localized and unilateral, whereas in others they are limited to the CNS.

Angiofibromas are firm, pink to skin-colored papules that measure from 3 mm to several centimeters in diameter. When they are located on the central cheeks (adenoma sebaceum) or multiple fibromas are seen around the nails, the patient has tuberous sclerosis. It is an autosomal disorder due to mutations in two different genes, and the associated findings are discussed in the section on ash leaf spots as well as inChap. 370. Multiple facial angiofibromas have also been observed in patients with multiple endocrine neoplasia (MEN) syndrome, type 1.

Neuromas (benign proliferations of nerve fibers) are also firm, skin-colored papules. They are more commonly found at sites of amputation and as rudimentary supernumerary digits. However, when there are multiple neuromas on the eyelids, lips, distal tongue, and/or oral mucosa, the patient should be investigated for other signs of theMENsyndrome, type 2b. Associated findings include marfanoid habitus, protuberant lips, intestinal ganglioneuromas, and medullary thyroid carcinoma (>75% of patients;Chap. 339).

Adnexal tumors are derived from pluripotential cells of the epidermis that can differentiate toward hair, sebaceous, apocrine, or eccrine glands or remain undifferentiated. *Basal cell epitheliomas* (BCEs) are examples of adnexal tumors that have little or no evidence of differentiation. Clinically, they are translucent papules with rolled borders, telangiectasias, and central erosion. BCEs commonly arise in sun-damaged skin of the head and neck. When a patient has multiple BCEs, especially prior to age 30, the possibility of the basal cell nevus syndrome should be raised. It is inherited as an autosomal dominant trait and is associated with jaw cysts, palmar and plantar pits, frontal bossing, medulloblastomas and calcification of the falx cerebri and diaphragma sellae. *Tricholemmomas* are also skin-colored adnexal tumors but differentiate toward hair follicles and can have a wartlike appearance. The presence of multiple tricholemmomas on the face and cobblestoning of the oral mucosa points to the diagnosis of Cowden's disease (multiple hamartoma syndrome) due to mutations in the *PTEN* gene. Internal organ involvement (in decreasing order of frequency) includes fibrocystic disease and carcinoma of the breast, adenomas and carcinomas of the thyroid, and gastrointestinal polyposis. Keratoses of the palms, soles, and dorsa of the hands are also seen.

Pink Lesions The cutaneous lesions associated with primary systemic *amyloidosis* are pink in color and translucent. Common locations are the face, especially the periorbital and perioral regions, and flexural areas. On biopsy, homogeneous deposits of amyloid are seen in the dermis and in the walls of blood vessels; the latter lead to an increase in vessel wall fragility. As a result, petechiae and purpura develop in clinically normal skin as well as in lesional skin following minor trauma, hence the term "pinch purpura." Amyloid deposits are also seen in the striated muscle of the tongue and result in macroglossia.

Even though specific mucocutaneous lesions are rarely seen in secondary amyloidosis and are present in only about 30% of the patients with primary amyloidosis, a rapid

diagnosis of systemic amyloidosis can be made by an examination of abdominal subcutaneous fat. By special staining, deposits are seen around blood vessels or individual fat cells in 40 to 50% of patients. There are also three forms of amyloidosis that are limited to the skin and that should not be construed as cutaneous lesions of systemic amyloidosis. They are macular amyloidosis (upper back), lichenoid amyloidosis (usually lower extremities), and nodular amyloidosis. In macular and lichenoid amyloidosis, the deposits are composed of altered epidermal keratin. Recently, macular and lichenoid amyloidosis have been associated withMENsyndrome, type 2a.

Patients with *multicentric reticulohistiocytosis* also have pink-colored papules and nodules on the face and mucous membranes as well as on the extensor surface of the hands and forearms. They have a polyarthritis that can mimic rheumatoid arthritis clinically. On histologic examination, the papules have characteristic giant cells that are not seen in biopsies of rheumatoid nodules. Pink to skin-colored papules that are firm, 2 to 5 mm in diameter, and often in a linear arrangement are seen in patients with *papular mucinosis*. This disease is also referred to as *lichen myxedematosus* or *scleromyxedema*. The latter name comes from the brawny induration of the face and extremities that may accompany the papular eruption. Biopsy specimens of the papules show localized mucin deposition, and serum protein electrophoresis demonstrates a monoclonal spike of IgG, usually with a l light chain.

Yellow Lesions Several systemic disorders are characterized by yellow-colored cutaneous papules or plaques -- hyperlipidemia (xanthomas), gout (tophi), diabetes (necrobiosis lipoidica), pseudoxanthoma elasticum, and Torre syndrome (sebaceous tumors). Eruptive xanthomas are the most common form of *xanthomas*, and are associated with hypertriglyceridemia (types I, III, IV, and V). Crops of yellow papules with erythematous halos occur primarily on the extensor surfaces of the extremities and the buttocks, and they spontaneously involute with a fall in serum triglycerides. Increasedb-lipoproteins (primarily types II and III) result in one or more of the following types of xanthoma: xanthelasma, tendon xanthomas, and plane xanthomas. Xanthelasma are found on the eyelids, whereas tendon xanthomas are frequently associated with the Achilles and extensor finger tendons; plane xanthomas are flat and favor the palmar creases, face, upper trunk, and scars. Tuberous xanthomas are frequently associated with hypertriglyceridemia, but they are also seen in patients with hypercholesterolemia (type II) and are found most frequently over the large joints or hand. Biopsy specimens of xanthomas show collections of lipid-containing macrophages (foam cells).

Patients with several disorders, including biliary cirrhosis, can have a secondary form of hyperlipidemia with associated tuberous and planar xanthomas. However, patients with myeloma have *normolipemic* flat xanthomas. This latter form of xanthoma may be^{3}12 cm in diameter and is most frequently seen on the upper trunk or side of the neck. It is also important to note that the most common setting for eruptive xanthomas is uncontrolled diabetes mellitus. The least specific sign for hyperlipidemia is xanthelasma, because at least 50% of the patients with this finding have normal lipid profiles.

In *tophaceous gout* there are deposits of monosodium urate in the skin around the joints, particularly those of the hands and feet. Additional sites of *tophi* formation include

the helix of the ear and the olecranon and prepatellar bursae. The lesions are firm, yellow in color, and occasionally discharge a chalky material. Their size varies from 1 mm to 7 cm, and the diagnosis can be established by polarization of the aspirated contents of a lesion. Lesions of *necrobiosis lipoidica* are found primarily on the shins (90%), and patients can have diabetes mellitus or develop it subsequently. Characteristic findings include a central yellow color, atrophy (transparency), telangiectasias, and an erythematous border. Ulcerations can also develop within the plaques. Biopsy specimens show necrobiosis of collagen, granulomatous inflammation, and obliterative endarteritis.

In *pseudoxanthoma elasticum* (PXE) there is an abnormal deposition of calcium on the elastic fibers of the skin, eye, and blood vessels. In the skin, the flexural areas such as the neck, axillae, antecubital fossae, and inguinal area are the primary sites of involvement. Yellow papules coalesce to form reticulated plaques that have an appearance similar to that of plucked chicken skin. In severely affected skin, hanging, redundant folds develop. Some patients have a more subtle macular form of the disease, and careful inspection is required. Biopsy specimens of involved skin show swollen and irregularly clumped elastic fibers with deposits of calcium. In the eye, the calcium deposits in Bruch's membrane lead to angioid streaks and choroiditis; in the arteries of the heart, kidney, gastrointestinal tract, and extremities, the deposits lead to angina, hypertension, gastrointestinal bleeding, and claudication, respectively. Long-term administration of D-penicillamine can lead to PXE-like skin changes as well as elastic fiber alterations in internal organs.

Adnexal tumors that have differentiated toward sebaceous glands include sebaceous adenoma, sebaceous epithelioma, sebaceous carcinoma, and sebaceous hyperplasia. Except for sebaceous hyperplasia, which is commonly seen on the face, these tumors are fairly rare. Patients with Torre syndrome have *sebaceous adenomas*, and in the majority of cases there are multiple such tumors. These patients can also have sebaceous carcinomas and sebaceous hyperplasia as well as keratoacanthomas. The internal manifestations of Torre syndrome include *multiple* carcinomas of the gastrointestinal tract (primarily colon) as well as cancers of the larynx, genitourinary tract, and endometrium. Some patients also have a strong family history of cancer.

Red Lesions Cutaneous lesions that are red in color have a wide variety of etiologies; in an attempt to simplify their identification, they will be subdivided into papules, papules/plaques, and subcutaneous nodules. Common red papules include *arthropod bites* and *cherry hemangiomas*; the latter are small, bright-red, dome-shaped papules that represent benign proliferation of capillaries. In patients with AIDS, the development of multiple red hemangioma-like lesions points to bacillary angiomatosis, and biopsy specimens show clusters of bacilli that stain positive with the Warthin-Starry stain; the pathogens have been identified as *Bartonella henselae* and *B. quintana*. Disseminated visceral disease is seen primarily in immunocompromised hosts but can occur in immunocompetent individuals.

Multiple *angiokeratomas* are seen in Fabry's disease, an X-linked recessive lysosomal storage disease that is due to a deficiency of a-galactosidase A. The lesions are red to red-blue in color and can be quite small in size (1 to 3 mm), with the most common location being the lower trunk. Associated findings include chronic renal failure,

peripheral neuropathy, and corneal opacities (cornea verticillata). Electron photomicrographs of angiokeratomas and clinically normal skin demonstrate lamellar lipid deposits in fibroblasts, pericytes, and endothelial cells that are diagnostic of this disease. Widespread acute eruptions of erythematous papules are discussed in the section on exanthems.

There are several infectious diseases that present as erythematous papules or nodules in a sporotrichoid pattern, that is, in a linear arrangement along the lymphatic channels. The two most common etiologies are *Sporothrix schenckii* (sporotrichosis) and *M. marinum* (atypical mycobacteria). The organisms are introduced as a result of trauma, and a primary inoculation site is often seen in addition to the lymphatic nodules. Additional causes include *Nocardia*, *Leishmania*, and other dimorphic fungi; culture of lesional tissue will aid in the diagnosis.

The diseases that are characterized by erythematous plaques with scale are reviewed in the papulosquamous section, and the various forms of dermatitis are discussed in the section on erythroderma. Additional disorders in the differential diagnosis of red papules/plaques include *erysipelas*, *polymorphous light eruption* (PMLE), *lymphocytoma cutis*, *cutaneous lupus*, *lymphoma cutis*, and *leukemia cutis*. The first three diseases represent primary cutaneous disorders. PMLE is characterized by erythematous papules and plaques in a primarily sun-exposed distribution -- dorsum of the hand, extensor forearm, and face. Lesions follow exposure to UV-B and/or UV-A, and in northern latitudes PMLE is most severe in the late spring and early summer. A process referred to as "hardening" occurs with continued UV exposure, and the eruption fades, but in temperate climates it will recur in the spring. PMLE must be differentiated from cutaneous lupus, and this is accomplished by histologic examination and direct immunofluorescence of the lesions. Lymphocytoma cutis (pseudolymphoma) is a *benign* polyclonal proliferation of lymphocytes in the skin that presents as infiltrated pink-red to red-purple papules and plaques; it must be distinguished from lymphoma cutis.

Several types of red plaques are seen in patients with systemic *lupus*, including (1) erythematous urticarial plaques across the cheeks and nose in the classic butterfly rash; (2) erythematous discoid lesions with fine or "carpet-tack" scale, telangiectasias, central hypopigmentation, peripheral hyperpigmentation, follicular plugging, and atrophy located on the face, scalp, external ears, arms, and upper trunk; and (3) psoriasiform or annular lesions of subacute lupus with hypopigmented centers located on the face, extensor arms, and upper trunk. Additional cutaneous findings include (1) a violaceous flush on the face and V of the neck; (2) urticarial vasculitis (see "Urticaria"); (3) lupus panniculitis (see below); (4) diffuse alopecia; (5) alopecia secondary to discoid lesions; (6) periungual telangiectasias and erythema; (7) erythema multiforme-like lesions that may become bullous; and (8) distal ulcerations secondary to Raynaud's phenomenon, vasculitis, or livedoid vasculitis. Patients with only discoid lesions usually have the form of lupus that is limited to the skin. However, 2 to 10% of these patients eventually develop systemic lupus. Direct immunofluorescence of involved skin shows deposits of IgG or IgM and C3 in a granular distribution along the dermal-epidermal junction.

In *lymphoma cutis* there is a proliferation of malignant lymphocytes or histiocytes in the skin, and the clinical appearance resembles that of lymphocytoma cutis -- infiltrated pink-red to red-purple papules and plaques. Lymphoma cutis can occur anywhere on

the surface of the skin, whereas the sites of predilection for lymphocytomas include the malar ridge, tip of the nose, and earlobes. Patients with non-Hodgkin's lymphomas have specific cutaneous lesions more often than those with Hodgkin's disease, and occasionally, the skin nodules precede the development of extracutaneous non-Hodgkin's lymphoma or represent the only site of involvement. Arcuate lesions are sometimes seen in lymphoma and lymphocytoma cutis as well as in CTCL. *Leukemia cutis* has the same appearance as lymphoma cutis, and specific lesions are seen more commonly in monocytic leukemias than in lymphocytic or granulocytic leukemias. Cutaneous chloromas (granulocytic sarcomas) may precede the appearance of circulating blasts in acute nonlymphocytic leukemia and, as such, represent a form of aleukemic leukemia cutis.

Common causes of erythematous subcutaneous nodules include inflamed epidermoid inclusion cysts, acne cysts, and furuncles. *Panniculitis*, an inflammation of the fat, also presents as subcutaneous nodules and is frequently a sign of systemic disease. There are several forms of panniculitis, including erythema nodosum, erythema induratum, lupus profundus, lipomembranous lipodermatosclerosis,a_1-antitrypsin deficiency, facticial, and fat necrosis secondary to pancreatic disease. Except for erythema nodosum, these lesions may break down and ulcerate or heal with a scar. The shin is the most common location for the nodules of erythema nodosum, whereas the calf is the most common location for lesions of erythema induratum. In erythema nodosum the nodules are initially red but then develop a blue color as they resolve. Patients with erythema nodosum but no underlying systemic illness can still have fever, malaise, leukocytosis, arthralgias, and/or arthritis. However, the possibility of an underlying illness should be excluded, and the most common associations are streptococcal infections, upper respiratory infections, sarcoidosis, and inflammatory bowel disease. The less common associations include tuberculosis, histoplasmosis, coccidioidomycosis, psittacosis, drugs (oral contraceptives, sulfonamides, aspartame, bromides, iodides), cat-scratch fever, and infections with *Yersinia*, *Salmonella*, and *Chlamydia*.

In some patients, erythema induratum/nodular vasculitis is an idiopathic disease; however, in approximately 25 to 70% of patients, polymerase chain reaction (PCR) analysis will demonstrate *M. tuberculosis* complex DNA. The lesions of lupus profundus are found primarily on the upper arms and buttocks (sites of abundant fat) and are seen in both the cutaneous and systemic forms of lupus. The overlying skin may be normal, erythematous, or have the changes of discoid lupus. The subcutaneous fat necrosis that is associated with pancreatic disease is presumably secondary to circulating lipases and is seen in patients with pancreatic carcinoma as well as in patients with acute and chronic pancreatitis. In this disorder there may be an associated arthritis, fever, and inflammation of visceral fat. Histologic examination of deep incisional biopsy specimens will aid in the diagnosis of the particular type of panniculitis.

Subcutaneous erythematous nodules are also seen in *cutaneous polyarteritis nodosa* (PAN) and as a manifestation of *systemic vasculitis*, e.g., systemic PAN, allergic granulomatosis, or Wegener's granulomatosis (Chap. 317). Cutaneous PAN presents with painful subcutaneous nodules and ulcers within a red-purple, netlike pattern of livedo reticularis. The latter is due to slowed blood flow through the superficial horizontal venous plexus. The majority of lesions are found on the lower extremity, and while

arthralgias and myalgias may accompany cutaneous PAN, there is no evidence of systemic involvement. In both the cutaneous and systemic forms of vasculitis, skin biopsy specimens of the associated nodules will show the changes characteristic of a vasculitis; the size of the vessel involved will depend on the particular disease.

Red-Brown Lesions The cutaneous lesions in *sarcoidosis* (Chap. 318) are classically red to red-brown in color, and with diascopy (pressure with a glass slide) a yellow-brown residual color is observed that is secondary to the granulomatous infiltrate. The waxy papules and plaques may be found anywhere on the skin, but the face is the most common location. Usually there are no surface changes, but occasionally the lesions will have scale. Biopsy specimens of the papules show "naked" granulomas in the dermis, i.e., granulomas surrounded by a minimal number of lymphocytes. Other cutaneous findings in sarcoidosis include annular lesions with an atrophic or scaly center, papules within scars, hypopigmented macules and papules, alopecia, acquired ichthyosis, erythema nodosum, and lupus pernio (see below). Additional physical findings are peripheral lymphadenopathy and parotid and lacrimal gland enlargement. When there is cutaneous involvement of the hands, radiographs will often show lytic lesions in the underlying bone.

The differential diagnosis of sarcoidosis includes foreign-body granulomas produced by chemicals such as beryllium and zirconium, late secondary syphilis, and *lupus vulgaris*. Lupus vulgaris is a form of cutaneous tuberculosis that is seen in previously infected and sensitized individuals. There is often underlying active tuberculosis elsewhere, usually in the lungs or lymph nodes. At least 90% of the lesions occur in the head and neck area and are red-brown plaques with a yellow-brown color on diascopy. Secondary scarring and squamous cell carcinomas can develop within the plaques. Cultures orPCRanalysis of the lesions should be done because it is rare for the acid-fast stain to show bacilli within the dermal granulomas.

Sweet's syndrome is characterized by red to red-brown plaques and nodules that are frequently painful and occur primarily on the head, neck, and upper extremities. The patients also have fever, neutrophilia, and a dense dermal infiltrate of neutrophils in the lesions. In approximately 10% of the patients there is an associated malignancy, most commonly acute nonlymphocytic leukemia. Sweet's syndrome has also been reported with lymphoma, chronic leukemia, myeloma, myelodysplastic syndromes, and solid tumors (primarily of the genitourinary tract). The differential diagnosis includes neutrophilic eccrine hidradenitis and atypical forms of pyoderma gangrenosum. Extracutaneous sites of involvement include joints, muscles, eye, kidney (proteinuria, occasionally glomerulonephritis), and lung (neutrophilic infiltrates). The idiopathic form of Sweet's syndrome is seen more often in women, following a respiratory tract infection.

A generalized distribution of red-brown macules and papules is seen in the form of mastocytosis known as *urticaria pigmentosa* (Chap. 310). Each lesion represents a collection of mast cells in the dermis, with hyperpigmentation of the overlying epidermis. Stimuli such as rubbing cause these mast cells to degranulate, and this leads to the formation of localized urticaria (Darier's sign). Additional symptoms can result from mast cell degranulation and include headache, flushing, diarrhea, and pruritus. Mast cells also infiltrate various organs such as the liver, spleen, and gastrointestinal tract in up to

30 to 50% of patients with urticaria pigmentosa, and accumulations of mast cells in the bones may produce either osteosclerotic or osteolytic shadows on radiographs. In the majority of these patients, however, the internal involvement remains fairly static. A subtype of chronic leukocytoclastic vasculitis, *erythema elevatum diutinum* (EED), also presents with papules that are red-brown in color. The papules coalesce into plaques on the extensor surfaces of knees, elbows, and the small joints of the hand. Flares of EED have been associated with streptococcal infections.

Blue Lesions Lesions that are blue in color are the result of either vascular ectasias and tumors or melanin pigment in the dermis. *Venous lakes* (ectasias) are compressible dark-blue lesions that are found commonly in the head and neck region. *Venous malformations* are also compressible blue papules and nodules that can occur anywhere on the body, including the oral mucosa. When they are multiple rather than single congenital lesions, the patient may have the blue rubber bleb syndrome or Mafucci's syndrome. Patients with the blue rubber bleb syndrome also have vascular anomalies of the gastrointestinal tract that may bleed, whereas patients with Mafucci's syndrome have associated dyschondroplasia and osteochondromas. *Blue nevi* (moles) are seen when there are collections of pigment-producing nevus cells in the dermis. These benign papular lesions are dome-shaped and occur most commonly on the dorsum of the hand or foot.

Violaceous Lesions Violaceous papules and plaques are seen in *lupus pernio*, *lymphoma cutis*, and *cutaneous lupus*. Lupus pernio is a particular type of sarcoidosis that involves the tip of the nose and the earlobes, with lesions that are violaceous in color rather than red-brown. This form of sarcoidosis is associated with involvement of the upper respiratory tract. The plaques of lymphoma cutis and cutaneous lupus may be red or violaceous in color and were discussed above.

Purple Lesions Purple-colored papules and plaques are seen in vascular tumors, such as *Kaposi's sarcoma* (Chap. 309) and *angiosarcoma*, and when there is extravasation of red blood cells into the skin in association with inflammation, as in *palpable purpura* (see "Purpura"). Patients with congenital or acquiredAVfistulas and venous hypertension can develop purple papules on the lower extremities that can resemble Kaposi's sarcoma clinically and histologically; this condition is referred to as pseudo-Kaposi sarcoma (acral angiodermatitis). Angiosarcoma is found most commonly on the scalp and face of elderly patients or within areas of chronic lymphedema and presents as purple papules and plaques. In the head and neck region the tumor often extends beyond the clinically defined borders and may be accompanied by facial edema.

Brown and Black Lesions Brown- and black-colored papules are reviewed in "Hyperpigmentation."

Cutaneous Metastases These are discussed last because they can have a wide range of colors. Most commonly they present as either firm, skin-colored subcutaneous nodules or firm, red to red-brown papulonodules. The lesions of lymphoma cutis range from pink-red to plum in color, whereas metastatic melanoma can be pink, blue, or black in color. Cutaneous metastases develop from hematogenous or lymphatic spread and are most often due to the following primary carcinomas: in men, lung, colon, melanoma,

and oral cavity; and in women, breast, colon, and lung. These metastatic lesions may be the initial presentation of the carcinoma, especially when the primary site is the lung, kidney, or ovary.

PURPURA (Table 57-16)

Purpura are seen when there is an extravasation of red blood cells into the dermis, and as a result, the lesions do not blanch with pressure. This is in contrast to those erythematous or violet-colored lesions that are due to localized vasodilatation -- they do blanch with pressure. Purpura (³3 mm) and petechiae (£2 mm) are divided into two major groups, palpable and nonpalpable. The most frequent causes of *nonpalpable* petechiae and purpura are primary cutaneous disorders such as *trauma*, *solar purpura*, and *capillaritis*. Less common causes are *steroid purpura* and *livedoid vasculitis* (see "Ulcers"). Solar purpura are seen primarily on the extensor forearms, while glucocorticoid purpura secondary to potent topical steroids or endogenous or exogenous Cushing's syndrome can be more widespread. In both cases there is alteration of the supporting connective tissue that surrounds the dermal blood vessels. In contrast, the petechiae that result from capillaritis are found primarily on the lower extremities. In capillaritis there is an extravasation of erythrocytes as a result of perivascular lymphocytic inflammation. The petechiae are bright red, 1 to 2 mm in size, and scattered within annular or coin-shaped yellow-brown macules. The yellow-brown color is caused by hemosiderin deposits within the dermis.

Systemic causes of nonpalpable purpura fall into several categories, and those secondary to clotting disturbances and vascular fragility will be discussed first. The former group includes *thrombocytopenia* (Chap. 116), *abnormal platelet function* as is seen in uremia, and *clotting factor defects*. The initial site of presentation for thrombocytopenia-induced petechiae is the distal lower extremity. Capillary fragility leads to nonpalpable purpura in patients with systemic *amyloidosis* (see "Papulonodular Skin Lesions"), disorders of collagen production such as *Ehlers-Danlos syndrome*, and *scurvy*. In scurvy there are flattened corkscrew hairs with surrounding hemorrhage on the lower extremities, in addition to gingivitis. Vitamin C is a cofactor for lysyl hydroxylase, an enzyme involved in the posttranslational modification of procollagen that is necessary for cross-link formation.

In contrast to the previous group of disorders, the purpura seen in the following group of diseases are associated with thrombi formation within vessels. It is important to note that these thrombi are demonstrable in skin biopsy specimens. This group of disorders includes disseminated intravascular coagulation (DIC), monoclonal cryoglobulinemia, thrombotic thrombocytopenic purpura, and reactions to warfarin. DIC is triggered by several types of infection (gram-negative, gram-positive, viral, and rickettsial) as well as by tissue injury and neoplasms. Widespread purpura and hemorrhagic infarcts of the distal extremities are seen. Similar lesions are found in purpura fulminans, which is a form of DIC associated with fever and hypotension that occurs more commonly in children following an infectious illness such as varicella, scarlet fever, or an upper respiratory tract infection. In both disorders, hemorrhagic bullae can develop in involved skin.

Monoclonal cryoglobulinemia is associated with multiple myeloma, Waldenstrom's

macroglobulinemia, lymphocytic leukemia, and lymphoma. Purpura, primarily of the lower extremities, and hemorrhagic infarcts of the fingers and toes are seen in these patients. Exacerbations of disease activity can follow cold exposure or an increase in serum viscosity. Biopsy specimens show precipitates of the cryoglobulin within dermal vessels. Similar deposits have been found in the lung, brain, and renal glomeruli. Patients with *thrombotic thrombocytopenic purpura* can also have hemorrhagic infarcts as a result of intravascular thromboses. Additional signs include thrombocytopenic purpura, fever, and microangiopathic hemolytic anemia (Chap. 108).

Administration of *warfarin* can result in painful areas of erythema that become purpuric and then necrotic with an adherent black eschar. This reaction is seen more often in women and in areas with abundant subcutaneous fat -- breasts, abdomen, buttocks, thighs, and calves. The erythema and purpura develop between the third and tenth day of therapy, most likely as a result of a transient imbalance in the levels of anticoagulant and procoagulant vitamin K-dependent factors. Continued therapy does not exacerbate preexisting lesions, and patients with an inherited or acquired deficiency of protein C are at increased risk for this particular reaction as well as for purpura fulminans.

Purpura secondary to *cholesterol emboli* are usually seen on the lower extremities of patients with atherosclerotic vascular disease. They often follow anticoagulant therapy or an invasive vascular procedure such as an arteriogram but also occur spontaneously from disintegration of atheromatous plaques. Associated findings include livedo reticularis, gangrene, cyanosis, subcutaneous nodules, and ischemic ulcerations. Multiple step sections of the biopsy specimen may be necessary to demonstrate the cholesterol clefts with the vessels. Petechiae are also an important sign of *fat embolism* and occur primarily on the upper body 2 to 3 days after a major injury. By using special fixatives, the emboli can be demonstrated in biopsy specimens of the petechiae. Emboli of tumor or thrombus are seen in patients with atrial myxomas and marantic endocarditis.

In the *Gardner-Diamond syndrome* (autoerythrocyte sensitivity), female patients develop large ecchymoses within areas of painful, warm erythema. An episode of significant trauma frequently precedes the onset of this syndrome. Intradermal injections of autologous erythrocytes or phosphatidyl serine derived from the red cell membrane can reproduce the lesions in some patients; however, there are instances where a reaction is seen at an injection site of the forearm but not in the midback region. The latter has led some observers to view Gardner-Diamond syndrome as a cutaneous manifestation of severe emotional stress. *Waldenstrom's hypergammaglobulinemic purpura* is a chronic disorder characterized by petechiae on the lower extremities. There are circulating complexes of IgG-anti-IgG molecules, and exacerbations are associated with prolonged standing or walking.

Palpable purpura are further subdivided into vasculitic and embolic. In the group of vasculitic disorders, *leukocytoclastic vasculitis* (LCV), also known as *allergic vasculitis*, is the one most commonly associated with palpable purpura (Chap. 317). *Henoch-Schonlein purpura* is a subtype of acute LCV that is seen primarily in children and adolescents following an upper respiratory infection. The majority of lesions are found on the lower extremities and buttocks. Systemic manifestations include fever, arthralgias (primarily of the knees and ankles), abdominal pain, gastrointestinal

bleeding, and nephritis. Direct immunofluorescence examination shows deposits of IgA within dermal blood vessel walls. In *polyarteritis nodosa*, specific cutaneous lesions result from a vasculitis of arterial vessels rather than postcapillary venules as in LCV. The arteritis leads to ischemia of the skin, and this explains the irregular outline of the purpura (see below).

Several types of infectious emboli can give rise to palpable purpura. These embolic lesions are usually *irregular* in outline as opposed to the lesions of leukocytoclastic vasculitis, which are *circular* in outline. The irregular outline is indicative of a cutaneous infarct, and the size corresponds to the area of skin that received its blood supply from that particular arteriole or artery. The palpable purpura inLCV are circular because the erythrocytes simply diffuse out evenly from the postcapillary venules as a result of inflammation. Infectious emboli are most commonly due to gram-negative cocci (meningococcus, gonococcus), gram-negative rods (Enterobacteriaceae), and gram-positive cocci (staphylococcus). Additional causes include *Rickettsia* and, in immunocompromised patients, *Candida* and opportunistic fungi.

The embolic lesions in *acute meningococcemia* are found primarily on the trunk, lower extremities, and sites of pressure, and a gunmetal-gray color often develops within them. Their size varies from 1 mm to several centimeters, and the organisms can be cultured from the lesions. Associated findings include a preceding upper respiratory tract infection, fever, meningitis,DIC, and, in some patients, a deficiency of the terminal components of complement. In *disseminated gonococcal infection* (arthritis-dermatitis syndrome), a small number of papules and vesicopustules with central purpura or hemorrhagic necrosis are found over the joints of the distal extremities. Additional symptoms include arthralgias, tenosynovitis, and fever. To establish the diagnosis, a Gram stain of these lesions should be performed. *Rocky mountain spotted fever* is a tick-borne disease that is caused by *R. rickettsii*. A several-day history of fever, chills, severe headache, and photophobia precedes the onset of the cutaneous eruption. The initial lesions are erythematous macules and papules on the wrists, ankles, palms, and soles. With time, the lesions spread centripetally and become purpuric.

Lesions of *ecthyma gangrenosum* begin as edematous, erythematous papules or plaques and then develop central purpura and necrosis. Bullae formation also occurs in these lesions, and they are frequently found in the girdle region. The organism that is classically associated with ecthyma gangrenosum is *Pseudomonas aeruginosa*, but other gram-negative rods such as *Klebsiella*, *Escherichia coli*, and *Serratia* can produce similar lesions. In immunocompromised hosts, the list of potential pathogens is expanded to include *Candida* and opportunistic fungi.

ULCERS

The approach to the patient with a cutaneous ulcer, is outlined inTable 57-17.**Peripheral vascular diseases of the extremities are reviewed in Chap. 248, as is Raynaud's phenomenon.*

Livedoid vasculitis (atrophie blanche) represents a combination of a vasculopathy with intravascular thrombosis. Purpuric lesions and livedo reticularis are found in association with painful ulcerations of the lower extremities. These ulcers are often slow to heal, but

when they do, irregularly shaped white scars are formed. The majority of cases are secondary to venous hypertension, but possible underlying illnesses include cryofibrinogenemia and disorders of hypercoagulability, e.g., the antiphospholipid syndrome (Chap. 117).

In *pyoderma gangrenosum*, the border of the ulcers has a characteristic appearance of an undermined necrotic bluish edge and a peripheral erythematous halo. The ulcers often begin as pustules that then expand rather rapidly to a size as large as 20 cm. Although these lesions are most commonly found on the lower extremities, they can arise anywhere on the surface of the body, including sites of trauma (pathergy). An estimated 30 to 50% of cases are idiopathic, and the most common associated disorders are ulcerative colitis and Crohn's disease. Less commonly, it is associated with chronic active hepatitis, seropositive rheumatoid arthritis, acute and chronic granulocytic leukemia, polycythemia vera, and myeloma. Additional findings in these patients, even those with idiopathic disease, are cutaneous anergy and a benign monoclonal gammopathy. Because the histology of pyoderma gangrenosum is nonspecific, the diagnosis is made clinically by excluding less common causes of similar-appearing ulcers such as necrotizing vasculitis, Meleney's ulcer (synergistic infection at a site of trauma or surgery), dimorphic fungi, cutaneous amebiasis, spider bites, and factitial. In the myeloproliferative disorders, the ulcers may be more superficial with a pustulobullous border, and these lesions provide a connection between classic pyoderma gangrenosum and acute febrile neutrophilic dermatosis (Sweet's syndrome).

FEVER AND RASH

The major considerations in a patient with a fever and a rash are inflammatory diseases versus infectious diseases. In the hospital setting, the most common scenario is a patient who has a drug rash plus a fever secondary to an underlying infection. However, it should be emphasized that a drug reaction can lead to both a cutaneous eruption and a fever ("drug fever"). Additional inflammatory diseases that are often associated with a fever include pustular psoriasis, erythroderma, and Sweet's syndrome. Lyme disease, secondary syphilis, and viral and bacterial exanthems (see "Exanthems") are examples of infectious diseases that produce a rash and a fever. Lastly, it is important to determine whether or not the cutaneous lesions represent septic emboli (see "Purpura"). Such lesions usually have evidence of ischemia in the form of purpura, necrosis, or impending necrosis (gunmetal-gray color). In the patient with thrombocytopenia, however, purpura can be seen in inflammatory reactions such as morbilliform drug eruptions and infectious lesions.

58. IMMUNOLOGICALLY MEDIATED SKIN DISEASES - *Kim B. Yancey*, *Thomas J. Lawley*

A number of immunologically mediated skin diseases and cutaneous manifestations of immunologically mediated systemic disorders are now recognized as distinct entities with relatively consistent clinical, histologic, and immunopathologic findings. Many of these disorders are due to autoimmune mechanisms. Clinically, they are characterized by morbidity (pain, pruritus, disfigurement) and in some instances by mortality (largely due to loss of epidermal barrier function and/or secondary infection). The major features of the more common immunologically mediated skin diseases are summarized in this chapter (Table 58-1).

PEMPHIGUS VULGARIS

Pemphigus vulgaris (PV) is a blistering skin disease seen predominantly in elderly patients. Patients with PV have an increased incidence of the HLA-DR4 and -DRw6 serologically defined haplotypes. This disorder is characterized by the loss of cohesion between epidermal cells (a process termed *acantholysis*) with the resultant formation of intraepidermal blisters. Clinical lesions of PV typically consist of flaccid blisters on either normal-appearing or erythematous skin. These blisters rupture easily, leaving denuded areas that may crust and enlarge peripherally (Plate IIE-69). Substantial portions of the body surface may be denuded in severe cases. Manual pressure to the skin of these patients may elicit the separation of the epidermis (Nikolsky's sign). This finding, while characteristic of PV, is not specific to this disorder and is also seen in toxic epidermal necrolysis, Stevens-Johnson syndrome, and a few other skin diseases. Lesions in PV typically present on the oral mucosa, scalp, face, neck, axilla, and trunk. In half or more of patients, lesions begin in the mouth; approximately 90% of patients have oromucosal involvement at some time during the course of their disease. Involvement of other mucosal surfaces (e.g., pharyngeal, laryngeal, esophageal, conjunctival, vulval, or rectal) can occur in severe disease. Pruritus may be a feature of early pemphigus lesions; extensive denudation may be associated with severe pain. Lesions usually heal without scarring, except at sites complicated by secondary infection or mechanically induced dermal wounds. Nonetheless, postinflammatory hyperpigmentation is usually present at sites of healed lesions for some time.

Biopsies of early lesions demonstrate intraepidermal vesicle formation secondary to loss of cohesion between epidermal cells (i.e., acantholytic blisters). Blister cavities contain acantholytic epidermal cells, which appear as round homogeneous cells containing hyperchromatic nuclei. Basal keratinocytes remain attached to the epidermal basement membrane, hence blister formation is within the suprabasal portion of the epidermis. Lesional skin may contain focal collections of intraepidermal eosinophils within blister cavities; dermal alterations are slight, often limited to an eosinophil-predominant leukocytic infiltrate. Direct immunofluorescence microscopy of lesional or intact patient skin shows deposits of IgG on the surface of keratinocytes; in contrast, deposits of complement components are typically found in lesional but not uninvolved skin. Deposits of IgG on keratinocytes are derived from circulating autoantibodies directed against cell-surface antigens. Circulating autoantibodies can be demonstrated in 80 to 90% ofPVpatients by indirect immunofluorescence microscopy; monkey esophagus is the optimal substrate for demonstration of these autoantibodies. Patients with PV have

IgG autoantibodies directed against desmogleins (Dsgs), transmembrane desmosomal glycoproteins that belong to the cadherin supergene family of calcium-dependent adhesion molecules. While Dsg3 is specifically recognized by PV autoantibodies, approximately 50% of PV sera also contain IgG against Dsg1. Most patients with early PV and only mucosal involvement have only anti-Dsg3 autoantibodies, whereas most patients with advanced disease (i.e., involvement of skin and mucosa) have both anti-Dsg3 and anti-Dsg1 autoantibodies. Recent studies have shown that the anti-Dsg autoantibody profile in these patients' sera as well as the tissue distribution of Dsg3 and Dsg1 determine the site of blister formation in patients with pemphigus. Experimental studies have also shown that these autoantibodies are pathogenic (i.e., responsible for blister formation) and that their titer correlates with disease activity.

PVcan be life-threatening. Prior to the availability of glucocorticoids, the mortality ranged from 60 to 90%; the current mortality is approximately 5%. Common causes of morbidity and mortality are infection and complications of treatment with glucocorticoids. Bad prognostic factors include advanced age, widespread involvement, and the requirement for high doses of glucocorticoids (with or without other immunosuppressive agents) for control of disease. The course of PV in individual patients is variable and difficult to predict. Some patients achieve remission (40% of patients in some series), but others may require long-term treatment or succumb to complications of their disease or its treatment. The mainstay of treatment is systemic glucocorticoids. Patients with moderate to severe disease are usually started on prednisone, 60 to 80 mg/d. If new lesions continue to appear after 1 to 2 weeks of treatment, the dose should be increased. Many regimens combine an immunosuppressive agent with systemic glucocorticoids for control of PV. The two most frequently used are either azathioprine (1 mg/kg per day) or cyclophosphamide (1 mg/kg per day). It is important to bring severe or progressive disease under control quickly to lessen the severity and/or duration of this disorder.

PEMPHIGUS FOLIACEUS

Pemphigus foliaceus (PF) is distinguished fromPV by several features. In PF, acantholytic blisters are located high within the epidermis, usually just beneath the stratum corneum. Hence PF is a more superficial blistering disease than PV. The distribution of lesions in the two disorders is much the same, except that in PF mucous membrane lesions are very rare. Patients with PF rarely demonstrate intact blisters but rather exhibit shallow erosions associated with erythema, scale, and crust formation. Mild cases of PF resemble severe seborrheic dermatitis; severe PF may cause extensive exfoliation. Sun exposure (ultraviolet irradiation) may be an aggravating factor. A blistering skin disease endemic to south central Brazil known as *fogo selvagem*, or *Brazilian pemphigus*, is clinically, histologically, and immunopathologically indistinguishable from PF.

Patients withPF have immunopathologic features in common withPV. Specifically, direct immunofluorescence microscopy of perilesional skin demonstrates IgG on the surface of keratinocytes. As in PV, patients with PF frequently have circulating IgG autoantibodies against keratinocyte cell surface antigens. Guinea pig esophagus is the optimal substrate for indirect immunofluorescence microscopy studies of sera from patients with PF. In PF, autoantibodies are directed against Dsg1, a 160-kDa desmosomal cadherin.

As noted for PV, the autoantibody profile in patients with PF (i.e., anti-Dsg1) and the normal tissue distribution of this autoantigen (i.e., low expression in oral mucosa) is thought to account for the distribution of lesions in this disease.

Although pemphigus has been associated with several autoimmune diseases, its association with thymoma and/or myasthenia gravis is particularly notable. To date, more than 30 cases of thymoma and/or myasthenia gravis have been reported in association with pemphigus, usually withPF. Patients may also develop pemphigus as a consequence of drug exposure. The most frequently implicated agent is penicillamine; other offenders include captopril, rifampin, piroxicam, penicillin, and phenobarbital. Drug-induced pemphigus usually resembles PF rather thanPV; autoantibodies in these patients have the same antigenic specificity as they do in other pemphigus patients. In most patients, lesions resolve following discontinuation of the drug; however, some patients require treatment with systemic glucocorticoids and/or immunosuppressive agents.

PFis generally a far less severe disease thanPV and carries a better prognosis. Localized disease can be treated conservatively with topical or intralesional glucocorticoids; more active cases can usually be controlled with systemic glucocorticoids.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus (PNP) is an autoimmune acantholytic mucocutaneous disease associated with an occult or confirmed neoplasm. Patients with PNP typically show painful mucosal erosive lesions in association with pruritic papulosquamous eruptions that often progress to blisters. Palm and sole involvement is common in these patients and raises the possibility that prior reports of neoplasia-associated erythema multiforme actually may have represented unrecognized cases of PNP. Biopsies of lesional skin from these patients show varying combinations of acantholysis, keratinocyte necrosis, and vacuolar-interface dermatitis. Direct immunofluorescence microscopy of patient skin shows deposits of IgG and complement on the surface of keratinocytes and (variably) similar immunoreactants in the epidermal basement membrane zone. Patients with PNP have IgG autoantibodies against cytoplasmic proteins that are members of the plakin family (e.g., desmoplakins I and II, bullous pemphigoid antigen 1, envoplakin, periplakin, and plectin) and cell-surface proteins that are members of the cadherin family (e.g., Dsg3 and Dsg1). Because immunoadsorption of anti-Dsg3 IgG is sufficient to eliminate the ability of PNP sera to induce blisters in an experimental passive transfer animal model, these particular autoantibodies are thought to play a key pathogenic role in blister formation in these patients.

Although PNP is generally resistant to conventional therapies (i.e., those used to treat PV), patients may improve (or even remit) following resection of underlying neoplasms. The predominant neoplasms associated with this disorder are non-Hodgkin's lymphoma, chronic lymphocytic leukemia, Castleman's disease, thymoma, and spindle cell tumors.

BULLOUS PEMPHIGOID

Bullous pemphigoid (BP) is an autoimmune subepidermal blistering disease usually

seen in the elderly. Lesions typically consist of tense blisters on either normal-appearing or erythematous skin (Plate IIE-72). The lesions are usually distributed over the lower abdomen, groin, and flexor surface of the extremities; oral mucosal lesions are found in 10 to 40% of patients. Pruritus may be nonexistent or severe. As lesions evolve, tense blisters tend to rupture and be replaced by flaccid lesions or erosions with or without surmounting crust. Nontraumatized blisters heal without scarring. The major histocompatibility complex class II allele HLA-DQb1*0301 is prevalent in patients with BP. Despite isolated reports, several studies have shown that patients with BP do not have an increased incidence of malignancy in comparison with appropriately age- and sex-matched controls.

While biopsies of early lesional skin demonstrate subepidermal blisters, the histologic features depend on the character of the particular lesion. Lesions on normal-appearing skin generally show a sparse perivascular leukocytic infiltrate with some eosinophils; conversely, biopsies of inflammatory lesions typically show an eosinophil-rich infiltrate within the papillary dermis at sites of vesicle formation and in perivascular areas. In addition to eosinophils, cell-rich lesions also contain mononuclear cells and neutrophils. It is not always possible to distinguishBP from other subepidermal blistering diseases by routine histologic techniques.

Immunopathologic studies have broadened our understanding of this disease and aided its diagnosis. Direct immunofluorescence microscopy of normal-appearing perilesional skin shows linear deposits of IgG and/or C3 in the epidermal basement membrane. The sera of approximately 70% of these patients contain circulating IgG autoantibodies that bind the epidermal basement membrane of normal human skin in indirect immunofluorescence microscopy. An even higher percentage of patients shows reactivity to the epidermal side of 1 *M* NaCl split skin [an alternative immunofluorescence microscopy test substrate that is commonly used to distinguish circulating IgG anti-basement membrane autoantibodies in patients with BPfrom those in patients with similar, yet different, subepidermal blistering diseases (e.g., epidermolysis bullosa acquisita, see below)]. No correlation exists between the titer of these autoantibodies and disease activity. In BP, circulating autoantibodies recognize 230- and (in approximately 70% of BP patients) 180-kDa hemidesmosome-associated proteins in basal keratinocytes [i.e., bullous pemphigoid antigen (BPAG)1 and BPAG2, respectively]. Autoantibodies are thought to develop against these antigens (more specifically, initially against BPAG2), deposit in situ, and activate complement that subsequently produces dermal mast cell degranulation and granulocyte-rich infiltrates that cause tissue damage and blister formation.

BPmay persist for months to years, with exacerbations or remissions. Although extensive involvement may result in widespread erosions and compromise cutaneous integrity, the mortality rate is low even in the absence of treatment. Nonetheless, deaths may occur in elderly and/or debilitated patients. The mainstay of treatment is systemic glucocorticoids. Patients with local or minimal disease can sometimes be controlled with topical glucocorticoids alone; patients with more extensive lesions generally respond to systemic glucocorticoids either alone or in combination with immunosuppressive agents. Patients will usually respond to prednisone, 40 to 60 mg/d. In some instances, azathioprine (1 mg/kg per day) or cyclophosphamide (1 mg/kg per day) are necessary adjuncts.

PEMPHIGOID GESTATIONIS

Pemphigoid gestationis (PG), also known as herpes gestationis, is a rare, nonviral, subepidermal blistering disease of pregnancy and the puerperium. PG may begin during any trimester of pregnancy or present shortly after delivery. Lesions are usually distributed over the abdomen, trunk, and extremities; mucous membrane lesions are rare. Skin lesions in these patients may be quite polymorphic and consist of erythematous urticarial papules and plaques, vesiculopapules, and/or frank bullae. Lesions are almost always very pruritic. Severe exacerbations of PG frequently occur after delivery, typically within 24 to 48 h. PG tends to recur in subsequent pregnancies, often beginning earlier during such gestations. Brief flare-ups of disease may occur with resumption of menses and may develop in patients later exposed to oral contraceptives. Occasionally, infants of affected mothers demonstrate transient skin lesions.

Biopsies of early lesional skin show teardrop-shaped subepidermal vesicles forming in dermal papillae in association with an eosinophil-rich leukocytic infiltrate. Differentiation ofPG from other subepidermal bullous diseases by light microscopy is often difficult. However, direct immunofluorescence microscopy of perilesional skin from PG patients reveals the immunopathologic hallmark of this disorder -- linear deposits of C3 in the epidermal basement membrane zone. These deposits develop as a consequence of complement activation produced by low titer IgG anti-basement membrane zone autoantibodies. Recent studies have shown that the majority of PG sera contain autoantibodies that recognizeBPAG2, the same 180-kDa hemidesmosome-associated protein that is targeted by autoantibodies in roughly 70% of patients withBP -- a subepidermal bullous disease that resembles PG morphologically, histologically, and immunopathologically.

The goals of therapy in patients withPG are to prevent the development of new lesions, relieve intense pruritus, and care for erosions at sites of blister formation. Most patients require treatment with moderate doses of daily glucocorticoids (i.e., 20 to 40 mg of prednisone) at some point in their course. Mild cases (or brief flare-ups) may be controlled by vigorous use of potent topical glucocorticoids. Although PG was once thought to be associated with an increased risk of fetal morbidity and mortality, the best evidence now suggests that these infants may only be at increased risk of being slightly premature or "small for dates." Current evidence suggests that there is no difference in the incidence of uncomplicated live births in PG patients treated with systemic glucocorticoids and in those managed more conservatively. If systemic glucocorticoids are administered, newborns are at risk for development of reversible adrenal insufficiency.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis (DH) is an intensely pruritic, papulovesicular skin disease characterized by lesions symmetrically distributed over extensor surfaces (i.e., elbows, knees, buttocks, back, scalp, and posterior neck) (Plate IIE-68). The primary lesion in this disorder is a papule, papulovesicle, or urticarial plaque. Because pruritus is prominent, patients may present with excoriations and crusted papules but no observable primary lesions. Patients sometimes report that their pruritus has a

distinctive burning or stinging component; the onset of such local symptoms reliably heralds the development of distinct clinical lesions 12 to 24 h later. Almost all DH patients have an associated, usually subclinical, gluten-sensitive enteropathy (Chap. 286), and more than 90% express the HLA-B8/DRw3 and HLA-DQw2 haplotypes. DH may present at any age, including childhood; onset in the second to fourth decades is most common. The disease is typically chronic.

Biopsy of early lesional skin reveals neutrophil-rich infiltrates within dermal papillae. Neutrophils, fibrin, edema, and microvesicle formation at these sites are characteristic of early disease. Older lesions may demonstrate nonspecific features of a subepidermal bulla or an excoriated papule. Because the clinical and histologic features of this disease can be variable and resemble other subepidermal blistering disorders, the diagnosis is confirmed by direct immunofluorescence microscopy of normal-appearing perilesional skin. Such studies demonstrate granular deposits of IgA (with or without complement components) in the papillary dermis and along the epidermal basement membrane zone. IgA deposits in the skin are unaffected by control of disease with medication; however, these immunoreactants may diminish in intensity or disappear in patients maintained for long periods on a strict gluten-free diet (see below). Patients with granular deposits of IgA in their epidermal basement membrane zone typically do not have circulating IgA anti-basement membrane autoantibodies and should be distinguished from individuals with linear IgA deposits at this site (see below).

Although mostDHpatients do not report overt gastrointestinal symptoms or laboratory evidence of malabsorption, biopsies of small bowel usually reveal blunting of intestinal villi and a lymphocytic infiltrate in the lamina propria. As is true for patients with celiac disease, this gastrointestinal abnormality can be reversed by a gluten-free diet. Moreover, if maintained, this diet alone may control the skin disease and eventuate in clearance of IgA deposits from these patients' epidermal basement membrane zone. Subsequent gluten exposure in such patients alters the morphology of their small bowel, elicits a flare-up of their skin disease, and is associated with the reappearance of IgA in their epidermal basement membrane zone. Additional evidence that DH develops as a consequence of dietary gluten exposure is the demonstration of IgA anti-endomysial antibodies in these patients' sera (as found in the sera of patients with ordinary gluten-sensitive enteropathy). Recent studies have shown that such autoantibodies are directed against tissue transglutaminase. Patients with DH also have an increased incidence of thyroid abnormalities, achlorhydria, atrophic gastritis, and antigastric parietal cell antibodies. These associations likely relate to the high frequency of the HLA-B8/DRw3 haplotype in these patients, since this marker is commonly linked to autoimmune disorders. The mainstay of treatment of DH is dapsone, a sulfone. Patients respond rapidly (24 to 48 h) to dapsone but require careful pretreatment evaluation and close follow-up to ensure that complications are avoided or controlled. All patients on more than 100 mg/d dapsone will have some hemolysis and methemoglobinemia. These are expected pharmacologic side effects of this agent. Gluten restriction can control DH and lessen dapsone requirements; this diet must rigidly exclude gluten to be of maximal benefit. Many months of dietary restriction may be necessary before a beneficial result is achieved. Good dietary counselling by a trained dietitian is essential.

LINEAR IGA DISEASE

Linear IgA disease, once considered a variant form of dermatitis herpetiformis, is actually a separate and distinct entity. Clinically, these patients may resemble patients with typical cases ofDH,BP, or other subepidermal blistering diseases. Lesions typically consist of papulovesicles, bullae, and/or urticarial plaques, predominantly on extensor (as seen in "classic" DH), central, or flexural sites. Oral mucosal involvement occurs in some patients. Severe pruritus resembles that in patients with DH. Patients with linear IgA disease do not have an increased frequency of the HLA-B8/DRw3 haplotype or an associated enteropathy and hence are not candidates for a gluten-free diet.

The histologic alterations in early lesions may be virtually indistinguishable from those inDH. However, direct immunofluorescence microscopy of normal-appearing perilesional skin reveals linear deposits of IgA (and often C3) in the epidermal basement membrane zone. Most patients with linear IgA disease demonstrate circulating IgA anti-basement membrane autoantibodies against epitopes in the extracellular domain ofBPAG2, a transmembrane protein found in hemidesmosomes of basal keratinocytes. These patients generally respond to treatment with dapsone, 50 to 150 mg/d.

EPIDERMOLYSIS BULLOSA ACQUISITA

EBAis a rare, noninherited, polymorphic, subepidermal blistering disease. (The inherited form is discussed in Chap. 351.) Patients with classic or noninflammatory EBA have blisters on noninflamed skin, atrophic scars, milia, nail dystrophy, and oral lesions. Because lesions generally occur at sites exposed to minor trauma, classic EBA is considered to be a mechanobullous disease. Other patients with EBA have widespread inflammatory, scarring, bullous lesions and oromucosal involvement that resembles severeBP. Some patients present with an inflammatory bullous disease that evolves into the classic noninflammatory form of this disorder. In general, EBA is chronic; associations with multiple myeloma, amyloidosis, inflammatory bowel disease, and diabetes mellitus have been reported. The HLA-DR2 haplotype is found with increased frequency in these patients.

The histology of lesional skin varies depending on the character of the lesion being studied. Noninflammatory bullae show subepidermal blisters with a sparse leukocytic infiltrate and resemble those in patients with porphyria cutanea tarda. Inflammatory lesions consist of a subepidermal blister and neutrophil-rich leukocytic infiltrates in the superficial dermis.EBApatients have continuous deposits of IgG (and frequently C3 as well as other complement components) in a linear pattern within the epidermal basement membrane zone. Ultrastructurally, these immunoreactants are found in the sublamina densa region in association with anchoring fibrils, wheat stack-like structures that extend from the lamina densa into the underlying papillary dermis. Approximately 25 to 50% of EBA patients have circulating IgG anti-basement membrane autoantibodies directed against type VII collagen -- the collagen species that comprises anchoring fibrils. Such IgG autoantibodies bind the dermal side of 1 *M* NaCl split skin (in contrast to IgG autoantibodies in patients withBP that bind either epidermal or both sides of this indirect immunofluorescence microscopy test substrate).

Treatment ofEBA is generally unsatisfactory. Some patients with inflammatory EBA may respond to systemic glucocorticoids, either alone or in combination with immunosuppressive agents. Other patients (especially those with neutrophil-rich

inflammatory lesions) may respond to dapsone. The chronic, noninflammatory form of this disease is largely resistant to treatment, although some patients may respond to cyclosporine.

CICATRICIAL PEMPHIGOID

Cicatricial pemphigoid (CP) is a rare, acquired, subepithelial blistering disease characterized by erosive lesions of mucous membranes and skin that result in scarring of at least some sites of involvement. Immunopathologically, perilesional mucosa and skin of patients with CP demonstrate in situ deposits of immunoreactants in epithelial basement membranes. Common sites of involvement include the oral mucosa (especially the gingiva) and conjunctiva; other sites that may be affected include the nasopharyngeal, laryngeal, esophageal, urogenital, and rectal mucosa. Skin lesions (present in about one-third of patients) tend to predominate on the scalp, face, and upper trunk and generally consist of a few scattered erosions or tense blisters on an erythematous or urticarial base. CP is typically a chronic and progressive disorder. Serious complications may arise as a consequence of ocular, laryngeal, esophageal, or urogenital lesions. Erosive conjunctivitis may result in shortened fornices, symblephara, ankyloblepharon, entropion, corneal opacities, and (in severe cases) blindness. Similarly, erosive lesions of the larynx may cause hoarseness, pain, and tissue loss that if unrecognized and untreated may eventuate in complete destruction of the airway. Esophageal lesions may result in stenosis and/or strictures that may place patients at risk for aspiration. Strictures may also complicate urogenital involvement.

Biopsies of lesional tissue generally demonstrate subepithelial vesiculobullae and a mononuclear leukocytic infiltrate. Neutrophils and eosinophils may be seen in biopsies of early lesions; older lesions may demonstrate a scant leukocytic infiltrate and fibrosis. Direct immunofluorescence microscopy of perilesional tissue typically demonstrates deposits of IgG, IgA, and/or C3 in these patients' epithelial basement membranes. Because many of these patients show no evidence of circulating anti-basement membrane autoantibodies, testing of perilesional skin is important diagnostically. AlthoughCP was once thought to be a single nosologic entity, it is now largely regarded as a disease phenotype that may develop as a consequence of an autoimmune reaction against a variety of different molecules in epithelial basement membranes (e.g.,BPAG2, laminin 5, type VII collagen, and other antigens yet to be completely defined). Treatment of CP is largely dependent upon sites of involvement. Due to potentially severe complications, ocular, laryngeal, esophageal, and/or urogenital involvement require aggressive systemic treatment with dapsone, prednisone, or the latter in combination with another immunosuppressive agent (e.g., azathioprine or cyclophosphamide). Less threatening forms of the disease may be managed with topical or intralesional glucocorticoids.

AUTOIMMUNE SYSTEMIC DISEASES WITH PROMINENT CUTANEOUS FEATURES

DERMATOMYOSITIS

The cutaneous manifestations of dermatomyositis (Chap. 382) are often distinctive but at times may resemble those of systemic lupus erythematosus (SLE) (Chap. 311), scleroderma (Chap. 313), or other overlapping connective tissue diseases (Chap. 313).

The extent and severity of cutaneous disease may or may not correlate with the extent and severity of the myositis. Patients with severe muscle involvement may have relatively minor skin changes, whereas patients with marked skin involvement may have mild muscle disease. The cutaneous manifestations of dermatomyositis are similar whether the disease appears in childhood or old age, except that calcification of subcutaneous tissue is a common late sequela in childhood dermatomyositis.

The cutaneous signs of dermatomyositis may precede or follow the development of myositis by weeks to years. Cases lacking muscle involvement (i.e., dermatomyositis sine myositis) have also been reported. The most common manifestation is a purple-red discoloration of the upper eyelids, sometimes associated with scaling ("heliotrope" erythema; Plate IIE-63) and periorbital edema. Erythema on the cheeks and nose in a "butterfly" distribution may resemble the eruption inSLE. Erythematous or violaceous scaling patches are common on the upper anterior chest, posterior neck, scalp, and the extensor surfaces of the arms, legs, and hands. Erythema and scaling may be particularly prominent over the elbows, knees, and the dorsal interphalangeal joints. Approximately one-third of patients have violaceous, flat-topped papules over the dorsal interphalangeal joints that are pathognomonic of dermatomyositis (Gottron's sign or Gottron's papules; Plate IIE-65). These lesions can be contrasted with the erythema and scaling on the dorsum of the fingers in some patients with SLE, which spares the skin over the interphalangeal joints. Periungual telangiectasia may be prominent, and a lacy or reticulated erythema may be associated with fine scaling on the extensor surfaces of the thighs and upper arms. Other patients, particularly those with long-standing disease, develop areas of hypopigmentation, hyperpigmentation, mild atrophy, and telangiectasia known as *poikiloderma vasculare atrophicans*. Poikiloderma is rare in both SLE and scleroderma and thus can serve as a clinical sign that distinguishes dermatomyositis from these two diseases. Cutaneous changes may be similar in scleroderma and dermatomyositis and may include thickening and binding down of the skin of the hands (sclerodactyly) as well as Raynaud's phenomenon. However, the presence of severe muscle disease, Gottron's papules, heliotrope erythema, and poikiloderma serve to distinguish patients with dermatomyositis. Skin biopsy of erythematous, scaling lesions of dermatomyositis may reveal only mild nonspecific inflammation but sometimes may show changes indistinguishable from those found in SLE, including epidermal atrophy, hydropic degeneration of basal keratinocytes, edema of the upper dermis, and a mild mononuclear cell infiltrate. Direct immunofluorescence microscopy of lesional skin is usually negative, although granular deposits of immunoglobulin(s) and complement in the epidermal basement membrane zone have been described in some patients. Treatment should be directed at the systemic disease. In the few instances where adjunctive cutaneous therapy is desirable, topical glucocorticoids are sometimes useful. These patients should avoid exposure to ultraviolet irradiation and use photoprotective measures such as sunscreens.

LUPUS ERYTHEMATOSUS

The cutaneous manifestations of lupus erythematosus (LE) (Chap. 311) can be divided into acute, subacute, and chronic (i.e., discoid LE) types. *Acute cutaneous LE* is characterized by erythema of the nose and malar eminences in a "butterfly" distribution (Plate IIE-61). The erythema is often sudden in onset, accompanied by edema and fine scale, and correlated with systemic involvement. Patients may have widespread

involvement of the face as well as erythema and scaling of the extensor surfaces of the extremities and upper chest. These acute lesions, while sometimes evanescent, usually last for days and are often associated with exacerbations of systemic disease. Skin biopsy of acute lesions may show only a sparse dermal infiltrate of mononuclear cells and dermal edema. In some instances, cellular infiltrates around blood vessels and hair follicles are notable, as is hydropic degeneration of basal cells of the epidermis. Direct immunofluorescence microscopy of lesional skin frequently reveals deposits of immunoglobulin(s) and complement in the epidermal basement membrane zone. Treatment is aimed at control of systemic disease; photoprotection in this, as well as in other forms of LE, is very important.

Subacute cutaneous lupus erythematosus (SCLE) is characterized by a widespread photosensitive, nonscarring eruption. About half of these patients haveSLE in which severe renal and central nervous system involvement is uncommon. SCLE may present as a papulosquamous eruption that resembles psoriasis or annular lesions that resemble those seen in erythema multiforme. In the papulosquamous form, discrete erythematous papules arise on the back, chest, shoulders, extensor surfaces of the arms, and the dorsum of the hands; lesions are uncommon on the face, flexor surfaces of the arms, and below the waist. The slightly scaling papules tend to merge into large plaques, some with a reticulate appearance. The annular form involves the same areas and presents with erythematous papules that evolve into oval, circular, or polycyclic lesions. The lesions of SCLE are more widespread but have less tendency for scarring than do lesions of discoidLE. Skin biopsy reveals a dense mononuclear cell infiltrate around hair follicles and blood vessels in the superficial dermis, combined with hydropic degeneration of basal cells in the epidermis. Direct immunofluorescence microscopy of lesional skin reveals deposits of immunoglobulin(s) in the epidermal basement membrane zone in about half these cases. A particulate pattern of IgG deposition around basal keratinocytes has recently been associated with SCLE. Most SCLE patients have anti-Ro antibodies. Local therapy is usually unsuccessful, and most patients require treatment with aminoquinoline antimalarials. Low-dose therapy with oral glucocorticoids is sometimes necessary; photoprotective measures against both ultraviolet B and A wavelengths are very important.

Discoid lupus erythematosus (DLE) is characterized by discrete lesions, most often on the face, scalp, or external ears. The lesions are erythematous papules or plaques with a thick, adherent scale that occludes hair follicles (follicular plugging). When the scale is removed, its underside will show small excrescences that correlate with the openings of hair follicles and is termed a "carpet tack" appearance. This finding is relatively specific for DLE. Long-standing lesions develop central atrophy, scarring, and hypopigmentation but frequently have erythematous, sometimes raised borders at the periphery (Plate IIE-62). These lesions persist for years and tend to expand slowly. Only 5 to 10% of patients with DLE meet the American Rheumatism Association criteria forSLE. However, typical discoid lesions are frequently seen in patients with SLE. Biopsy of DLE lesions shows hyperkeratosis, follicular plugging, and atrophy of the epidermis. The dermal-epidermal junction reveals hydropic degeneration of basal keratinocytes, and a mononuclear cell infiltrate surrounding hair follicles and blood vessels. Direct immunofluorescence microscopy demonstrates immunoglobulin(s) and complement deposits at the basement membrane zone in about 90% of cases. Treatment is focused on control of local cutaneous disease and consists mainly of photoprotection and topical

or intralesional glucocorticoids. If local therapy is ineffective, use of aminoquinoline antimalarials may be indicated.

SCLERODERMA AND MORPHEA

The skin changes of scleroderma (Chap. 313) usually begin on the hands, feet, and face, with episodes of recurrent nonpitting edema. Sclerosis of the skin begins distally on the fingers (sclerodactyly) and spreads proximally, usually accompanied by resorption of bone of the fingertips, which may have punched out ulcers, stellate scars, or areas of hemorrhage (Plate IIE-66). The fingers may actually shrink in size and become sausage-shaped, and since the fingernails are usually unaffected, the nails may curve over the end of the fingertips. Periungual telangiectasias are usually present, but periungual erythema is rare. In advanced cases, the extremities show contractures and calcinosis cutis. Face involvement includes a smooth, unwrinkled brow, taut skin over the nose, shrinkage of tissue around the mouth, and perioral radial furrowing (Plate IIE-64). Matlike telangiectasias are often present, particularly on the face and hands. Involved skin feels indurated, smooth, and bound to underlying structures; hyperpigmentation and hypopigmentation are also often present. Raynaud's phenomenon, i.e., cold-induced blanching, cyanosis, and reactive hyperemia, is present in almost all patients and can precede development of scleroderma by many years. The combination of calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia has been termed the *CREST syndrome*. Anticentromere antibodies have been reported in a very high percentage of patients with the CREST syndrome but in only a small minority of patients with scleroderma. Skin biopsy reveals thickening of the dermis and homogenization of collagen bundles. Direct immunofluorescence microscopy of lesional skin is usually negative.

Morphea, which has been called *localized scleroderma*, is characterized by localized thickening and sclerosis of skin, usually affecting young adults or children. Morphea begins as erythematous or flesh-colored plaques that become sclerotic, develop central hypopigmentation, and demonstrate an erythematous border. In most cases, patients have one or a few lesions, and the disease is termed *localized morphea*. In some patients, widespread cutaneous lesions may occur, without systemic involvement. This form is called *generalized morphea*. Most patients with morphea do not have autoantibodies. Skin biopsy of morphea is indistinguishable from that of scleroderma. Linear scleroderma is a limited form of disease that presents in a linear, bandlike distribution and tends to involve deep as well as superficial layers of skin. Scleroderma and morphea are usually quite resistant to therapy. For this reason, physical therapy to prevent joint contractures and to maintain function is employed and is often helpful.

Diffuse fasciitis with eosinophilia is a clinical entity that can sometimes be confused with scleroderma. There is usually the sudden onset of swelling, induration, and erythema of the extremities frequently following significant physical exertion. The proximal portions of extremities (arms, forearms, thighs, legs) are more often involved than are the hands and feet. While the skin is indurated, it is usually not bound down as in scleroderma; contractures may occur early secondary to fascial involvement. The latter may also cause muscle groups to be separated (i.e., the "groove sign") and veins to appear depressed (i.e., sunken veins). These skin findings are accompanied by peripheral blood eosinophilia, increased erythrocyte sedimentation rate, and sometimes

hypergammaglobulinemia. Deep biopsy of affected areas of skin reveals inflammation and thickening of the deep fascia overlying muscle. An inflammatory infiltrate composed of eosinophils and mononuclear cells is usually found. Patients with eosinophilic fasciitis appear to be at increased risk to develop bone marrow failure or other hematologic abnormalities. While the ultimate course of eosinophilic fasciitis is uncertain, many patients respond favorably to treatment with prednisone in doses ranging from 40 to 60 mg/d.

The *eosinophilia-myalgia syndrome*, a disorder reported in epidemic numbers in 1989 and linked to ingestion of L-tryptophan manufactured by a single company in Japan, is a multisystem disorder characterized by debilitating myalgias and absolute eosinophilia in association with varying combinations of arthralgias, pulmonary symptoms, and peripheral edema. In a later phase (i.e., 3 to 6 months after initial symptoms), these patients often develop localized sclerodermatous skin changes, weight loss, and/or neuropathy (Chap. 313). The precise cause of this syndrome, which may resemble other sclerotic skin conditions, is unknown. However, the implicated lots of L-tryptophan contained the contaminant 1,1-ethylidene bis[tryptophan]. This contaminant may be pathogenic or a marker for another substance that provokes the disorder.

59. CUTANEOUS DRUG REACTIONS - *Robert S. Stern*, *Olivier M. Chosidow*, *Bruce U. Wintroub*

Cutaneous reactions are among the most frequent adverse reactions to drugs. Prompt recognition of these reactions, drug withdrawal, and appropriate therapeutic interventions can minimize toxicity. This chapter focuses on adverse cutaneous reactions to drugs other than topical agents and reviews the incidence, patterns, and pathogenesis of cutaneous reactions to drugs and other therapeutic agents.

USE OF PRESCRIPTION DRUGS IN THE UNITED STATES

More than 1.5 billion prescriptions for 60,000 drug products, which include over 2000 different active agents, are dispensed each year in the United States. Hospital inpatients alone annually receive about 120 million courses of drug therapy, and half of adult Americans receive prescription drugs on a regular outpatient basis. Many additional patients use over-the-counter medicines that may cause adverse cutaneous reactions.

INCIDENCE OF CUTANEOUS REACTIONS

Although adverse drug reactions are common, it is difficult to ascertain their incidence, seriousness, and ultimate health effects. Available information comes from evaluations of hospitalized patients, epidemiologic surveys, premarketing studies, and voluntary reporting, most notably to the U.S. Food and Drug Administration's Medwatch System. None of these efforts provides comprehensive comparable data on the risk of cutaneous reactions associated with most medicines.

In one study about 2% of medical inpatients had skin reactions consisting of rash, urticaria, or pruritus during hospitalization. The overall reaction rate per course of drug therapy was about 3:1000. Among inpatients, penicillins, sulfonamides, and blood products accounted for two-thirds of cutaneous reactions. Among outpatients, reaction rates for many antibiotics were comparable to those observed in inpatients. Fluoroquinolones are notable causes of cutaneous reactions not observed in earlier studies. Reaction rates for selected commonly used antibiotics are summarized in Table 59-1. Most cutaneous reactions occur within 2 weeks of exposure to a drug. The risk of allergic reactions does not vary greatly with age or sex. Among outpatients, the risk of a reaction to an antibiotic was comparable for first and subsequent courses of a given drug.

The distribution of morphologic patterns of drug eruptions cared for within a Finnish hospital dermatology department with a special interest in fixed drug eruptions included exanthematous reactions (32%), urticaria and/or angioedema (20%), fixed drug eruptions (34%), erythema multiforme (2%), Stevens-Johnson syndrome (SJS; 1%), exfoliative dermatitis (1%), and photosensitivity reactions (3%). Other studies suggest that about 80% of all cutaneous reactions are morbilliform or erythematous, 10 to 15% are urticaria or angioedema, and all other types of reactions are relatively rare.

The relative risk ofSJS and toxic epidermal necrolysis (TEN), perhaps the most important severe cutaneous reactions, has been quantified in an international case control study and case series. Sulfonamide antibiotics, allopurinol, amine antiepileptic

drugs (phenytoin and carbamazepine), and lamotrigine (a new antiepileptic) are associated with the highest risk of these reactions.

PATHOGENESIS OF DRUG REACTIONS

Untoward cutaneous responses to drugs can arise as a result of immunologic or nonimmunologic mechanisms. Immunologic reactions require activation of host immunologic pathways and are designated *drug allergy*. Drug reactions occurring through nonimmunologic mechanisms may be due to activation of effector pathways, overdosage, cumulative toxicity, side effects, ecologic disturbance, interactions between drugs, metabolic alterations, exacerbation of preexisting dermatologic conditions, or inherited protein or enzyme deficiencies. It is often not possible to specify the responsible drug or pathogenic mechanism because the skin responds to a variety of stimuli through a limited number of reaction patterns. The mechanism of many drug reactions is unknown.

IMMUNOLOGIC DRUG REACTIONS

Drugs frequently elicit an immune response, but only a small number of individuals experience clinical hypersensitivity reactions. For example, most patients exposed to penicillin develop demonstrable antibodies to penicillin but do not manifest drug reactions when exposed to penicillin. Multiple factors determine the capacity of a drug to elicit an immune response, including the molecular characteristics of the drug and host effects.

Increases in *molecular* size and complexity are associated with increased immunogenicity, and macromolecular drugs such as protein or peptide hormones are highly antigenic. Most drugs are small organic molecules <1000 Da in size, and the capacity of such small molecules to elicit an immune response depends on their ability to act as haptens, i.e., to form stable, usually covalent, bonds with tissue macromolecules, an extremely rare event.

Route of administration of a drug or simple chemical can influence the nature of the *host* immune response. For example, topical application of antigens tends to induce delayed hypersensitivity, and exposure to antigens via oral or nasal cavities stimulates production of secretory immunoglobins, IgA and IgE, and occasionally IgM. Frequency of sensitization through intravenous administration of drugs varies, but anaphylaxis is a more likely consequence with this route of exposure than following oral administration.

The degree of drug exposure and individual variability in absorption and metabolism of a given agent may alter immunogenic load. The variable degree of in vivo acetylation of hydralazine provides a clinical example of this phenomenon. Hydralazine produces a lupus-like syndrome associated with antinuclear antibody formation more frequently in patients who acetylate the drug slowly. Frequent high-dose and interrupted courses of therapy are also important risk factors for development of drug allergy.

Pathogenesis of Allergic Drug Reactions> >

> >*IgE-Dependent Reactions* IgE-dependent drug reactions are usually manifest in the

skin and gastrointestinal, respiratory, and cardiovascular systems (Chap. 310). Primary symptoms and signs include pruritus, urticaria, nausea, vomiting, cramps, bronchospasm, and laryngeal edema and, on occasion, anaphylactic shock with hypotension and death. Immediate reactions may occur within minutes of drug exposure, and accelerated reactions occur hours or days after drug administration. Accelerated reactions are usually urticarial and may include laryngeal edema. Penicillin and related drugs are the most frequent causes of IgE-dependent reactions. Release of chemical mediators such as histamine, adenosine, leukotrienes, prostaglandins, platelet-activating factor, enzymes, and proteoglycans from sensitized tissue, mast cells, or circulating basophilic leukocytes results in vasodilation and edema. Release is triggered when polyvalent drug protein conjugates cross-link IgE molecules fixed to sensitized cells. The clinical manifestations are determined by interaction of the released chemical mediator with its target organ, i.e., skin, respiratory, gastrointestinal, and/or cardiovascular systems. Certain routes of administration favor different clinical patterns (i.e., oral route: gastrointestinal effects; intravenous route: circulatory effects).

Immune-Complex-Dependent Reactions Serum sickness is produced by circulating immune complexes and is characterized by fever, arthritis, nephritis, neuritis, edema, and an urticarial, papular, or purpuric rash (Chap. 317). The syndrome requires an antigen that remains in the circulation for prolonged periods so that when antibody is synthesized, circulating antigen-antibody complexes are formed. Serum sickness was first described following administration of foreign sera, but drugs are now the usual cause. Drugs that produce serum sickness include the penicillins, sulfonamides, thiouracils, cholecystographic dyes, phenytoin, aminosalicylic acid, heparin, and antilymphocyte globulin. Cephalosporin administration in febrile children is associated with a high risk of a clinically similar reaction, but the mechanism of this reaction is unknown. In classic serum sickness, symptoms develop 6 days or more after exposure to a drug, the latent period representing the time needed to synthesize antibody. The antibodies responsible for immune-complex-dependent drug reactions are largely of the IgG or IgM class. Vasculitis, a relatively rare cutaneous complication of drugs, may also be a result of immune complex deposition (Chap. 317).

Cytotoxicity and Delayed Hypersensitivity Cytotoxicity and delayed hypersensitivity mechanisms may be important in the etiology of morbilliform exanthema, hypersensitivity syndrome,SJS, orTEN, but this is not proven. Systemic manifestations occur frequently. The nature of the antigen leading to cytotoxic reactions is unknown, but it is likely that different T lymphocyte populations are activated. T_H1 type cells will lead to the production of interleukin (IL)-2 and interferon (IFN)-g and subsequent activation of cytotoxic T cells. In early lesions of morbilliform exanthema or TEN, histopathologic studies have shown expression of HLA-DR and intercellular adhesion molecule (ICAM-1) by keratinocytes, CD4 cells (in the dermis), and CD8 T cells (in the epidermis) and apoptosis of keratinocytes (facilitated by tumor necrosis factora secretion and *fas*-ligand expression). T_H2 type cells produce cytokines such as IL-5, which may be involved in hypersensitivity syndrome (see below).

NONIMMUNOLOGIC DRUG REACTIONS

Nonimmunologic mechanisms are responsible for the majority of drug reactions; however, only the most important mechanisms will be discussed.

Nonimmunologic Activation of Effector Pathways Drug reactions may result from nonimmunologic activation of effector pathways by three mechanisms: First, drugs may release mediators directly from mast cells and basophils and present as anaphylaxis, urticaria, and/or angioedema. Urticarial anaphylactic reactions induced by opiates, polymyxin B, tubocurarine, radiocontrast media, and dextrans may occur by this mechanism. Second, drugs may activate complement in the absence of antibody. This is an additional mechanism through which radiocontrast media may act. Third, drugs such as aspirin and other nonsteroidal anti-inflammatory agents (NSAIDs) may alter pathways of arachidonic acid metabolism and induce urticaria.

Phototoxicity Phototoxic reactions may be drug-induced or may occur in metabolic disorders in which a photosensitizing chemical is overproduced. A phototoxic reaction occurs when enough chromophore (drug or metabolic product) absorbs sufficient radiation to cause a reaction or interaction with target tissue. Drug-induced phototoxic reactions can occur on first exposure. The incidence of phototoxicity is a direct function of the concentration of sensitizer and the amount of light of the appropriate wavelengths. At least three distinct photochemical mechanisms have been described: (1) the reaction between the excited state of a phototoxic molecule and a biologic target may cause formation of a covalent photoaddition product, (2) the phototoxic molecule may form stable photoproducts that are toxic to biologic substrates, and (3) radiation of a phototoxic molecule may result in transfer of energy to oxygen molecules and cause formation of toxic oxygen species, such as singlet oxygen superoxide anion, or hydroxyl radicals. Interaction of these reactive species with biologic targets produces photooxidized molecules. Phototoxic injury is usually manifest as a sunburn-like reaction.

Exacerbation of Preexisting Diseases A variety of agents can exacerbate preexisting diseases. For example, lithium can exacerbate acne and psoriasis in a dose-dependent manner. Beta-blocking agents andIFN-amay induce psoriasis. Withdrawal of glucocorticoids can exacerbate psoriasis or atopic dermatitis.

Inherited Enzyme or Protein Deficiencies Specific genetically determined defects in the ability of an individual to detoxify toxic reactive drug metabolites may predispose such individuals to the development of severe drug reactions, especially hypersensitivity syndrome, and perhapsTENassociated with use of sulfonamides and anticonvulsants.

Alterations of Immunologic Status Alterations in patients' immunologic status may also modify the risk of cutaneous reactions. Bone marrow transplant patients, HIV-infected persons, and persons with Epstein-Barr virus infection are at higher risk of developing cutaneous reactions to drugs. Skin reactions to trimethoprim-sulfamethoxazole are seen in about a third of HIV-infected users of this drug, but desensitization can be accomplished. Dapsone, trimethoprim alone, and amoxicillin-clavulanate are also frequent causes of drug eruptions in HIV-infected patients. The advent of highly active antiretroviral therapy (HAART) may have decreased the risk of cutaneous reactions in HIV patients (Chap. 309).

A CLINICAL CLASSIFICATION OF CUTANEOUS DRUG REACTIONS

URTICARIA/ANGIOEDEMA

Urticaria is a skin reaction characterized by pruritic, red wheals. Lesions may vary from a small point to a large area. Individual lesions rarely last more than 24 h. When deep dermal and subcutaneous tissues are also swollen, this reaction is known as *angioedema*. Angioedema may involve mucous membranes and may be part of a life-threatening anaphylactic reaction. Urticarial lesions, along with pruritus and morbilliform (or maculopapular) eruptions, are among the most frequent types of cutaneous reactions to drugs.

Drug-induced urticaria may be caused by three mechanisms: an IgE-dependent mechanism, circulating immune complexes (serum sickness), and nonimmunologic activation of effector pathways. IgE-dependent urticarial reactions usually occur within 36 h but can occur within minutes. Reactions occurring within minutes to hours of drug exposure are termed *immediate reactions*, whereas those that occur 12 to 36 h after drug exposure are designated *accelerated reactions*. Immune-complex-induced urticaria associated with serum sickness usually occurs from 6 to 12 days after first exposure. In this syndrome, the urticarial eruption may be accompanied by fever, hematuria, arthralgias, hepatic dysfunction, and neurologic symptoms.

Certain drugs, such asNSAIDs, angiotensin-converting enzyme (ACE) inhibitors, and radiographic dyes, may induce urticarial reactions, angioedema, and anaphylaxis in the absence of drug-specific antibody. Although ACE inhibitors, aspirin, penicillin, and blood products are the most frequent causes of urticarial eruptions, urticaria has been observed in association with nearly all drugs. Drugs also may cause chronic urticaria, which lasts more than 6 weeks. Aspirin frequently exacerbates this problem.

The treatment of urticaria or angioedema depends on the severity of the reaction and the rate at which it is evolving. In severe cases, especially with respiratory or cardiovascular compromise, epinephrine is the mainstay of therapy, but its effect is reduced in patients using beta blockers. For more seriously affected patients, treatment with systemic glucocorticoids, sometimes intravenously administered, are helpful. In addition to drug withdrawal, for patients with only cutaneous symptoms and without symptoms of angioedema or anaphylaxis, oral antihistamines are usually sufficient.

PHOTOSENSITIVITY ERUPTIONS

Photosensitivity eruptions are usually most marked in sun-exposed areas but may extend to sun-protected areas. Phototoxic reactions are more common with some drugs. Photoallergic reactions to systemically administered drugs are very rare. Phototoxic reactions usually resemble sunburn and can occur with the first exposure to a drug. Their severity depends on the tissue level of the drug, the extent of exposure to light, and the efficiency of the photosensitizer (Chap. 60).

Orally administered phototoxic drugs include many fluoroquinolones, chlorpromazine, tetracycline, thiazides, and at least twoNSAIDs(benoxaprofen and piroxicam). The majority of the common phototoxic drugs have action spectrums in the long-wave ultraviolet A (UV-A) range. Phototoxic reactions abate with removal of either the drug or ultraviolet radiation. Because UV-A and visible light, which trigger these reactions, are

not easily absorbed by nonopaque sunscreens and are transmitted through window glass, these reactions may be difficult to block.

Photosensitivity reactions are treated by avoiding exposure to ultraviolet light (sunlight) and treating the reaction as one would a sunburn. Rarely, individuals develop persistent reactivity to light, necessitating long-term avoidance of sun exposure.

PIGMENTATION CHANGES

Drugs may cause a variety of pigmentary changes in the skin. Some drugs stimulate melanocytic activity and increase pigmentation. Drug deposition can also lead to pigmentation; this phenomenon occurs with heavy metals. Phenothiazines may be deposited in the skin and cause a slate-gray color. Antimalarial drugs may cause a slate-gray or yellow pigmentation. Long term minocycline use may cause slate-gray hyperpigmentation, especially in areas of chronic inflammation. Inorganic arsenic, once used to treat psoriasis, is associated with diffuse macular pigmentation. Other heavy metals that cause pigmentary changes include silver, gold, bismuth, and mercury. Long-term use of phenytoin can produce a chloasma-like pigmentation in women. Certain cytostatic agents can also cause pigmentary changes. Histologic examination is often diagnostic for drug deposition diseases.

Zidovudine (AZT) is a frequent cause of pigmentation, especially of the nails (Chap. 309). Nicotinic acid in large doses may cause brown pigmentation, and oral contraceptives may produce chloasma. In addition, amiodarone may cause violaceous hyperpigmentation that is increased in sun-exposed skin. Drugs such as heavy metals, copper antimalarial and arsenical agents, and ACTH also may discolor oral mucosa.

VASCULITIS

Cutaneous necrotizing vasculitis often presents as palpable purpuric lesions that may be generalized or limited to the lower extremities or other dependent areas (Chap. 317). Urticarial lesions, ulcers, and hemorrhagic blisters also occur. Vasculitis may involve other organs, including the liver, kidney, brain, and joints. Drugs are only one cause of vasculitis, with infection and collagen vascular disease responsible for the majority of cases.

Propylthiouracil induces a cutaneous vasculitis that is accompanied by leukopenia and splenomegaly. Direct immunofluorescent changes in these lesions suggest immune-complex deposition. Drugs implicated in vasculitic eruptions include allopurinol, thiazides, sulfonamides, penicillin, and someNSAIDs.

HYPERSENSITIVITY SYNDROME

Initially described with phenytoin, hypersensitivity syndrome presents as an erythematous eruption that may become purpuric and is accompanied by many of the following features: fever, facial and periorbital edema, tender generalized lymphadenopathy, leukocytosis (often with atypical lymphocytes and eosinophils), hepatitis, and sometimes nephritis or pneumonitis. The cutaneous reaction usually begins 1 to 6 weeks after phenytoin is begun and usually resolves with drug cessation,

but symptoms, especially hepatitis, may persist. The eruption recurs with rechallenge, and cross-reactions among aromatic anticonvulsants, including phenytoin, carbamazepine, and barbiturates, are frequent. With phenytoin, an increased risk of this syndrome is associated with an inherited deficiency of epoxide hydrolase, an enzyme required for metabolism of a toxic intermediate arene oxide that is formed during metabolism of phenytoin by the cytochrome P450 system. Other drugs causing this syndrome include lamotrigine, dapsone, allopurinol, sulfonamides, minocycline, and sulfones. Systemic glucocorticoids (prednisone, 0.5 to 1.0 mg/kg) seem to reduce symptoms. Mortality as high as 10% has been reported.

WARFARIN NECROSIS OF THE SKIN

This rare reaction occurs usually between the third and tenth days of therapy with warfarin derivatives, usually in women. Lesions are sharply demarcated, erythematous, indurated, and purpuric and may resolve or progress to form large, irregular, hemorrhagic bullae with eventual necrosis and slow-healing eschar formation.

Development of the syndrome is unrelated to drug dose or underlying condition. Favored sites are breasts, thighs, and buttocks. The course is not altered by discontinuation of the drug after onset of the eruption. Similar reactions have been associated with heparin. Warfarin reactions are associated with protein C deficiency. Protein C is a vitamin K-dependent protein with a shorter half-life than other clotting proteins and is in part responsible for control of fibrinolysis. Since warfarin inhibits synthesis of vitamin K-dependent coagulation factors, warfarin anticoagulation in heterozygotes for protein C deficiency causes a precipitous fall in circulating levels of protein C, permitting hypercoagulability and thrombosis in the cutaneous microvasculature, with consequent areas of necrosis. Heparin-induced necrosis may have clinically similar features but is probably due to heparin-induced platelet aggregation with subsequent occlusion of blood vessels.

Warfarin-induced cutaneous necrosis is treated with vitamin K and heparin. Vitamin K reverses the effects of warfarin, and heparin acts as an anticoagulant. Treatment with protein C concentrates may also be helpful in individuals with deficiencies of protein C, the predisposing factor for development of these reactions.

MORBILLIFORM REACTIONS

Morbilliform or maculopapular eruptions are the most common of all drug-induced reactions, often start on the trunk or areas of pressure or trauma, and consist of erythematous macules and papules that are frequently symmetric and may become confluent. Involvement of mucous membranes, palms, and soles is variable; the eruption may be associated with moderate to severe pruritus and fever.

The pathogenesis is unclear. A hypersensitivity mechanism has been suggested, although these reactions do not always recur following drug rechallenge. Diagnosis is rarely assisted by laboratory or patch testing; differentiation from viral exanthem is the principal differential diagnostic consideration. Unless the suspect drug is essential it should be discontinued. Occasionally these eruptions may decrease or fade with continued use of the responsible drug.

Morbilliform reactions usually develop within 1 week of initiation of therapy and last 1 to 2 weeks; however, reactions to some drugs, especially penicillin and drugs with long half-lives, may begin more than 2 weeks after therapy has begun and last as long as 2 weeks after therapy has ceased.

Morbilliform eruptions are usually treated by discontinuing the suspect medications symptomatically. Oral antihistamines, emollients, and soothing baths are useful for treatment of pruritus. Short courses of potent topical glucocorticoids can reduce inflammation and symptoms and are probably helpful. The beneficial effect of systemic glucocorticoids relative to risk is less clear.

FIXED DRUG REACTIONS

These reactions are characterized by one or more sharply demarcated, erythematous lesions in which hyperpigmentation results after resolution of the acute inflammation; with rechallenge, the lesion recurs in the same (i.e., "fixed") location. Lesions often involve the lips, hands, legs, face, genitalia, and oral mucosa and cause burning. Most patients have multiple lesions. Patch testing is useful to establish the etiology. Fixed drug eruptions have been associated with phenolphthalein, sulfonamides, tetracyclines, phenylbutazone,NSAIDs, and barbiturates. Although cross-sensitivity appears to occur between different tetracycline compounds, cross-sensitivity was not elicited when different sulfonamide compounds were administered to patients as part of provocation testing.

LICHENOID DRUG ERUPTIONS

A lichenoid cutaneous reaction, clinically and morphologically indistinguishable from lichen planus, is associated with a variety of drugs and chemicals. Eosinophils are more common when the reaction is drug-induced. Gold and antimalarials are most often associated with this eruption. Antihypertensive agents, including beta blockers and captopril, have also been reported to cause lichenoid reactions.

BULLOUS ERUPTIONS

Blisters accompany a wide variety of cutaneous reactions, including fixed drug eruptions, severe morbilliform eruptions in dependent areas of the body, and phototoxic reactions.SJS andTEN are the most serious and important bullous reactions to drugs. Nalidixic acid and furosemide cause blistering eruptions indistinguishable from the primary bullous diseases. A pemphigus foliaceus-like eruption is seen with penicillamine.

PUSTULAR ERUPTIONS

Acute generalized exanthematous pustulosis is often associated with exposure to drugs, most notably antibiotics. Usually beginning on the face or intertriginous areas, small nonfollicular pustules overlying erythematous and edematous skin may coalesce and lead to superficial ulceration. Fever is present and differentiating this eruption fromTEN in its initial stages may be difficult. Acute generalized exanthematous pustulosis often

begins within a few days of initiating drug treatment.

ERYTHEMA MULTIFORME

Erythema multiforme is an acute, self-limited inflammatory disorder of skin and mucous membranes characterized by distinctive iris or target lesions, usually acrally distributed and often associated with sore throat, mucosal lesions, and malaise. Classic erythema multiforme usually has nondrug causes, most commonly herpes simplex infection, and must be differentiated from trueSJS, which is usually drug related.

STEVENS-JOHNSON SYNDROME

SJSis a blistering disorder that is usually more severe than erythema multiforme. Initial presentation is often a sore throat, malaise, and fever. Within a few days, in addition to erosions of multiple mucous membranes, small blisters developing on dusky or purpuric macules or atypical target lesions characterize this eruption. Total percent of body surface area blistering and eventual detachment is less than 10%. Overlap SJS/TENshares characteristics of both SJS and TEN, with 10 to 30% of body surface area exhibiting epidermal detachment.

TOXIC EPIDERMAL NECROLYSIS

TENis the most serious cutaneous drug reaction and may be fatal. Drugs are usually the cause of TEN. Onset is generally acute and is characterized by fever>39°C (102.2°F), blisters or ulcers of multiple mucous membranes, malaise, and epidermal necrosis involving>30% of body surface area. Intestinal and pulmonary involvement is associated with a poor prognosis, as is a greater extent of epidermal detachment and older age. About 30% of affected persons die. Many treatments affecting immune response or cytokines (thalidomide) or apoptosis (intravenous immunoglobulin) have been advocated, but none have been shown to be efficacious in well-controlled trials. In spite of its theoretical potential benefits, thalidomide therapy increases TEN-associated mortality. Supportive treatment in burn units is helpful in reducing morbidity and mortality.

DRUGS OF SPECIAL INTEREST

PENICILLIN

The incidence of cutaneous reactions to penicillin is about 1%. About 85% of cutaneous reactions to penicillin are morbilliform, and about 10% are urticaria or angioedema.

IgG, IgM, and IgE antibodies can be produced; IgG and IgM anti-penicillin antibodies play a role in the development of hemolytic anemia, whereas anaphylaxis and serum sickness appear to be due to IgE antibodies in serum.

In patients with suspected IgE-mediated reactions to penicillin for whom future treatment is anticipated, accurate tests for sensitization are available. Current practice is to perform skin testing with a commercially available penicilloyl determinant preparation (Pre-pen, Kremers-Urban) and with fresh penicillin and, if possible, with another source

of minor (nonpenicilloyl) determinants such as aged or base-treated penicillin. Antibodies to minor determinants are common in patients experiencing anaphylaxis, but testing with major determinants alone detects most patients at risk for anaphylaxis.

About one-fourth of patients with positive history of penicillin allergy have a positive skin test, while 6% (3 to 10%) with no history of penicillin sensitivity demonstrate a positive skin response to penicillin. Administering penicillin to those patients with a positive skin test produces reactions in a high proportion (50 to 100%); conversely, only a few patients (0.5%) with a negative skin test react to the drug, and reactions tend to be mild and to occur late. Since a false-negative skin test may occur during or just after an acute reaction, testing should be performed either prospectively or several months after a suspected reaction. As many as 80% of patients lose anaphylactic sensitivity and IgE antibody after several years. Radioallergosorbent tests and other in vitro tests offer no advantage over properly performed skin testing. Some cross-reactivity between penicillin and nonpenicillin b-lactam antibiotics (e.g., cephalosporins) occurs, but the majority of penicillin-allergic patients will tolerate cephalosporins. Persons who have negative skin tests to penicillin rarely develop reactions to cephalosporins.

In the face of a positive clinical history of penicillin reaction, another drug should be chosen. If this is not feasible or prudent (e.g., in a pregnant patient with syphilis or with enterococcal endocarditis), skin testing with penicillin is warranted. If skin tests are negative, cautious administration of penicillin is acceptable, although some recommend desensitization of such patients if the reaction was likely to be IgE-mediated. In those with positive skin tests, desensitization is mandatory if therapeutic use ofb-lactam antibiotics is to be undertaken. Various protocols are available, including oral and parenteral approaches. Oral desensitization appears to have lower risk of serious anaphylactic reactions during desensitization. However, desensitization carries the risk of anaphylaxis regardless of how it is performed. After desensitization, many patients experience non-life-threatening IgE-mediated untoward reactions to penicillin during their course of therapy. Desensitization is not effective in those with exfoliative dermatitis or morbilliform reactions due to penicillin.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs, including aspirin and indomethacin (indometacin), cause two broad categories of allergic-like symptoms in susceptible individuals: (1) approximately 1% of persons experience urticaria or angioedema, and (2) about half as many (0.5%) experience rhinosinusitis and asthma; however, about 10% of adults with asthma and one-third of individuals with nasal polyposis and sinusitis may respond adversely to aspirin.

Urticaria/angioedema may be delayed up to 24 h and may occur at any age. The rhinosinusitis-asthma syndrome generally develops within 1 h of drug administration. In young patients, the reaction pattern often begins as watery rhinorrhea, which can be complicated by nasal and sinus infection, and polyposis, bloody discharge, and nasal eosinophilia. In many individuals with this syndrome, asthma that can be life-threatening eventually ensues whenever NSAIDs are subsequently ingested, and symptoms may persist despite avoidance of these drugs. Proof of the association of symptoms and NSAID use requires either clear-cut history of symptoms following drug ingestion or an oral challenge. For the latter to be performed with relative safety, (1) asthma must be

under good control, (2) the procedure must be conducted in a hospital setting by experienced personnel capable of recognizing and treating acute respiratory responses, and (3) the challenge should begin with very low doses (i.e., not>30 mg) of aspirin and increase every 1 to 2 h in doubling doses as tolerated to 650 mg.

While cross-reactivity betweenNSAIDsis common, it is not immunologic, and patients who are sensitive to NSAIDs cannot be identified by assessment of IgE antibody to aspirin, lymphocyte sensitization, or in vitro immunologic testing.

RADIOCONTRAST MEDIA

Large numbers of patients are exposed to radiocontrast agents. High-osmolality radiocontrast media are about five times more likely to induce urticaria (1%) or anaphylaxis than newer low-osmolality media. Severe reactions are rare with either type of contrast media. About one-third of those with mild reactions to previous exposure rereact on reexposure. In most cases, these reactions are probably not immunologic. Pretreatment with prednisone and diphenhydramine reduces reaction rates. Persons with a reaction to a high-osmolality contrast media should be given low-osmolality media if later contrast studies are required.

ANTICONVULSANTS

Of the anticonvulsants, the single orally administered agent with the highest risk of severe adverse cutaneous reactions is the antiseizure medicine lamotrigine. Older anticonvulsants, including phenytoin and carbamazepine, are also associated with many types of severe reactions and a high incidence of less severe reactions, particularly in children. In addition toSJS,TEN, and the hypersensitivity syndrome discussed above, the aromatic anticonvulsants can induce a pseudolymphoma syndrome and induce gingival hyperplasia.

SULFONAMIDES

Sulfonamides have perhaps the highest risk of causing cutaneous eruptions and are the drugs most frequently implicated inSJS andTEN. The combination of sulfamethoxazole and trimethoprim frequently induces adverse cutaneous reactions in patients with AIDS (Chap. 309). Desensitization is often successful in AIDS patients with morbilliform eruptions but is a high-risk procedure in AIDS patients who manifest erythroderma, fever, or a bullous reaction in response to their earlier sulfonamide exposure.

AGENTS USED IN CANCER CHEMOTHERAPY

Since many agents used in cancer chemotherapy inhibit cell division, rapidly proliferating elements of the skin, including hair, mucous membranes, and appendages, are sensitive to their effects; as a result, stomatitis and alopecia are among the most frequent dose-dependent side effects of chemotherapy. Onychodystrophy (dystrophic changes in nails) is also seen with bleomycin, hydroxyurea (hydroxycarbamide), and 5-fluorouracil. Sterile cellulitis and phlebitis and ulceration of pressure areas occur with many of these agents. Urticaria, angioedema, exfoliative dermatitis, and erythema of the palms and soles have also been seen, as has local and diffuse hyperpigmentation.

GLUCOCORTICOIDS

Both systemic and topical glucocorticoids cause a variety of skin changes, including acneiform eruptions, atrophy, striae, and other stigmata of Cushing's syndrome, and in sufficiently high doses can retard wound healing. Patients using glucocorticoids are at higher risk for bacterial, yeast, and fungal skin infections that may be misinterpreted as drug eruptions but are instead drug side effects.

CYTOKINE THERAPY

Alopecia is a common complication ofIFN-a. Induction or exacerbation of various immune-mediated disorders (psoriasis, lichen planus, lupus erythematosus) has been also reported with this agent. IFN-b injection has been associated with local necrosis of the skin. Granulocyte colony stimulating factor may induce various neutrophilic dermatosis, including Sweet's syndrome, pyoderma gangrenosum, neutrophilic eccrine hidradenitis, and vasculitis, and can exacerbate psoriasis.

IL-2 is associated with frequent cutaneous reactions including exanthema, facial edema, xerosis, and pruritus. Cases of pemphigus vulgaris, linear IgA disease, psoriasis, and vitiligo have also been described in association with this drug.

ANTIMALARIAL AGENTS

Antimalarial agents are used as therapy for several skin diseases, including the skin manifestations of lupus and polymorphous light eruption, but they can also induce cutaneous reactions. Although also used to treat porphyria cutanea tarda at low doses, in patients with asymptomatic porphyria cutanea tarda, higher doses of chloroquine increase porphyrin levels to such an extent that they may exacerbate the disease.

Pigmentation disturbances, including black pigmentation of the face, mucous membranes, and pretibial and subungual areas, occur with antimalarials. Quinacrine (mepacrine) causes generalized, cutaneous yellow discoloration.

GOLD

Chrysotherapy has been associated with a variety of dose-related dermatologic reactions (including maculopapular eruptions), which can develop as long as 2 years after initiation of therapy and require months to resolve. Erythema nodosum, psoriasiform dermatitis, vaginal pruritus, eruptions similar to those of pityriasis rosea, hyperpigmentation, and lichenoid eruptions resembling those seen with antimalarial agents have been reported. After a cutaneous reaction, it is sometimes possible to reinstitute gold therapy at lower doses without recurrence of the dermatitis.

DIAGNOSIS OF DRUG REACTIONS

Possible causes of an adverse reaction can be assessed as definite, probable, possible, or unlikely based on six variables: (1) previous experience with the drug in the general population, (2) alternative etiologic candidates, (3) timing of events, (4) drug levels or

evidence of overdose, (5) patient reaction to drug discontinuation, and (6) patient reaction to rechallenge.

PREVIOUS EXPERIENCE

Tables of relative reaction rates are available and are useful to assess the likelihood that a given drug is responsible for a given cutaneous reaction. The specific morphologic pattern of a drug reaction, however, may modify these reaction rates by increasing or decreasing the likelihood that a given drug is responsible for a given reaction. For example, since fixed eruptions due to drugs are more often seen with barbiturates than with penicillin, a fixed drug reaction in a patient taking both types of agents is more likely to be due to the barbiturate, even though penicillins have a higher overall drug reaction rate.

ALTERNATIVE ETIOLOGIC CANDIDATES

A cutaneous eruption may be due to exacerbation of preexisting disease or to development of new disease unrelated to drugs. For example, a patient with psoriasis may have a flare-up of disease coincidental with administration of penicillin for streptococcal infection; in this case, infection is a more likely cause for the flare-up than drug reaction.

TIMING OF EVENTS

Most drug reactions of the skin occur within 1 to 2 weeks of initiation of therapy. Hypersensitivity syndrome may occur later (up to 8 weeks) after initiating drug therapy. Fixed drug reactions and generalized exanthematous pustulosis often occur earlier (within 48 h), as do reactions of all types in persons with prior sensitization to that drug or a cross-sensitizing agent.

DRUG LEVELS

Some cutaneous reactions are dependent on dosage or cumulative toxicity. For example, lichenoid dermatoses due to gold administration appear more often in patients taking high doses.

DISCONTINUATION

Most adverse cutaneous reactions to drugs remit with discontinuation of the suspected agent. A reaction is considered unlikely to be drug-related if improvement occurs while the drug is continued or if a patient fails to improve after stopping the drug and appropriate therapy.

RECHALLENGE

Rechallenge provides the most definitive information concerning adverse cutaneous reactions to drugs, since a reaction failing to recur on rechallenge with a drug is unlikely to be due to that agent. Rechallenge is usually impractical, however, because the need to ensure patient safety and comfort outweighs the value of the possible information

derived from rechallenge.

Of special importance is the rapid recognition of reactions that may become serious or life-threatening. Table 59-2 lists clinical and laboratory features that, if present, suggest the reaction may be serious. Table 59-3 provides key features of the most serious adverse cutaneous reactions.

DIAGNOSIS OF DRUG ALLERGY

Tests for IgE responses include in vivo and in vitro methods, but such tests are available for only a limited number of drugs, including penicillins and cephalosporins, some peptide and protein drugs (insulin, xenogeneic sera), and some agents used for general anesthesia. In vivo testing is accomplished by prick puncture and/or by intradermal skin testing. A wheal-and-flare response 2´ 2 mm greater than that seen with a saline control within 20 min is considered indicative of IgE-mediated mast cell degranulation, provided (1) the patient is not dermographic, (2) the drug does not nonspecifically degranulate mast cells, (3) the drug concentration is not high enough to be irritating, and (4) the buffer itself does not cause wheal-and-flare responses.

Skin testing with major and minor determinants of penicillins or cephalosporins has proved useful for identifying patients at risk of anaphylactic reactions to these agents. However, skin tests themselves carry a small risk of anaphylaxis. Negative skin tests do not rule out IgE-mediated reactivity, and the risk of anaphylaxis in response to penicillin administration in patients with negative skin tests is about 1%; about two-thirds of patients with a positive skin test and history of a previous adverse reaction to penicillin experience an allergic response on rechallenge. Skin tests may be negative in allergic patients receiving antihistamines or in those whose allergy is to determinants not present in the test reagent. Although less well studied, similar techniques can identify patients who are sensitive to protein drugs and to agents such as gallamine and succinylcholine. Most other drugs are small molecules, and skin testing with them is unreliable.

There are no generally available and reliable tests for assessing causality of non-IgE-mediated reactions, except possibly patch tests for assessment of fixed drug reactions. Therefore, diagnosis usually relies on clinical factors rather than test results.

60. PHOTOSENSITIVITY AND OTHER REACTIONS TO LIGHT - *David R. Bickers*

SOLAR RADIATION

Sunlight is the most visible and obvious source of comfort in the environment. This natural proclivity for the sun has the beneficial results of warmth and vitamin D synthesis but also can produce pathologic consequences. Few effects of sun exposure beyond those affecting the skin have been identified, but cutaneous exposure to sunlight can evoke immunosuppressive responses and genetic changes that may be relevant to the pathogenesis of nonmelanoma skin cancer and perhaps infections such as herpes simplex.

The sun's energy encompasses a broad range from ultrashort highly energetic ionizing radiation (10^{-2}um) to ultralong radiowaves of very low photon energy (10^{7}um). Thus, the emission spectrum ranges over nine orders of magnitude, but that reaching the earth's surface is narrow and is limited to components of the ultraviolet (UV), visible light, and portions of the infrared. The cutoff at the short end of the UV is at approximately 290 nm, because stratospheric ozone is formed by ionizing radiation of wavelengths less than 100 nm and absorbs solar energy between 120 and 310 nm, thereby preventing penetration to the earth's surface of the shorter, more energetic, potentially more harmful wavelengths of solar radiation. Indeed, concern about destruction of the ozone layer by chlorofluorocarbons released into the atmosphere has led to international agreements to reduce production of these chemicals.

Measurements of solar flux indicate that there is a twentyfold regional variation in the amount of energy at 300 nm that reaches the earth's surface. This variability relates to seasonal effects, the path of sunlight transmission through ozone and air, the altitude (4% increase for each 300 m of elevation), the latitude (increasing intensity with decreasing latitude), and the amount of cloud cover, fog, and pollution.

The major components of the photobiologic action spectrum include theUV and visible wavelengths between 290 and 700 nm. In addition, the wavelengths beyond 700 nm in the infrared primarily evoke heat, but warming of the skin may enhance biologic responses to wavelengths in the UV and visible spectrum.

TheUVspectrum is arbitrarily divided into three major segments: C, B, and A. This includes the wavelengths between 10 and 400 nm. Ultraviolet C (UV-C) consists of wavelengths between 10 and 290 nm and does not reach the earth because of its absorption by stratospheric ozone. These wavelengths are not a cause of photosensitivity except in occupational settings where artificial sources of this energy are employed -- e.g., for germicidal effects. Ultraviolet B (UV-B) consists of wavelengths between 290 and 320 nm. This portion of the photobiologic action spectrum is the most efficient in producing redness or erythema in human skin and hence is sometimes known as the "sunburn spectrum." Ultraviolet A (UV-A) represents those wavelengths between 320 and 400 nm and is approximately 1000-fold less efficient in producing skin hyperemia than is UV-B. The UV-A has also been divided into two parts known as UV-A 1 (340 to 400 nm) and UV-A 2 (320 to 340 nm).

The visible wavelengths between 400 and 700 nm include the familiar white light which

when directed through a prism can be shown to consist of various colors including violet, indigo, blue, green, yellow, orange, and red. The energy possessed by photons in the visible spectrum is not capable of damaging human skin in the absence of a photosensitizing chemical. The absorption of energy is critical to the development of photosensitivity. Thus the *absorption spectrum* of a molecule is defined as the range of wavelengths absorbed by it, whereas the *action spectrum* for an effect of incident radiation is defined as the range of wavelengths that evoke the response.

Photosensitivity occurs when a photon-absorbing chemical (chromophore) present in the skin absorbs incident energy, becomes excited, and transfers the absorbed energy to various structures or to oxygen. The absorbed energy must be dissipated by processes including heat, fluorescence, and phosphorescence. It is important to emphasize that absorption spectra and action spectra need not be superimposable, but there must be overlap at some point to produce photosensitization.

STRUCTURE AND FUNCTION OF SKIN

The skin's exposure to sunlight permits the absorption of some wavelengths and the transmission of others. Essentially, human skin is a sandwich of two distinctive compartments, the epidermis and dermis, separated by a basement membrane. The outer epidermis is a stratified squamous epithelium comprising the surface stratum corneum (a protein- and lipid-rich compact membrane), the stratum granulosum, stratum spinosum, and the basal cell layer. The basal cell layer contains a heterogeneous population of cells, a subset of which migrate upward in the process of terminal differentiation that results in the expression of specific keratin genes and the formation of the stratum corneum. Epidermal cells include resident keratinocytes and melanocytes and immigrant cells, including the immunologically active Langerhans cells, lymphocytes, polymorphonuclear leukocytes, monocytes, and macrophages, making the epidermis a major component of the immune system. Branches of sensory nerve endings also reach into this compartment.

The second major component of skin is the dermis, which is relatively large and less densely populated with cells that include fibroblasts, endothelial cells within dermal vessels, and mast cells. Tissue macrophages and sparsely distributed inflammatory cells are also present. All these cells exist within an extracellular matrix of collagen, elastin, and glycosaminoglycans. In contrast to the epidermis, rich vascularization of the dermis allows it to play an important role in temperature regulation and in inflammatory responses to skin injury.

UV RADIATION (UVR) AND SKIN

The epidermis and the dermis contain several chromophores capable of interacting with incident solar energy. These interactions include reflection, refraction, absorption, and transmission. The stratum corneum is a major impediment to the transmission ofUV-B, and less than 10% of incident wavelengths in this region penetrate the basement membrane. Approximately 3% of radiation below 300 nm, 20% of radiation below 360 nm, and 33% of short visible radiation reaches the basal cell layer in untanned human skin. Proteins and nucleic acids absorb intensely in the short UV-B. In contrast, UV-A 1 and 2 penetrate the epidermis efficiently to reach the dermis, where they likely produce

changes in structural and matrix proteins that contribute to the aged appearance of chronically sun-exposed skin, particularly in individuals of light complexion.

One of the consequences ofUV-B absorption by DNA is the production of pyrimidine dimers. These structural changes can be repaired by mechanisms that result in their recognition and excision, and the reestablishment of normal base sequences. The efficient repair of these structural aberrations is crucial, since individuals with defective DNA repair are at high risk for the development of cutaneous cancer. For example, patients with xeroderma pigmentosum, an autosomal recessive disorder, are characterized by variably decreased repair of UV-induced photoproducts, and their skin may develop the xerotic appearance of photoaging as well as basal cell and squamous cell carcinomas and melanoma in the first two decades of life. Studies in mice using knockout gene technology have verified the importance of genes regulating these repair pathways in preventing the development of UV-induced cancer.

Cutaneous Optics and Chromophores Chromophores are endogenous or exogenous chemical components that can absorb physical energy. Endogenous chromophores of skin are of two types: (1) chemicals that are normally present, including nucleic acids, proteins, lipids, and 7-dehydrocholesterol, the precursor of vitamin D; and (2) chemicals, such as porphyrins, synthesized elsewhere in the body that circulate in the bloodstream and diffuse into the skin. Normally, only trace amounts of porphyrins are present in the skin, but in the diseases known as the porphyrias, increased amounts are released into the circulation and are transported to the skin, where they absorb incident energy both in the Soret band around 400 nm (short visible) and to a lesser extent in the red portion of the visible spectrum (580 to 660 nm). This results in structural damage to the skin that may be manifest as erythema, edema, urticaria, or blister formation (Chap. 346).

Acute Effects of Sun Exposure The immediate cutaneous consequences of sun exposure include sunburn and vitamin D synthesis.

Sunburn This very common affliction of human skin is caused by exposure toUVR. Generally speaking, the individual's ability to tolerate sunlight is inversely proportional to his or her melanin pigmentation. Melanin is a complex polymer of tyrosine that functions as an efficient neutral-density filter with broad absorbance within theUVportion of the solar spectrum. Melanin is synthesized in specialized epidermal dendritic cells termed *melanocytes* and is packaged into *melanosomes* that are transferred via dendritic processes into *keratinocytes*, where they provide photoprotection. Sun-induced melanogenesis is a consequence of increased tyrosinase activity in melanocytes that in turn may be due to a combination of eicosanoid and endothelin-1 release. Tolerance of sun exposure is a function of the efficiency of the epidermal-melanin unit and can usually be ascertained by asking an individual two questions: (1) Do you burn after sun exposure? and (2) Do you tan after sun exposure? By the answers to these questions, it is usually possible to divide the population into six skin types varying from type I (always burn, never tan) to type VI (never burn, always tan) (Table 60-1).

There are two general theories about the pathogenesis of the sunburn response. First, the lag phase in time between skin exposure and the development of visible redness (usually 4 to 12 h) suggests an epidermal chromophore that causes delayed production and/or release of vasoactive mediator(s), or cytokines, that diffuse to the dermal

vasculature to evoke vasodilatation. Indeed,UVRstimulates the release of numerous proinflammatory cytokines and nitric oxide by keratinocytes. Second, it is possible that the small amount of incidentUV-B radiation (10% or less) that penetrates to the dermis can be absorbed directly by endothelial cells in the vasculature, thereby resulting in vasodilatation. The issue remains unresolved.

The action spectrum for sunburn erythema includes theUV-B and UV-A regions. Photons in the shorter UV-B are at least 1000-fold more efficient than photons in the longer UV-B and the UV-A in evoking the response. However, UV-A may contribute to sunburn erythema at midday when much more UV-A than UV-B is present.

The mechanism of injury remains poorly defined, but the action spectrum forUV-B erythema closely resembles the absorption spectrum for DNA after adjusting for the absorbance of incident energy by the stratum corneum. Apoptotic keratinocytes (so-called sunburn cells) are visible histologically within an hour of exposure and are maximal within 24 h. UV-A is less effective than UV-B in producing sunburn cells. Mast cells may release inflammatory mediators after exposure to UV-B and UV-A. For example, erythema doses of both UV-B and UV-A increase histamine levels in experimentally induced suction blisters of human skin that return to normal after 24 h (before visible erythema has subsided). Prostaglandin E_2increases to approximately 150% of control levels after 24 h and then diminishes. Since prostaglandins evoke both pain and redness when injected intradermally, their presence in suction blisters after UV-B exposure suggests a role in UV-B erythema. Age-related declines occur in the amount of inflammatory mediators detectable in human skin after UV-B irradiation. UV-A erythema results in few epidermal sunburn cells, but vascular endothelial injury is greater than with UV-B. In addition, there are increased levels of arachidonic acid and of prostaglandins D_2, E_2, and I_2 that peak within 5 to 9 h and then subside before peak redness occurs. Despite evidence for the role of prostaglandins in both UV-B- and UV-A-irradiated skin, administration of nonsteroidal anti-inflammatory drugs is more effective in reducing erythema evoked by UV-B than by UV-A. UV-B also induces cutaneous matrix-degrading metalloproteinases within hours of exposure.

Vitamin D Photochemistry Cutaneous exposure toUV-B causes photolysis of epidermal previtamin D_3(7-dehydrocholesterol) to previtamin D_3, which then undergoes a temperature-dependent isomerization to form the stable hormone vitamin D_3. This compound then diffuses to the dermal vasculature and circulates systemically where it is converted to the functional hormone 1,25-dihydroxy vitamin D_3[$1,25(OH)_2D_3$]. Vitamin D metabolites from the circulation or those produced in the skin itself can augment epidermal differentiation signaling. Aging substantially decreases the ability of human skin to produce vitamin D_3. This, coupled with the widespread use of sunscreens that filter outUV-B, has led to concern that vitamin D deficiency may become a significant clinical problem in the elderly. Indeed, studies have shown that the use of sunscreens can diminish the production of vitamin D_3 in human skin.

Chronic Effects of Sun Exposure: Nonmalignant The clinical features of photodamaged sun-exposed skin consist of wrinkling, blotchiness, telangiectasia, and a roughened, irregular, "weather-beaten" appearance. Whether these changes, which some refer to as *photoaging* or *dermatoheliosis*, represent accelerated chronologic aging or a separate and distinct process is not clear.

Within chronically sun-exposed epidermis, there is thickening (acanthosis) and morphologic heterogeneity within the basal cell layer. Higher but irregular melanosome content may be present in some keratinocytes, indicating prolonged residence of the cells in the basal cell layer. These structural changes may help to explain the leathery texture and the blotchy discoloration of sun-damaged skin.

The dermis is the major site for sun-associated chronic damage, manifest as a massive increase in thickened irregular masses of tangled elastic fibers resulting from enhanced expression of elastin genes. Collagen fibers are also abnormally clumped in the deeper dermis. Fibroblasts are increased in number and show morphologic signs suggesting activation. Degraded mast cells may be present in the dermis, the relevance of which remains unclear.

These morphologic changes, both gross and microscopic, are features of chronically sun-exposed skin. The chromophore(s), the action spectra, and the specific biochemical events orchestrating these changes are unknown.

Chronic Effects of Sun Exposure: Malignant One of the major known consequences of chronic skin exposure to sunlight is nonmelanoma skin cancer. The two types of nonmelanoma skin cancer are basal cell and squamous cell carcinoma (Chap. 86). There are three major steps for cancer induction: initiation, promotion, and progression. Chronic exposure of animal skin to artificial light sources that mimic solarUVRresults in *initiation*, a step whereby structural (mutagenic) changes in DNA evoke an irreversible alteration in the target cell (keratinocyte) that begins the tumorigenic process. Exposure to a tumor initiator is believed to be a necessary but not sufficient step in the malignant process, since initiated skin cells not exposed to tumor promoters do not generally develop tumors. The second stage in tumor development is *promotion*, a multistep process whereby initiated cells are exposed to chemical and physical agents that evoke epigenetic changes that culminate in the clonal expansion of initiated cells and cause the development, over a period of weeks to months, of benign growths known as *papillomas*. Again, using transgenic animals, the importance ofUVeffects on the expression of additional oncogenes such as *fos* and *jun* in developing papillomas has been demonstrated. UV-B is a *complete carcinogen*, meaning that it can function as both an initiator and a promoter, leading to tumor induction. *Incomplete carcinogens* can initiate tumorigenesis but require additional skin exposure to tumor promoters to elicit tumors. The prototype tumor promoter is the phorbol ester 12-*O*-tetradecanoyl phorbol-13-acetate. Tumor promotion usually requires multiple exposures over time to evoke a neoplasm.

The final step in the malignant process is the conversion of benign precursors into malignant lesions, a process thought to require additional genetic alterations in already transformed cells. Indeed, *ras* gene mutations have been detected in a minority of human nonmelanoma skin cancers. Mutations of the tumor suppressor gene p53 also occur in sun-damaged human skin.

Sun exposure causes nonmelanoma and melanoma cancers of the skin, although the evidence is far more direct for its role in nonmelanoma (basal cell and squamous cell carcinoma) than in melanoma. Approximately 80% of nonmelanoma skin cancers

develop on exposed body area, including the face, the neck, and the hands. Men of fair complexion who work outdoors are twice as likely as women to develop these types of cancers. Whites of darker complexions (e.g., Hispanics) have one-tenth the risk of developing such cancers as do light-skinned individuals. Blacks are at lowest risk for all forms of skin cancer. Between 600,000 and 800,000 individuals in the United States develop nonmelanoma skin cancer annually, and the lifetime risk for a white individual to develop such a neoplasm is estimated at approximately 15%. A consensus exists that the incidence of nonmelanoma skin cancer in the population is rising, for reasons that are unclear.

The relationship of sun exposure to melanoma is less clear-cut, but suggestive evidence supports an association. Melanomas occasionally develop by the teenage years, indicating that the latent period for tumor growth is less than that of nonmelanoma skin cancer. Melanomas are among the most rapidly increasing of all human malignancies (Chap. 86). Epidemiologic studies of immigrants of similar ethnic stock indicate that individuals born in one area or who migrated to the same locale before age 10 have higher age-specific melanoma rates than individuals arriving later. It is thus reasonable to conclude that life in a sunny climate from birth or early childhood increases the risk of melanoma. In general, risk does not correlate with cumulative sun exposure but may relate to sequelae of sun exposure in childhood. Thus, a blistering sunburn is associated with a doubling of melanoma risk at the site of the reaction.

Immunologic Effects Exposure to solar radiation influences both local and systemic immune responses.UV-B appears to be most efficient in altering immune responses, likely related to the capacity of such energy to affect antigen presentation in skin by interacting with epidermal Langerhans cells. These bone marrow-derived dendritic cells possess surface markers characteristic of monocytes and macrophages. Following skin exposure to erythema doses of UV-B, Langerhans cells undergo both morphologic and functional changes that result in decreased contact allergic responses when haptens are applied to the irradiated site. This diminished capacity for sensitization is due to the induction of antigen-specific suppressor T lymphocytes. Indeed, while the immunosuppressive effect of irradiation is limited to haptens applied to the irradiated site, the net result is systemic immune suppression to that antigen because of the induction of suppressor T cells.

Higher doses of radiation evoke diminished immunologic responses to antigens introduced either epicutaneously or intracutaneously at sites distant from the irradiated site. These suppressed responses are also associated with the induction of antigen-specific suppressor T lymphocytes and may be mediated by as yet undefined factors that are released from epidermal cells at the irradiated site. The implications of this generalized immune suppression in terms of altered susceptibility to cutaneous cancer or to infection remain to be defined.

It is known thatUV-induced tumors in murine skin are antigenic and are rapidly rejected when transplanted into normal syngeneic animals. If the tumors are transplanted into animals previously exposed to subcarcinogenic doses of UV-B, they are not rejected and instead grow progressively in the recipients. This failure of irradiated animals to reject the transplanted tumors is due to the development of T suppressor cells that prevent the rejection response. While the mechanism of suppression of tumor rejection

is unknown, such a response might be a critical determinant of cancer risk in human skin.

PHOTOSENSITIVITY DISEASES

The diagnosis of photosensitivity requires a careful history to define the duration of the signs and symptoms, the length of time between exposure to sunlight and the development of subjective complaints, and visible changes in the skin. The age of onset also can be a helpful clue; for example, the acute photosensitivity of erythropoietic protoporphyria almost always begins in childhood, whereas the chronic photosensitivity of porphyria cutanea tarda typically begins in the fourth and fifth decades. A history of exposure to topical and systemic drugs and chemicals may provide important information. Many classes of drugs can cause photosensitivity on the basis of either phototoxicity or photoallergy. Fragrances such as musk ambrette that were previously present in numerous cosmetic products are also potent photosensitizers.

Examination of the skin may also offer important clues. Anatomic areas that are naturally protected from direct sunlight such as the hairy scalp, the upper eyelids, the retroauricular areas, and the infranasal and submental regions may be spared, whereas exposed areas show characteristic features of the pathologic process. These anatomic localization patterns are often helpful but not infallible in making the diagnosis. For example, airborne contact sensitizers that are blown onto the skin may produce dermatitis that can be difficult to distinguish from photosensitivity, despite the fact that such material may trigger skin reactivity in areas shielded from direct sunlight.

Many dermatologic conditions may be caused or aggravated by light (Table 60-2). The role of light in evoking these responses may be dependent on genetic abnormalities ranging from well-described defects in DNA repair that occur in xeroderma pigmentosum to the inherited abnormalities in heme synthesis that characterize the porphyrias. In certain photosensitivity diseases, the chromophore has been identified, whereas in the majority, the energy-absorbing agent is unknown.

Polymorphous Light Eruption After sunburn, the most common type of photosensitivity disease is *polymorphous light eruption*, the mechanism of which is unknown. Many affected individuals never seek medical attention because the condition is often transient, becoming manifest each spring with initial sun exposure but then subsiding spontaneously with continuing exposure, a phenomenon known as "hardening." The major manifestations of polymorphous light eruption include pruritic (often intensely so) erythematous papules that may coalesce into plaques on exposed areas of the face and arms or other areas as well, making the distribution spotty and uneven.

The diagnosis can be confirmed by skin biopsy and by performing phototest procedures in which skin is exposed to multiple erythema doses ofUV-A and UV-B. The action spectrum for polymorphous light eruption is usually within these portions of the solar spectrum.

Treatment of this disease includes the induction of hardening by the cautious administration ofUVlight, either alone or in combination with photosensitizers such as

the psoralens (see below).

Phototoxicity and Photoallergy These photosensitivity disorders are related to the topical or systemic administration of drugs and other chemicals. Both reactions require the absorption of energy by a drug or chemical resulting in the production of an excited-state photosensitizer that can transfer its absorbed energy to a bystander molecule or to molecular oxygen, thereby generating tissue-destructive chemical species.

Phototoxicity is a nonimmunologic reaction caused by drugs and chemicals, a few of which are listed in Table 60-3. The usual clinical manifestations include erythema resembling a sunburn that quickly desquamates or "peels" within several days. In addition, edema, vesicles, and bullae may occur.

Photoallergy is distinct in that the immune system participates in the pathologic process. The excited-state photosensitizer may create highly unstable haptenic free radicals that bind covalently to macromolecules to form a functional antigen capable of evoking a delayed hypersensitivity response. Some of the drugs and chemicals that produce photoallergy are listed in Table 60-4. The clinical manifestations typically differ from those of phototoxicity in that an intensely pruritic eczematous dermatitis tends to predominate and evolves into lichenified, thickened, "leathery" changes in sun-exposed areas. A small subset (perhaps 5 to 10%) of patients with photoallergy may develop a persistent exquisite hypersensitivity to light even when the offending drug or chemical is identified and eliminated. Known as *persistent light reaction*, this may be incapacitating for years. Some have used the term *chronic actinic dermatitis* to encompass these chronic hyperresponsive states.

Diagnostic confirmation of phototoxicity and photoallergy often can be obtained using phototest procedures. In patients with suspected phototoxicity, determination of the minimal erythema dose (MED) while the patient is exposed to a suspected agent and then repeating the MED after discontinuation of the agent may provide a clue to the causative drug or chemical. Photopatch testing can be performed to confirm the diagnosis of photoallergy. This is a simple variant of ordinary patch testing in which a series of known photoallergens is applied to the skin in duplicate and one set is irradiated with a suberythema dose ofUV-A. Development of eczematous changes at sites exposed to sensitizer and light is a positive result. The characteristic abnormality in patients with persistent light reaction is a diminished threshold to erythema evoked by UV-B. Patients with chronic actinic dermatitis may have a broad spectrum of UV hyperresponsiveness.

The management of drug photosensitivity is first and foremost to eliminate exposure to the chemical agents responsible for the reaction and to minimize sun exposure. The acute symptoms of phototoxicity may be ameliorated by cool, moist compresses, topical glucocorticoids, and systemically administered nonsteroidal antiinflammatory agents. In severely affected individuals, a rapidly tapered course of systemic glucocorticoids may be useful. Judicious use of analgesics may be necessary.

Photoallergic reactions require a similar management approach. Furthermore, individuals suffering from persistent light reactivity must be meticulously protected

against light exposure. In selected patients in whom chronic systemic high-dose glucocorticoids pose unacceptable risks, it may be necessary to employ cytotoxic agents such as azathioprine or cyclophosphamide.

Porphyria The porphyrias (Chap. 346) are a group of diseases that have in common various derangements in the synthesis of heme. Heme is an iron-chelated tetrapyrrole or porphyrin, and the nonmetal chelated porphyrins are potent photosensitizers that absorb light intensely in both the short (400 to 410 nm) and the long (580 to 650 nm) portions of the visible spectrum.

Heme cannot be reutilized and must be continuously synthesized, and the two body compartments with the largest capacity for its production are the bone marrow and the liver. Accordingly, the porphyrias originate in one or the other of these organs, with the end result of excessive endogenous production of potent photosensitizing porphyrins. The porphyrins circulate in the bloodstream and diffuse into the skin, where they absorb solar energy, become photoexcited, and evoke cutaneous photosensitivity. The mechanism of porphyrin photosensitization is known to be photodynamic or oxygen-dependent and is mediated by reactive oxygen species such as superoxide anions.

Porphyria cutanea tarda is the most common type of human porphyria and is associated with decreased activity of the enzyme uroporphyrinogen decarboxylase associated with a number of gene mutations. There are two basic types of porphyria cutanea tarda: the sporadic or acquired type, generally seen in individuals ingesting ethanol or receiving estrogens; and the inherited type, in which there is autosomal dominant transmission of deficient enzyme activity. Both forms are associated with increased hepatic iron stores.

In both types of porphyria cutanea tarda, the predominant feature is a chronic photosensitivity characterized by increased fragility of sun-exposed skin, particularly areas subject to repeated trauma such as the dorsa of the hands, the forearms, the face, and the ears. The predominant skin lesions are vesicles and bullae that rupture, producing moist erosions, often with a hemorrhagic base, that heal slowly with crusting and purplish discoloration of the affected skin. Hypertrichosis, mottled pigmentary change, and scleroderma-like induration are associated features. Biochemical confirmation of the diagnosis can be obtained by measurement of urinary porphyrin excretion, plasma porphyrin assay, and by assay of erythrocyte and/or hepatic uroporphyrinogen decarboxylase. Multiple mutations of the uroporphyrinogen decarboxylase gene have been identified in human populations, including exon skipping and base substitutions.

Treatment consists of repeated phlebotomies to diminish the excessive hepatic iron stores and/or intermittent low doses of the antimalarial drugs chloroquine and hydroxychloroquine. Long-term remission of the disease can be achieved if the patient eliminates exposure to porphyrinogenic agents.

Erythropoietic protoporphyria originates in the bone marrow and is due to a decrease in the mitochondrial enzyme ferrochelatase secondary to numerous gene mutations. The major clinical features include an acute photosensitivity characterized by subjective burning and stinging of exposed skin that often develops during or just after exposure.

There may be associated skin swelling and, after repeated episodes, a waxlike scarring.

The diagnosis is confirmed by demonstration of measurement of free elevated erythrocyte protoporphyrin. Detection of increased plasma protoporphyrin helps to differentiate lead poisoning and iron-deficiency anemia, in both of which elevated erythrocyte protoporphyrin occurs in the absence of cutaneous photosensitivity and of elevated plasma protoporphyrin.

Treatment consists of reducing sun exposure and the oral administration of the carotenoidb-carotene, which is an effective scavenger of free radicals. This drug increases tolerance to sun exposure in many affected individuals, although it has no effect on deficient ferrochelatase.

An algorithm for the approach to a patient with photosensitivity is illustrated inFig. 60-1.

PHOTOPROTECTION

Since photosensitivity of the skin results from exposure to sunlight, it follows that avoidance of the sun would eliminate these disorders. Unfortunately, social pressures make this an impractical alternative for most individuals, and this has led to a search for better approaches to photoprotection.

Natural photoprotection is provided by structural proteins in the epidermis, particularly keratins and melanin. The amount of melanin and its distribution in cells is genetically regulated, and individuals of darker complexion (skin types IV to VI) are at decreased risk for the development of cutaneous malignancy.

Other forms of photoprotection include clothing and sunscreens. Clothing constructed of tightly woven sun-protective fabrics, irrespective of color, affords substantial protection. Wide-brimmed hats, long sleeves, and trousers all reduce direct exposure. Sunscreens are of two major types -- chemical and physical. Chemical sunscreens are chromophores that absorb energy in theUV-B and/or UV-A regions, thereby diminishing photon absorption by the skin (Table 60-5). Sunscreens are rated for their photoprotective effect by their *sun protective factor* (SPF). The SPF is simply a ratio of the time required to produce sunburn erythema with and without sunscreen application. SPF ratings of 15 or higher provide effective protection against UV-B and, to a lesser extent, UV-A. The major categories of chemical sunscreens include *p*-aminobenzoic acid and its esters, benzophenones, anthranilates, cinnamates, and salicylates. Physical sunscreens are light-opaque mixtures containing metal particles such as titanium oxide and zinc oxide that scatter light, thereby reducing photon absorption by the skin.

In addition to light absorption, a critical determinant of the photoprotective effect of sunscreens is their ability to remain on the skin, a property known as *substantivity*. In general, the *p*-aminobenzoic acid esters formulated in moisturizing vehicles provide the greatest substantivity.

Photoprotection can also be achieved by limiting the time of exposure during the day. Since the majority of an individual's total lifetime sun exposure may occur by the age of

18, it is important to educate parents and young children about the hazards of sunlight. Simply eliminating exposure at midday will substantially reduce lifetimeUV-B exposure.

PHOTOTHERAPY AND PHOTOCHEMOTHERAPY

UVRcan also be used therapeutically. The administration ofUV-B alone or in combination with topically applied agents can induce remissions of psoriasis and atopic dermatitis.

Photochemotherapy in which topically applied or systemically administered *psoralens* are combined withUV-A (PUVA) is also effective in treating psoriasis and in the early stages of cutaneous T cell lymphoma and vitiligo. Psoralens are tricyclic furocoumarins that, when intercalated into DNA and exposed to UV-A, form adducts with pyrimidine bases and eventually form DNA cross-links. These structural changes are thought to decrease DNA synthesis and relate to improvement that occurs in psoriasis. The reason that PUVA photochemotherapy is effective in cutaneous T cell lymphoma is not clear.

In addition to its effects on DNA, PUVA photochemotherapy also stimulates melanin synthesis, and this provides the rationale for its use in the depigmenting disease vitiligo. Oral 8-methoxypsoralen andUV-A appear to be most effective in this regard, but as many as 100 treatments extending over 12 to 18 months may be required to promote satisfactory repigmentation.

The major side effects ofUV-B phototherapy and PUVA photochemotherapy are due to the cumulative effects of photon absorption and include skin dryness, actinic keratoses, and an increased risk of nonmelanoma skin cancer. Despite these risks, the therapeutic index of these modalities is quite acceptable.

SECTION 10 -HEMATOLOGIC ALTERATIONS

61. ANEMIA AND POLYCYTHEMIA - *John W. Adamson*, *Dan L. Longo*

HEMATOPOIESIS AND THE PHYSIOLOGIC BASIS OF RED CELL PRODUCTION

Hematopoiesis is the process by which the formed elements of the blood are produced. The process is regulated through a series of steps beginning with the pluripotent hematopoietic stem cell. Stem cells are capable of producing red cells, all classes of granulocytes, monocytes, platelets, and the cells of the immune system. Commitment of the stem cell to the specific cell lineages appears not to be regulated by known exogenous growth factors or cytokines. Rather, stem cells develop into differentiated cell types through incompletely defined molecular events that are intrinsic to the stem cell itself (Chap. 104). Following lineage commitment (or differentiation), hematopoietic progenitor and precursor cells come increasingly under the regulatory influence of growth factors and hormones, such as erythropoietin (EPO) for red cell production. EPO is required for the maintenance of committed erythroid progenitor cells which, in the absence of the hormone, undergo programmed cell death (*apoptosis*). The regulated process of red cell production is *erythropoiesis*, and its key elements are illustrated in Fig. 61-1.

In the bone marrow, the first morphologically recognizable erythroid precursor is the pronormoblast. This cell can undergo 4 to 5 cell divisions that result in the production of 16 to 32 mature red cells. With increasedEPOproduction, or the administration of EPO as a drug, early progenitor cell numbers are amplified and, in turn, give rise to increased numbers of erythrocytes. The regulation of EPO production itself is linked to O_2transport.

In mammals, O_2 is transported to tissues bound to the hemoglobin contained within circulating red cells. The mature red cell is 8um in diameter, anucleate, discoid in shape, and extremely pliable in order for it to traverse the microcirculation successfully; its membrane integrity is maintained by the intracellular generation of ATP. Normal red cell production results in the daily replacement of 0.8 to 1% of all circulating red cells in the body. The average red cell lives 100 to 120 days. The machinery responsible for red cell production is called the *erythron*. The erythron is a dynamic organ made up of a rapidly proliferating pool of marrow erythroid precursor cells and a large mass of mature circulating red blood cells. The size of the red cell mass reflects the balance of red cell production and destruction. The physiologic basis of red cell production and destruction provides an understanding of the mechanisms that can lead to anemia.

The physiologic regulator of red cell production, the glycoprotein hormoneEPO, is produced and released by peritubular capillary lining cells within the kidney. These cells are highly specialized epithelial-like cells. A small amount of EPO is produced by hepatocytes. The fundamental stimulus for EPO production is the availability of O_2 for tissue metabolic needs. Impaired O_2delivery to the kidney can result from a decreased red cell mass (*anemia*), impaired O_2loading of the hemoglobin molecule (*hypoxemia*), or, rarely, impaired blood flow to the kidney (renal artery stenosis). EPO governs the day-to-day production of red cells, and ambient levels of the hormone can be measured in the plasma by sensitive immunoassays -- the normal level being 10 to 25 U/L. When

the hemoglobin concentration falls below 100 to 120 g/L (10 to 12 g/dL), plasma EPO levels increase logarithmically in inverse proportion to the severity of the anemia. In circulation, EPO has a half-clearance time of 6 to 9 h. EPO acts by binding to specific receptors on the surface of marrow erythroid precursors, inducing them to proliferate and to mature. Under the stimulus of EPO, red blood cell production can increase four- to fivefold within a 1- to 2-week period but only in the presence of adequate nutrients, especially iron. The functional capacity of the erythron, therefore, requires normal renal production of EPO, a functioning erythroid marrow, and an adequate supply of substrates for hemoglobin synthesis. A defect in any of these key components can lead to anemia. Generally, anemia is recognized in the laboratory when a patient's hemoglobin level or hematocrit is reduced below an expected value (the normal range). The likelihood and severity of anemia are defined based on the deviation of the patient's hemoglobin/hematocrit from values expected for age- and sex-matched normal subjects. The lower ranges of distribution of hemoglobin/hematocrit values for adult males and females are shown in Fig. 61-2. The hemoglobin concentration in adults has a Gaussian distribution. The mean hematocrit value for adult males is 47% (± SD 7) and that for adult females is 42% (± 5). Any individual hematocrit or hemoglobin value carries with it a likelihood of associated anemia. Thus, a hematocrit of£39% in an adult male or<35% in an adult female has only about a 25% chance of being normal. Suspected low hemoglobin or hematocrit values are more easily interpreted if there are historic values for the same patient for comparison.

The critical elements of erythropoiesis -- EPOproduction, iron availability, the proliferative capacity of the bone marrow, and effective maturation of red cell precursors -- are used for the initial classification of anemia (see "Definition and Classification, below).

ANEMIA

CLINICAL PRESENTATION OF ANEMIA

Signs and Symptoms Anemia is most often recognized by abnormal screening laboratory tests. Patients only occasionally present with advanced anemia and its attendant signs and symptoms. Acute anemia is nearly always due to blood loss or hemolysis. In fact, with acute blood loss, hypovolemia dominates the clinical picture and the hematocrit and hemoglobin levels do not reflect the volume of blood lost. Signs of vascular instability dominate with acute losses of 10 to 15% of the total blood volume. In such patients, the issue is not anemia but hypotension and decreased organ perfusion. When>30% of the blood volume is lost suddenly, patients are unable to compensate with the usual mechanisms of vascular contraction and changes in regional blood flow. The patient prefers to remain supine and will show postural hypotension and tachycardia if upright. If the volume of blood lost is >40% (i.e., >2 L in the average-sized adult), signs of hypovolemic shock including confusion, air hunger, diaphoresis, hypotension, and tachycardia appear (Chap. 108). Such patients have significant deficits in vital organ perfusion and require immediate volume replacement. With mild blood loss, enhanced O_2delivery is achieved through changes in the O_2-hemoglobin dissociation curve mediated by a decreased pH or increased CO_2(*Bohr effect*).

With acute hemolytic disease, the signs and symptoms depend on the mechanism that

leads to red cell destruction. Intravascular hemolysis with release of free hemoglobin may be associated with acute back pain, free hemoglobin in the plasma and urine, and renal failure. Symptoms associated with more chronic or progressive anemia depend on the age of the patient and the adequacy of blood supply to critical organs. Symptoms associated with moderate anemia include fatigue, loss of stamina, breathlessness, and tachycardia (particularly with physical exertion). However, because of the intrinsic compensatory mechanisms that govern the O_2-hemoglobin dissociation curve, the gradual onset of anemia -- particularly in young patients -- may not be associated with signs or symptoms until the anemia is severe [hemoglobin <70 to 80 g/L (7 to 8 g/dL)]. When anemia develops over a period of days or weeks, the total blood volume is normal to slightly increased and changes in cardiac output and regional blood flow help compensate for the overall loss in O_2-carrying capacity. Changes in the position of the O_2-hemoglobin dissociation curve account for some of the compensatory response to anemia. With chronic anemia, intracellular levels of 2,3-bisphosphoglycerate (BPG) rise, shifting the dissociation curve to the right and facilitating O_2unloading. This compensatory mechanism can only maintain normal tissue O_2delivery in the face of a 20 to 30 g/L (2 to 3 g/dL) deficit in hemoglobin concentration. Finally, further protection of O_2delivery to vital organs is achieved by the shunting of blood away from organs that are relatively rich in blood supply, particularly the kidney, gut, and skin.

Certain disorders are commonly associated with anemia. Chronic inflammatory states (e.g., infection, rheumatoid arthritis) are associated with mild to moderate anemia, whereas lymphoproliferative disorders, such as chronic lymphocytic leukemia and certain other B cell neoplasms, may be associated with autoimmune hemolysis.

Approach to the Patient

The evaluation of the patient with anemia requires a careful history and physical examination. Historic information that may be useful includes exposure to certain toxic agents or drugs and symptoms related to other disorders commonly associated with anemia. These include symptoms and signs such as bleeding, fatigue, malaise, fever, weight loss, night sweats, and other systemic symptoms. Clues to the mechanisms of anemia may be provided on physical examination by findings of infection, blood in the stool, lymphadenopathy, splenomegaly, or petechiae. Splenomegaly and lymphadenopathy suggest an underlying lymphoproliferative disease, while petechiae suggest platelet dysfunction. If it is uncertain whether a mild anemia represents an extreme normal value or an abnormal finding, past laboratory measurements may be helpful. Nutritional history related to drugs or alcohol intake and family history of anemia should always be assessed. Certain geographic backgrounds and ethnic origins are associated with an increased likelihood of an inherited disorder of the hemoglobin molecule or intermediary metabolism. Glucose-6-phosphate dehydrogenase deficiency and certain hemoglobinopathies are seen more commonly in those of middle-Eastern or African origin.

In the anemic patient, physical examination may demonstrate a forceful heartbeat, strong peripheral pulses, and a systolic "flow" murmur. The skin and mucous membranes may be pale if the hemoglobin is <80 to 100 g/L (8 to 10 g/dL). This part of the physical examination should focus on areas where vessels are close to the surface such as the mucous membranes, nail beds, and palmar creases. If the palmar creases

are lighter in color than the surrounding skin when the hand is hyperextended, the hemoglobin level is usually<80 g/L (8 g/dL).

Laboratory Evaluation Table 61-1 lists the tests used in the initial workup of anemia. A routine complete blood count (CBC) is required as part of the evaluation and includes the hemoglobin, hematocrit, and red cell indices: the mean cell volume (MCV) in femtoliters, mean cell hemoglobin (MCH) in picograms per cell, and mean concentration of hemoglobin per volume of red cells (MCHC) in grams per liter (non-SI: grams per deciliter). The red cell indices are calculated as shown in Table 61-2, and the normal variations in the CBC with age are shown in Table A-7. A number of physiologic factors affect the normal CBC values including age, gender, pregnancy, smoking, and altitude. High-normal hemoglobin values may be seen in men and women who live at altitude or smoke heavily. The elevations in smokers reflect normal compensation due to the displacement of O_2 by CO in hemoglobin binding. Other important information is provided by the reticulocyte count and measurements of iron supply including the *serum iron*, the *total iron-binding capacity* (TIBC; an indirect measure of the transferrin level), and *serum ferritin*. Marked alterations in the red cell indices usually reflect disorders of maturation or iron deficiency. Clinical laboratories also provide a description of both the red and white cells, a white cell differential count, and the platelet count. In patients with severe anemia and abnormalities in red blood cell morphology, a bone marrow aspirate or biopsy may be important to assist in the diagnosis. Other tests of value in the diagnosis of specific anemias are discussed in chapters on specific disease states.

The components of theCBC also help in the classification of anemia. *Microcytosis* is reflected by a lower than normalMCV(<80), whereas high values (>100) reflect *macrocytosis*. TheMCH andMCHCreflect defects in hemoglobin synthesis (*hypochromia*). Automated cell counters describe the red cell volume distribution width (RDW). The MCV (representing the peak of the distribution curve) is insensitive to the appearance of small populations of macrocytes or microcytes. An experienced laboratory technician will be able to identify minor populations of large or small cells or hypochromic cells before the red cell indices change.

PERIPHERAL BLOOD SMEAR The peripheral blood smear provides important information about defects in red cell production. As a complement to the red cell indices, the blood smear also reveals variations in cell size (*anisocytosis*) and shape (*poikilocytosis*). The degree of anisocytosis usually correlates with increases in theRDW or the range of cell sizes. Poikilocytosis suggests a defect in the maturation of red cell precursors in the bone marrow or fragmentation of circulating red cells. The blood smear may also reveal *polychromasia* -- red cells that are slightly larger than normal and grayish blue in color on the Wright-Giemsa stain. These cells are reticulocytes that have been prematurely released from the bone marrow, and their color represents residual amounts of ribosomal RNA. These cells appear in circulation in response toEPOstimulation or to architectural damage of the bone marrow (fibrosis, infiltration of the marrow by malignant cells, etc.) that results in their disordered release from the marrow. The appearance of nucleated red cells, Howell-Jolly bodies, target cells, sickle cells, and others may provide clues to specific disorders (see Plates V-2,V-3,V-8,V-9,V-16,V-21,V-24,V-26,V-27,V-28, andV-39).

RETICULOCYTE COUNT An accurate reticulocyte count is key to the initial

classification of anemia. Normally, reticulocytes are red cells that have been recently released from the bone marrow. They are identified by staining with a supravital dye that precipitates the residual ribosomal RNA. These precipitates appear as blue or black punctate spots. This residual RNA is metabolized over the first 24 to 36 h of the reticulocyte's lifespan in circulation. Normally, the reticulocyte count ranges from 1 to 2% and reflects the daily replacement of 0.8 to 1.0% of the circulating red cell population. A correctly interpreted reticulocyte count provides a reliable measure of red cell production.

In the initial classification of anemia, the patient's reticulocyte count is compared with the expected reticulocyte response. In general, if theEPO and erythroid marrow responses to moderate anemia [hemoglobin<100 g/L (10 g/dL)] are intact, the red cell production rate increases to two to three times normal within 10 days following the onset of anemia. In the face of established anemia, a reticulocyte response less than two to three times normal indicates an inadequate marrow response.

In order to use the reticulocyte count to estimate marrow response, two corrections are necessary. The first correction adjusts the reticulocyte count based on the reduced number of circulating red cells. With anemia, the percentage of reticulocytes may be increased while the absolute number is unchanged. To correct for this effect, the reticulocyte percentage is multiplied by the ratio of the patient's hemoglobin or hematocrit to the expected hemoglobin/hematocrit for the age and gender of the patient (Table 61-3). This provides an estimate of the absolute reticulocyte count. In order to convert the corrected reticulocyte count to an index of marrow production, a further correction is required, depending on whether some of the reticulocytes in circulation have been released from the marrow prematurely. For this second correction, the peripheral blood smear is examined to see if there are polychromatophilic macrocytes present. These cells, representing prematurely released reticulocytes, are referred to as "shift" cells, and the relationship between the degree of shift (and the necessary shift correction factor) is shown in Fig. 61-3. The correction is necessary because these prematurely released cells survive as reticulocytes in circulation for>1 day, thereby providing a falsely high estimate of daily red cell production. If polychromasia is increased, the reticulocyte count, already corrected for anemia, should be divided again by a factor of 2 to account for the prolonged reticulocyte maturation time. The second correction factor varies from 1 to 3 depending upon the severity of anemia. In general, a correction of 2 is commonly used. An appropriate correction is shown inTable 61-3. If polychromatophilic cells are not seen on the blood smear, the second correction is not required. The now doubly corrected reticulocyte count is the *reticulocyte production index*, and it provides an estimate of marrow production relative to normal.

Premature release of reticulocytes is normally due to increasedEPOstimulation. However, if the integrity of the bone marrow release process is lost through tumor infiltration, fibrosis, or other disorders, the appearance of nucleated red cells or polychromatophilic macrocytes should still invoke the second reticulocyte correction. The shift correction should always be applied to a patient with anemia and a very high reticulocyte count to provide a true index of effective red cell production. Patients with severe chronic hemolytic anemia may increase red cell production as much as six- to sevenfold. This measure alone, therefore, confirms the fact that the patient has an appropriate EPO response, a normally functioning bone marrow, and sufficient iron

available to meet the demands for new red cell formation. If the reticulocyte production index is <2 in the face of established anemia, a defect in erythroid marrow proliferation or maturation must be present.

TESTS OF IRON SUPPLY AND STORAGE The laboratory measurements that reflect the availability of iron for hemoglobin synthesis include the serum iron, theTIBC, and the percent transferrin saturation. The percent transferrin saturation is derived by dividing the serum iron level (´ 100) by the TIBC. The normal serum iron ranges from 9 to 27 umol/L (50 to 150 ug/dL), while the normal TIBC is 54 to 64 umol/L (300 to 360 ug/dL); the transferrin saturation ranges from 25 to 50%. A diurnal variation in the serum iron leads to a variation in the percent transferrin saturation. The serum ferritin is used to evaluate total-body iron stores. Adult males have serum ferritin levels that average about 100 ug/L, corresponding to iron stores of about 1 g. Adult females have lower serum ferritin levels averaging 30 ug/L, reflecting lower iron stores. A serum ferritin level of 10 to 15 ug/L represents depletion of body iron stores. However, ferritin is also an acute-phase reactant and, in the presence of acute or chronic inflammation, may rise severalfold above baseline levels. As a rule, a serum ferritin >200 ug/L means there is at least some iron in tissue stores.

BONE MARROW EXAMINATION A bone marrow aspirate and smear or a needle biopsy may be useful in the diagnosis of a marrow disorder such as myelofibrosis, a red cell maturation defect, or an infiltrative disease (Plates V-5,V-13,V-14,V-15,V-19,V-29, andV-33). The increase or decrease of one cell lineage (myeloid vs. erythroid) compared to another is obtained by a differential count of nucleated cells in a bone marrow smear [the erythroid/granulocytic (E/G) ratio]. A patient with a hypoproliferative anemia (see below) and a reticulocyte production index<2 will demonstrate an E/G ratio of 1:2 or 1:3. In contrast, patients with hemolytic disease and a production index>3 will have an E/G ratio of at least 1:1. Maturation disorders are identified from the discrepancy between a high E/G ratio and a low reticulocyte production index (see below). Either the marrow smear or biopsy can be stained for the presence of iron stores or iron in developing red cells. The storage iron is in the form of *ferritin* or *hemosiderin*. On carefully prepared bone marrow smears, small ferritin granules can normally be seen in 10 to 20% of developing erythroblasts. Such cells are called *sideroblasts*.

OTHER LABORATORY MEASUREMENTS

Additional laboratory tests may be of value in confirming specific diagnoses.**For details of these tests and how they are applied in individual disorders, see Chaps. 105 to 109.*

DEFINITION AND CLASSIFICATION OF ANEMIA

Initial Classification of Anemia Classifying an anemia according to the functional defect in red cell production helps organize the subsequent use of laboratory studies. The three major classes of anemia are: (1) marrow production defects (*hypoproliferation*), (2) red cell maturation defects (*ineffective erythropoiesis*), and (3) decreased red cell survival (*blood loss/hemolysis*). This functional classification of anemia then guides the selection of specific clinical and laboratory studies designed to complete the differential diagnosis and to plan appropriate therapy. The classification is

shown in Fig. 61-4. A hypoproliferative anemia is typically seen with a low reticulocyte production index together with little or no change in red cell morphology (a normocytic, normochromic anemia) (Chap. 105). Maturation disorders typically have a slight to moderately elevated reticulocyte production index that is accompanied by either macrocytic (Chap. 107) or microcytic (Chaps. 105,106) red cell indices. Increased red blood cell destruction secondary to hemolysis results in an increase in the reticulocyte production index to at least three times normal (Chap. 108), provided sufficient iron is available for hemoglobin synthesis. Hemorrhagic anemia does not typically result in production indices of more than 2.5 times normal because of the limitations placed on expansion of the erythroid marrow by iron availability.

In the first branch point of the classification of anemia, a reticulocyte production index>2.5 indicates that hemolysis is most likely. A reticulocyte production index of <2 indicates either a hypoproliferative anemia or maturation disorder. The latter two possibilities can often be distinguished by the red cell indices, by examination of the peripheral blood smear, or by a marrow examination. If the red cell indices are normal, the anemia is almost certainly hypoproliferative in nature. Maturation disorders are characterized by ineffective red cell production and a low reticulocyte production index with bizarre red cell shapes -- macrocytes or hypochromic microcytes on the peripheral blood smear. With a hypoproliferative anemia, no erythroid hyperplasia is noted in the marrow, whereas patients with ineffective red cell production have erythroid hyperplasia and an E/G ratio³1:1.

Hypoproliferative Anemias At least 75% of all cases of anemia are hypoproliferative in nature. A hypoproliferative anemia reflects absolute or relative marrow failure in which the erythroid marrow has not proliferated appropriately for the degree of anemia. The majority of hypoproliferative anemias are due to mild to moderate iron deficiency or inflammation. A hypoproliferative anemia can result from marrow damage, iron deficiency, or inadequateEPOstimulation. The last may reflect impaired renal function, suppression of EPO production by inflammatory cytokines such as interleukin 1, or reduced tissue needs for O_2 from metabolic disease such as hypothyroidism. Only occasionally is the marrow unable to produce red cells at a normal rate, and this is most prevalent in patients with renal failure. In general, hypoproliferative anemias are characterized by normocytic, normochromic red cells, although microcytic, hypochromic cells may be observed with mild iron deficiency or long-standing chronic inflammatory disease. The key laboratory tests in distinguishing between the various forms of hypoproliferative anemia include the serum iron and iron-binding capacity, evaluation of renal and thyroid function, a marrow biopsy or aspirate to detect marrow damage or infiltrative disease, and serum ferritin to assess iron stores. Occasionally, an iron stain of the marrow will be needed to determine the pattern of iron distribution. Patients with the anemia of acute or chronic inflammation show a distinctive pattern of serum iron (low),TIBC(normal or low), percent transferrin saturation (low), and serum ferritin (normal or high). A distinct pattern of results is noted in mild to moderate iron deficiency (low serum iron, high TIBC, low percent transferrin saturation, low serum ferritin) (Chap. 105). Marrow damage by a drug, infiltrative disease such as leukemia or lymphoma, or marrow aplasia can usually be diagnosed from the peripheral blood and bone marrow morphology. With infiltrative disease or fibrosis, a marrow biopsy will likely be required.

Maturation Disorders The presence of anemia with an inappropriately low reticulocyte

production index, macro- or microcytosis on smear, and abnormal red cell indices suggests a maturation disorder. Maturation disorders are divided into two categories: nuclear maturation defects, associated with macrocytosis and abnormal marrow development, and cytoplasmic maturation defects, associated with microcytosis and hypochromia usually from defects in hemoglobin production. The low reticulocyte production index is a reflection of the ineffective erythropoiesis that results from the destruction within the marrow of developing erythroblasts. Marrow morphology shows an E/G ratio of ³ 1:1, diagnostic of erythroid hyperplasia.

Nuclear maturation defects result from vitamin B_{12} or folic acid deficiency, drug damage, or myelodysplasia. Drugs that interfere with cellular DNA metabolism, such as methotrexate or alkylating agents, can produce a nuclear maturation defect. Alcohol, alone, is also capable of producing macrocytosis and a variable degree of anemia, but this is usually associated with coincident folic acid deficiency. Measurements of folic acid and vitamin B_{12} are key not only in identifying the specific vitamin deficiency but also because they reflect different pathogenetic mechanisms.

Cytoplasmic maturation defects result from severe iron deficiency or abnormalities in globin or heme synthesis. Iron deficiency occupies an unusual position in the classification of anemia. If the iron-deficiency anemia is mild to moderate, erythroid marrow proliferation is decreased and the anemia is classified as hypoproliferative. However, if the anemia is severe and prolonged, the erythroid marrow will become hyperplastic despite the inadequate iron supply, and the anemia will be classified as ineffective erythropoiesis with a cytoplasmic maturation defect. In either case, a reduced reticulocyte production index, microcytosis, and a classic pattern of iron values make the diagnosis clear and easily distinguish iron deficiency from other cytoplasmic maturation defects such as the thalassemias. Defects in heme synthesis, in contrast to globin synthesis, are less common and may be acquired or inherited (Chap. 346). Acquired abnormalities are usually associated with myelodysplasia, may lead to either a macro- or microcytic anemia, and are frequently associated with mitochondrial iron loading. In these cases, iron is taken up by the mitochondria of the developing erythroid cell but not incorporated into heme. The iron-encrusted mitochondria surround the nucleus of the erythroid cell, forming a ring. Based on the distinctive finding of so-called ringed sideroblasts on the marrow iron stain (seePlate V-37), patients are diagnosed as having a sideroblastic anemia -- almost always reflecting myelodysplasia. Again, studies of iron parameters are helpful in the differential diagnosis and management of these patients.

Blood Loss/Hemolytic Anemia In contrast to anemias associated with an inappropriately low reticulocyte production index, blood loss or hemolysis is associated with red cell production indices of ³2.5 times normal. The stimulated erythropoiesis is reflected in the blood smear by the appearance of increased numbers of polychromatophilic macrocytes. A marrow examination is rarely indicated if the reticulocyte production index is increased appropriately. The red cell indices are typically normocytic or slightly macrocytic, reflecting the increased number of reticulocytes. Acute blood loss is not associated with an increased reticulocyte production index because of the time required to increaseEPOproduction and, subsequently, marrow proliferation. Subacute blood loss may be associated with modest reticulocytosis because iron is lost along with the red cells. Anemia from chronic

blood loss more often presents as iron deficiency than with the picture of increased red cell production.

The evaluation of blood loss anemia is usually not difficult. Most problems arise when a patient presents with an increased red cell production index from an episode of acute blood loss that went unrecognized. The cause of the anemia and increased red cell production may not be obvious. The confirmation of a recovering state may require observations over a period of 2 to 3 weeks, during which the hemoglobin concentration will be seen to rise and the reticulocyte production index fall.

Hemolytic disease, while dramatic, is among the least common forms of anemia. The ability to sustain a high reticulocyte production index reflects the ability of the erythroid marrow to compensate for hemolysis and the efficient recycling of iron from the destroyed red cells to support new hemoglobin synthesis. The level of response will depend on the severity of the anemia and the nature of the underlying disease process.

Hemolytic anemias present in different ways. Some appear suddenly as an acute, self-limited episode of intravascular or extravascular hemolysis, a presentation pattern often seen in patients with autoimmune hemolysis or with inherited defects of the Embden-Myerhof pathway or the glutathione reductase pathway. Patients with inherited disorders of the hemoglobin molecule or red cell membrane generally have a lifelong clinical history typical of the disease process. Those with chronic hemolytic disease, such as hereditary spherocytosis, may actually present not with anemia but with a complication stemming from the prolonged increase in red cell destruction such as aplastic crisis, symptomatic bilirubin gallstones, or splenomegaly.

The differential diagnosis of an acute or chronic hemolytic event requires the careful integration of family history, pattern of clinical presentation, and a number of highly specific laboratory studies (Chap. 108). Some of the more common congenital hemolytic anemias may be identified from the red cell morphology, a routine laboratory test such as hemoglobin electrophoresis, or a screen for red cell enzymes. Acquired defects in red cell survival are often immunologically mediated and require the immunoglobulin test or a cold agglutinin titer to detect the presence of hemolytic antibodies or complement-mediated red cell destruction.

TREATMENT

An overriding principle is to not initiate treatment of mild to moderate anemia without a specific diagnosis. Rarely, in the acute setting, anemia may be so severe that red cell transfusions are required before a specific diagnosis is made. Whether the anemia is of acute or gradual onset, the selection of the appropriate treatment is determined by the documented cause(s) of the anemia. Often, the cause of the anemia may be multifactorial. For example, a patient with severe rheumatoid arthritis who has been taking anti-inflammatory drugs may have a hypoproliferative anemia associated with chronic inflammation as well as chronic blood loss associated with intermittent gastrointestinal bleeding. In every circumstance, it is important to evaluate the patient's iron status fully before and during the treatment of any anemia.**Transfusion is discussed in Chap. 114; iron therapy is discussed in Chap. 105; treatment of megaloblastic anemia is discussed in Chap. 107; treatment of other entities is discussed*

in their respective chapters (sickle cell anemia, Chap. 106; hemolytic anemias, Chap. 108; aplastic anemia and myelodysplasia, Chap. 109).

Therapeutic options for the treatment of anemias have expanded dramatically during the past 25 years. Blood component therapy is available and safe. RecombinantEPO as an adjunct to anemia management has transformed the lives of patients with chronic renal failure on dialysis. Improvements in the management of sickle cell crises and sickle cell anemia have also occurred. Eventually, patients with inherited disorders of globin synthesis or mutations in the globin gene, such as sickle cell disease, may benefit from the successful introduction of targeted genetic therapy (Chap. 69).

POLYCYTHEMIA

Polycythemia is defined as an increase in circulating red blood cells above normal. This increase may be real or only apparent (spurious or relative) because of a decrease in plasma volume. The term *erythrocytosis* may be used interchangeably with polycythemia, but some draw a distinction between them; erythrocytosis implies documentation of increased red cell mass, whereas polycythemia refers to any increase in red cells. Often patients with polycythemia are detected through an incidental finding of elevated hemoglobin or hematocrit levels. Concern that the hemoglobin level may be abnormally high is usually triggered at 170 g/L (17 g/dL) for men and 150 g/L (15 g/dL) for women. Hematocrit levels >50% in men or>45% in women may be abnormal. Hematocrits>60% in men and >55% in women are almost invariably associated with increased red cell mass.

Historic features useful in the differential diagnosis include smoking history; living at high altitude; or a history of congenital heart disease, peptic ulcer disease, sleep-apnea, chronic lung disease, or renal disease.

Patients with polycythemia may be asymptomatic or experience symptoms related to the increased red cell mass or an underlying disease process that leads to increased red cell production. The dominant symptoms from increased red cell mass are thrombotic (both venous and arterial), because the blood viscosity increases logarithmically at hematocrits >55%. Manifestations range from digital ischemia to Budd-Chiari syndrome with hepatic vein thrombosis. Abdominal thromboses are particularly common. Neurologic symptoms such as vertigo, tinnitus, headache, and visual disturbances may occur. Hypertension is often present. Patients with *polycythemia vera* may have aquagenic pruritus and symptoms related to hepatosplenomegaly. Patients may have easy bruising, epistaxis, or bleeding from the gastrointestinal tract. Patients with hypoxemia may develop cyanosis on minimal exertion or have headache, impaired mental acuity, and fatigue.

The physical examination usually reveals a ruddy complexion. Splenomegaly favors polycythemia vera as the diagnosis (Chap. 110). The presence of cyanosis or evidence of a right-to-left shunt suggests congenital heart disease presenting in the adult, particularly tetralogy of Fallot or Eisenmenger syndrome (Chap. 234). Increased blood viscosity raises pulmonary artery pressure; hypoxemia can lead to increased pulmonary vascular resistance. Together these factors can produce cor pulmonale.

Polycythemia can be spurious (related to a decrease in plasma volume; Gaisbock's syndrome), primary, or secondary in origin. The secondary causes are all associated with increases in EPO levels: either a physiologically adapted appropriate elevation based upon tissue hypoxia (lung disease, high altitude, CO poisoning, high-affinity hemoglobinopathy) or an abnormal overproduction (renal disease, tumors with ectopic EPO production). A rare familial form of polycythemia is associated with normal EPO levels but mutations producing hyperresponsive EPO receptors.

Approach to the Patient

As shown in Fig. 61-5, the first step is to document the presence of an increased red cell mass using the principle of isotope dilution by administering ^{51}Cr-labeled autologous red blood cells to the patient and sampling blood radioactivity over a 2-h period. If the red cell mass is normal (<36 mL/kg in men, <32 mL/kg in women), the patient has spurious polycythemia. If the red cell mass is increased (>36 mL/kg in men, >32 mL/kg in women), serum EPO levels should be measured. If EPO levels are low or absent, the patient most likely has polycythemia vera. Ancillary tests that support this diagnosis include elevated white blood cell count, increased absolute basophil count, thrombocytosis, elevated leukocyte alkaline phosphatase levels, and elevated serum vitamin B_{12} and vitamin B_{12}-binding protein levels.

If serum EPO levels are elevated, one attempts to distinguish whether the elevation is a physiologic response to hypoxia or is related to autonomous production. Patients with low arterial O_2 saturation (<92%) should be further evaluated for the presence of heart or lung disease, if they are not living at high altitude. Patients with normal O_2 saturation who are smokers may have elevated EPO levels because of CO displacement of O_2. If carboxyhemoglobin (COHb) levels are high, the diagnosis is smoker's polycythemia. Such patients should be urged to stop smoking. Those who cannot stop smoking require phlebotomy to control their polycythemia. Patients with normal O_2 saturation who do not smoke either have an abnormal hemoglobin that does not deliver O_2 to the tissues (evaluated by finding elevated O_2-hemoglobin affinity) or have a source of EPO production that is not responding to the normal feedback inhibition. Further workup is dictated by the differential diagnosis of EPO-producing neoplasms. Hepatoma, uterine leiomyoma, and renal disease or cysts are all detectable with abdominopelvic computed tomography scans. Cerebellar hemangiomas may produce EPO, but they nearly always present with localizing neurologic signs and symptoms rather than polycythemia-related symptoms.

ACKNOWLEDGEMENT

62. BLEEDING AND THROMBOSIS - *Robert I. Handin*

Hemorrhage, intravascular thrombosis, and embolism are common clinical manifestations of many diseases. The normal hemostatic system limits blood loss by precisely regulated interactions between components of the vessel wall, blood platelets, and plasma proteins. However, when disease or trauma damages large arteries and veins, excessive bleeding may occur, despite a normal hemostatic system. Less frequently, hemorrhage is caused by an inherited or acquired disorder of the hemostatic machinery itself. A large number of such bleeding disorders have been identified.

In addition, unregulated activation of the hemostatic system may cause thrombosis and embolism, which can reduce blood flow to critical organs such as the brain and myocardium. Although we understand less about the pathophysiology of thrombosis than of hemostatic failure, certain patient groups have been identified that are particularly prone to thrombosis and embolism. These include patients who (1) are immobilized after surgery, (2) have chronic congestive heart failure, (3) have atherosclerotic vascular disease, (4) have a malignancy, or (5) are pregnant. Most of these "thrombosis-prone" patients have inherited or acquired "hypercoagulable" or "prethrombotic" disorders.

Certain information in the patient's history, such as the mode of onset and sites of bleeding, a family bleeding tendency, and a record of drug ingestion, helps establish the correct diagnosis. Physical examination can identify bleeding in the skin or joint deformities due to previous hemarthroses. Ultimately, however, bleeding disorders are diagnosed by laboratory tests. General screening tests are used first, to document a systemic disorder, and are then supplemented by specific tests of coagulation protein or platelet function to arrive at an accurate diagnosis.

The hypercoagulable or prethrombotic patient can also be identified by a careful history. Three important clues to this diagnosis are: (1) repeated episodes of thromboembolism without an obvious predisposing condition, (2) a family history of thrombosis, and (3) well-documented thromboembolism in adolescents and young adults. All of the known inherited prethrombotic disorders can be diagnosed with specific immunologic, functional, and, in some cases, genetic tests.

NORMAL HEMOSTASIS

Accurate diagnosis and treatment of patients with either bleeding or thrombosis require knowledge of the pathophysiology of hemostasis. The process can be divided into primary and secondary components and is initiated when trauma, surgery, or disease disrupts the vascular endothelial lining and blood is exposed to subendothelial connective tissue. *Primary hemostasis* is the name given to the process of platelet plug formation at sites of injury. It occurs within seconds of injury and is of prime importance in stopping blood loss from capillaries, small arterioles, and venules (Fig. 62-1). *Secondary hemostasis* consists of the reactions of the plasma coagulation system that result in fibrin formation. It requires several minutes for completion. The fibrin strands that are produced strengthen the primary hemostatic plug. This reaction is particularly important in larger vessels and prevents bleeding from recurring hours or days after the injury. Although presented here as separate events, primary and secondary hemostasis

are closely linked. For example, activated platelets accelerate plasma coagulation, and products of the plasma coagulation reaction, such as thrombin, induce platelet activation.

Effective primary hemostasis requires three critical events -- platelet adhesion, granule release, and platelet aggregation. Within a few seconds of injury, platelets adhere to collagen fibrils in vascular subendothelium via a specific platelet collagen receptor, glycoprotein Ia/IIa, which is a member of the integrin family. As shown in Fig. 62-2, this interaction is stabilized by the von Willebrand factor, an adhesive glycoprotein that allows platelets to remain attached to the vessel wall despite the high shear forces generated within the vascular lumen. The von Willebrand factor accomplishes this task by forming a link between a platelet receptor site on glycoprotein Ib/IX and subendothelial collagen fibrils. The adherent platelets then release preformed granule constituents and generate de novo mediators like those depicted inFig. 62-1.

As in other cells, platelet activation and secretion are regulated by changes in the level of cyclic nucleotides, the influx of calcium, hydrolysis of membrane phospholipids, and phosphorylation of critical intracellular proteins. The relevant pathways are depicted inFigs. 62-3 and62-4. The binding of agonists such as epinephrine, collagen, or thrombin to platelet surface receptors activates two membrane enzymes -- phospholipase C and phospholipase A_2. These enzymes catalyze the release of arachidonic acid from two of the major membrane phospholipids, phosphatidylinositol and phosphatidylcholine. Initially, a small quantity of the released arachidonic acid is converted to thromboxane A_2(TXA_2), which, in turn, can activate phospholipase C. The formation of $TXA_2$from arachidonic acid is mediated by the enzyme cyclooxygenase (Fig. 62-3). This enzyme is inhibited by aspirin and nonsteroidal anti-inflammatory drugs. Inhibition of TXA_2synthesis is a cause of mild bleeding in some patients and is the same way some antithrombotic drugs work.

Hydrolysis of the membrane phospholipid phosphatidylinositol 4,5-bisphosphate produces diacylglycerol (DAG) and inositol triphosphate (IP_3), both of which play critical roles in platelet metabolism. IP_3mediates the movement of calcium into the platelet cytosol and stimulates the phosphorylation of myosin light chains. The latter interact with actin to facilitate granule movement and platelet shape change. DAG activates protein kinase C, which, in turn, phosphorylates several substrates, including myosin light chain kinase and a 47-kDa protein (plekstrin). Phosphorylation of these or other proteins may regulate platelet granule secretion.

A finely balanced mechanism controls the rate and extent of platelet activation (Fig. 62-3).TXA_2, a platelet product of arachidonic acid, stimulates platelet activation and secretion. In contrast, prostacyclin, an endothelial cell product of arachidonic acid metabolism, inhibits platelet activation by raising intraplatelet levels of cyclic adenosine monophosphate.

Following activation, platelets secrete their granule contents into plasma. Endoglycosidases and a heparin-cleaving enzyme are released from lysosomes; calcium, serotonin, and adenosine diphosphate (ADP) are released from the dense granules; and several proteins, including the von Willebrand factor, fibronectin, thrombospondin, the platelet-derived growth factor (PDGF), and a heparin-neutralizing

protein (platelet factor 4), are released froma granules. Released ADP binds to purinergic receptors, which, when activated, change the conformation of the glycoprotein IIb/IIIa complex so that it binds fibrinogen, linking adjacent platelets into a hemostatic plug (Fig. 62-2). Released PDGF stimulates the growth and migration of fibroblasts and smooth-muscle cells within the vessel wall, an important part of the repair process.

As the primary hemostatic plug is being formed, plasma coagulation proteins are activated to initiate secondary hemostasis. An overall picture of the coagulation scheme, including the role of various inhibitors, is shown inFig. 62-5. The coagulation pathway can be broken down into a series of reactions (Fig. 62-6) that culminate in the production of enough thrombin to convert a small amount of plasma fibrinogen to fibrin. Each of the reactions requires the formation of a surface-bound complex and the conversion of inactive precursor proteins into active proteases by limited proteolysis, and each is regulated by both plasma and cellular cofactors and calcium.

In *reaction 1*, the intrinsic or contact phase of coagulation, three plasma proteins, Hageman factor (factor XII), high-molecular-weight kininogen (HMWK), and prekallikrein (PK), form a complex on vascular subendothelial collagen. After binding to HMWK, factor XII is slowly converted to an active protease (XIIa), which then activates PK to kallikrein and factor XI to XIa. Kallikrein accelerates the conversion of XII to XIIa, while XIa participates in subsequent coagulation reactions. An alternative mechanism for the activation of factor XI may exist, as patients who are deficient in either factor XII, HMWK, or PK have apparently normal hemostasis and no clinical bleeding.

Reaction 2 provides a second pathway to initiate coagulation by activating factor VII to a protease. In this extrinsic or tissue-factor-dependent pathway, a complex is formed between factor VII, calcium, and tissue factor, a ubiquitous lipoprotein present in cellular membranes and exposed by cellular injury. The tissue factor-VII pathway is continuously active and makes a major contribution to basal coagulation. Factor VII and three other coagulation proteins -- factors II (prothrombin), IX, and X -- require calcium and vitamin K for biologic activity. These proteins are synthesized in the liver, where a vitamin K-dependent carboxylase catalyzes a unique posttranslational modification that adds a second carboxyl group to certain glutamic acid residues. Pairs of these di-g-carboxyglutamic acid (Gla) residues bind calcium, which alters protein comformation for binding to phospholipid surfaces and confers biologic activity. Inhibition of this modification by vitamin K antagonists (e.g., warfarin) is the basis of one of the most common forms of anticoagulant therapy.

In *reaction 3*, factor X is activated by the proteases generated in the two previous reactions. In one reaction, a calcium- and lipid-dependent complex is formed between factors VIII, IX, and X. Within this complex, factor IX is first converted to IXa by factor XIa that was generated within the intrinsic pathway (reaction 1). Factor X is then activated by factor IXa in concert with factor VIII. Alternatively, both factors IX and X can be activated more directly by factor VIIa, generated via the extrinsic pathway (reaction 2). Activation of factors IX and X provides a link between the intrinsic and extrinsic coagulation pathways (Fig. 62-5).

Reaction 4, the final step, converts prothrombin to thrombin in the presence of factor V,

calcium, and phospholipid. Although prothrombin conversion can take place on various natural and artificial phospholipid-rich surfaces, it proceeds several thousand times faster on the surface of activated platelets or endothelial cells. Thrombin has multiple functions in hemostasis. Although its principal role in hemostasis is the conversion of fibrinogen to fibrin, it also activates factors V, VIII, and XIII and stimulates platelet aggregation and secretion. Following the release of fibrinopeptides A and B from thea and b chains of fibrinogen, the modified molecule, now called *fibrin monomer*, polymerizes into an insoluble gel. The fibrin polymer is then stabilized by the cross-linking of individual chains by factor XIIIa, a plasma transglutaminase (Fig. 62-5).

Although the classic view of coagulation had clinical utility, it left several important questions unanswered: (1) Why does factor XII deficiency dramatically prolong partial thromboplastin time (PTT) but not cause bleeding? (2) Why is there heterogeneity in the bleeding symptoms of patients with factor XI deficiency? (3) Why do deficiencies in factors VIII or IX produce such dramatic bleeding even though the "extrinsic" pathway remains intact? Activation of factors IX and X by the tissue factor-VIIa complex is thought to play a major role in the initiation of hemostasis. Once coagulation is initiated by this interaction, the tissue factor pathway inhibitor (TFPI) blocks the pathway, and elements of the intrinsic pathway, particularly factors VIII and IX, become the dominant regulators of thrombin generation. This step in the pathway explains why factor XII-deficient patients are asymptomatic and why factor XI-deficient patients have only a mild to moderate bleeding diathesis (Fig. 62-7).

Clot lysis and vessel repair begin immediately after the formation of the definitive hemostatic plug. Three potential activators of the fibrinolytic system are: Hageman factor fragments, urinary plasminogen activator (uPA) or urokinase, and tissue plasminogen activator (tPA). The principal physiologic activators, tPA and uPA, diffuse from endothelial cells and convert plasminogen, adsorbed to the fibrin clot, into plasmin (Fig. 62-8). Plasmin then degrades fibrin polymer into small fragments, which are cleared by the monocyte-macrophage scavenger system. Although plasmin can also degrade fibrinogen, the reaction remains localized because (1) tPA and some forms of uPA activate plasminogen more effectively when it is adsorbed to fibrin clots; (2) any plasmin that enters the circulation is rapidly bound and neutralized by thea$_2$plasmin inhibitor (patients who lack this factor have unchecked fibrinolysis and bleed); and (3) endothelial cells release a plasminogen activator inhibitor (PAI-1), which blocks the action of tPA.

Only a small quantity of each coagulation enzyme is converted to its active form. As a consequence, the hemostatic plug does not propagate beyond the site of injury. Precise regulation is important, since each milliliter of blood contains enough clotting potential to clot all the fibrinogen in the body in 10 to 15 s. Blood fluidity is maintained by the flow of blood, the adsorption of coagulation factors to surfaces and their trapping in the emerging clot, and by multiple inhibitors in plasma. Antithrombin, proteins C and S, andTFPI are important inhibitors that maintain blood fluidity.

These inhibitors have distinct modes of action. Antithrombin forms complexes with all serine protease coagulation factors except factor VII (Fig. 62-5). Rates of complex formation are accelerated by heparin and heparin-like molecules on the surface of the endothelial cells. Heparin's ability to accelerate antithrombin activity is the basis for its

anticoagulant action. Protein C is converted to an active protease by thrombin after it is bound to an endothelial cell protein called *thrombomodulin*. Activated protein C then inactivates the two plasma cofactors V and VIII by limited proteolysis, which slows down two critical coagulation reactions. Protein C may also stimulate the release oftPA from endothelial cells. The inhibitory function of protein C is enhanced by protein S. Reduced levels of antithrombin or proteins C and S, or dysfunctional forms of these molecules, result in a hypercoagulable or prethrombotic state. In addition, a particularly common heritable defect associated with a hypercoagulable state is the presence of a form of factor V (factor V Leiden) that is resistant to protein C inhibition. Between 20 and 50% of patients with unexplained venous thromboembolism have this defect.

Blood coagulation is not uniform throughout the body. The composition of the blood clot varies with the site of injury. Hemostatic plugs or thrombi that form in veins where blood flow is slow are rich in fibrin and trapped red blood cells and contain relatively few platelets. They are often called *red thrombi* because of their appearance in surgical and pathologic specimens. The friable ends of these red thrombi, which most often form in leg veins, can break off and embolize to the pulmonary circulation. Conversely, clots that form in arteries under conditions of high flow are predominantly composed of platelets and have little fibrin. These *white thrombi* may readily dislodge from the arterial wall and embolize to distant sites, causing temporary or permanent ischemia. These clots are a particularly common cause of embolism in the cerebral and retinal circulation, where they may lead to transient neurologic dysfunction (transient ischemic attacks), including temporary monocular blindness (amaurosis fugax), or to strokes. In addition, most episodes of myocardial infarction are due to thrombi that form after the rupture of atherosclerotic plaques within diseased coronary arteries. Hemostatic plugs, which are a physiologic response to injury, are very similar to pathologic thrombi. Thrombosis has been described as coagulation occurring in the wrong place or at the wrong time.

CLINICAL EVALUATION

HISTORY

Certain elements of the history are particularly useful in determining whether bleeding is caused by an underlying hemostatic disorder or by a local anatomic defect. One clue is a history of bleeding following common hemostatic stresses such as dental extraction, childbirth, or minor surgery. Bleeding that is sufficiently severe to require a blood transfusion merits special attention. A family history of bleeding and bleeding from multiple sites that cannot be linked to trauma or surgery also suggest a systemic disorder. Since bleeding can be mild, lack of a family history of bleeding does not exclude an inherited hemostatic disorder.

Bleeding from a platelet disorder is usually localized to superficial sites such as the skin and mucous membranes, comes on immediately after trauma or surgery, and is readily controlled by local measures (Table 62-1). In contrast, bleeding from secondary hemostatic or plasma coagulation defects occurs hours or days after injury and is unaffected by local therapy. Such bleeding most often occurs in deep subcutaneous tissues, muscles, joints, or body cavities. A careful and thorough history may establish the presence of a hemostatic disorder and guide initial laboratory testing.

PHYSICAL EXAMINATION

The most common site to observe bleeding is in the skin and mucous membranes. Collections of blood in the skin are called *purpura* and may be subdivided on the basis of the site of bleeding in the skin. Small pinpoint hemorrhages into the dermis due to the leakage of red cells through capillaries are called *petechiae* and are characteristic of platelet disorders -- in particular, severe thrombocytopenia. Larger subcutaneous collections of blood due to leakage of blood from small arterioles and venules are called *ecchymoses* (common bruises) or, if somewhat deeper and palpable, *hematomas*. They are also common in patients with platelet defects and result from minor trauma. Dilated capillaries, or *telangiectasia*, may cause bleeding without any hemostatic defect. In addition, the loss of connective tissue support for capillaries and small veins that accompanies aging increases the fragility of superficial vessels, such as those on the dorsum of the hand, leading to extravasation of blood into subcutaneous tissue -- *senile purpura*. Menorrhagia is sometimes a serious problem in women with severe thrombocytopenia or platelet dysfunction. Some patients with primary hemostatic defects, especially von Willebrand's disease, may have recurrent gastrointestinal hemorrhage, often associated with angiodysplasia, a common vascular malformation in the gastrointestinal tract.

Bleeding into body cavities, the retroperitoneum, or joints is a common manifestation of plasma coagulation defects. Repeated joint bleeding may cause synovial thickening, chronic inflammation, and fluid collections and may erode articular cartilage and lead to chronic joint deformity and limited mobility. Such deformities are particularly common in deficiencies of factors VIII and IX, the two sex-linked coagulation disorders referred to as the *hemophilias*. For unclear reasons, hemarthroses are much less common in patients with other plasma coagulation defects. Blood collections in various body cavities or soft tissues can cause secondary necrosis of tissues or nerve compression. Retroperitoneal hematomas can cause femoral nerve compression, and large collections of poorly coagulated blood in soft tissues occasionally mimic malignant growths -- the pseudotumor syndrome. Two of the most life-threatening sites of bleeding are in the oropharynx, where bleeding can compromise the airway, and in the central nervous system. Intracerebral hemorrhage is one of the leading causes of death in patients with severe coagulation disorders. Because of their need for plasma and factor concentrates derived from multiple donors, many patients with hemophilia were infected with HIV before effective testing of donors was in place.

LABORATORY TESTS

The most important screening tests of the primary hemostatic system are (1) a *bleeding time* (a sensitive measure of platelet function), and (2) a *platelet count*. The latter correlates well with the propensity to bleed. The normal platelet count is 150,000 to 450,000/uL of blood. As long as the count is>100,000/uL, patients are usually not symptomatic and the bleeding time remains normal. Platelet counts of 50,000 to 100,000/uL cause mild prolongation of the bleeding time; bleeding occurs only from severe trauma or other stress. Patients with platelet counts<50,000/uL have easy bruising, manifested by skin purpura after minor trauma and bleeding after mucous membrane surgery. Patients with a platelet count <20,000/uL have an appreciable

incidence of spontaneous bleeding, usually have petechiae, and may have intracranial or other spontaneous internal bleeding. The major causes of thrombocytopenia are outlined in Table 62-2.

Patients with qualitative platelet abnormalities have a normal platelet count and a prolonged bleeding time (Table 62-3). The bleeding time is ascertained by making a small, superficial skin incision and timing the duration of blood flow from the wounded area. By careful standardization, bleeding time is a reliable and sensitive test of platelet function. A template or an automated scalpel controls the length and depth of the incision (usually 1 mm deep by 9 mm long), and a sphygmomanometer inflated to 40 mmHg distends the capillary bed of the forearm uniformly. The bleeding time test must be performed by an experienced technician, as small differences in technique have a big effect on outcome. Any patient with a bleeding time >10 min has an increased risk of bleeding, but the risk does not become great until the bleeding time >15 or 20 min. As shown inFig. 62-9, the relationship between the platelet count and the bleeding time is roughly linear. When a defect in primary hemostasis is uncovered, specialized testing is needed to determine the cause of the platelet dysfunction (Table 62-3). A precise diagnosis is important in determining the proper treatment. Occasional patients with a strong history of bleeding, particularly those with mild von Willebrand's disease, may have a normal bleeding time when initially tested, owing to cyclical variations in the level of the von Willebrand factor. Repeated testing may be necessary to establish an accurate diagnosis. Bleeding time is not an effective screening test for preoperative patients.

Plasma coagulation function is readily assessed with thePTT, prothrombin time (PT), thrombin time (TT), and quantitative fibrinogen determination (Fig. 62-5,Table 62-4). The PTT screens the intrinsic limb of the coagulation system and tests for the adequacy of factors XII,HMWK,PK, XI, IX, and VIII. The PT screens the extrinsic or tissue factor-dependent pathway. Both tests also evaluate the common coagulation pathway involving all the reactions that occur after the activation of factor X. Prolongation of the PT and PTT that does not resolve after the addition of normal plasma suggests a coagulation inhibitor. A specific test for the conversion of fibrinogen to fibrin is needed when both the PTT and PT are prolonged -- either a TT or a clottable fibrinogen level can be employed. When abnormalities are noted in any of the screening tests, more specific coagulation factor assays can be ordered to determine the nature of the defect.

Several rare coagulation abnormalities that may be missed as they do not affect these screening tests: factor XIII deficiency,$a_2$plasmin inhibitor deficiency,PAI-1deficiency (PAI-1 is the major inhibitor of plasminogen activators), and Scott's syndrome, a platelet coagulant defect. A test for factor XIII-dependent fibrin cross-linking, such as clot solubility in 5 *M* urea, should be ordered when thePT andPTT are both normal but the history of bleeding is strong. The fibrinolytic system can be assessed by measuring the rate of clot lysis with the euglobulin lysis or whole blood clot lysis tests and by measuring the levels of$a_2$plasmin inhibitor and PAI-1. Scott's syndrome can be detected by measuring the serum PT, which assesses the amount of residual prothrombin.

Conditions associated with thrombosis are listed in Table 62-5. Patients suspected of having a hypercoagulable or prethrombotic disorder on the basis of clinical information should be tested with specific assays to screen for the known defects. Currently

available tests can identify 50 to 60% of the cases of familial or recurrent venous thrombosis.

Inhibitor syndromes or circulating anticoagulants are usually due to antibodies that impair coagulation factor activity. They are an infrequent cause of bleeding and require specialized diagnostic testing. Inhibitors are likely when screening test abnormalities cannot be reversed by adding normal plasma to patient plasma. Antibodies against specific coagulation factors may develop in (1) postpartum women, (2) patients with autoimmune disorders such as systemic lupus erythematosus, (3) patients taking drugs such as penicillin and streptomycin, and (4) otherwise healthy elderly individuals. In addition, between 10 to 20% of patients with severe hemophilia who have received multiple plasma infusions develop inhibitory antibodies. Some patients, especially those with systemic lupus erythematosus, may also have a nonspecific form of anticoagulant antibody that interferes with phospholipid binding of coagulation factors and prolongs the PTand PTTbut does not cause clinical bleeding. The presence of the lupus anticoagulant may increase the risk of thromboembolism and may cause placental infarction, recurrent midtrimester abortion, and venous and arterial thrombosis. The lupus-like anticoagulant is one manifestation of the anticardiolipin antibody syndrome. Patients may have anticardiolipin antibodies that do not prolong the PTT, but patients are still at risk from thrombosis. Occasionally, patients develop inhibitors that are not antibodies. For example, several patients with clinical bleeding have been found to have circulating mucopolysaccharides that have heparin-like activity.

63. ENLARGEMENT OF LYMPH NODES AND SPLEEN - *Patrick H. Henry*, *Dan L. Longo*

This chapter is intended to serve as a guide to the evaluation of patients who present with enlargement of the lymph nodes (*lymphadenopathy*) or the spleen (*splenomegaly*). Lymphadenopathy is a rather common clinical finding in primary care settings, whereas palpable splenomegaly is less so.

LYMPHADENOPATHY

Lymphadenopathy may be an incidental finding in patients being examined for various reasons or it may be a presenting sign or symptom of the patient's illness. The physician must eventually decide whether the lymphadenopathy is a normal finding or one that requires further study, up to and including biopsy. Soft, flat, submandibular nodes (<1 cm) are often palpable in healthy children and young adults, and healthy adults may have palpable inguinal nodes of up to 2 cm, which are considered normal. Further evaluation of these normal nodes is not warranted. In contrast, if the physician believes the node(s) to be abnormal, then pursuit of a more precise diagnosis is needed.

Approach to the Patient

Lymphadenopathy may be a primary or secondary manifestation of numerous disorders, as shown inTable 63-1. Many of these disorders are infrequent causes of lymphadenopathy. Analysis of lymphadenopathy in primary care practice has shown that more than two-thirds of patients have nonspecific causes or upper respiratory illnesses (viral or bacterial), and fewer than 1% have a malignancy. In one study, researchers reported that 186 of 220 patients (84%) referred for evaluation of lymphadenopathy had a "benign" diagnosis. The remaining 34 patients (16%) had a malignancy (lymphoma or metastatic adenocarcinoma). Sixty-three percent (112) of the 186 patients with benign lymphadenopathy had a nonspecific or reactive etiology (no causative agent found), and the remainder had a specific cause demonstrated, most commonly infectious mononucleosis, toxoplasmosis, or tuberculosis. Thus, the vast majority of patients with lymphadenopathy will have a nonspecific etiology requiring few diagnostic tests.

Clinical Assessment The physician will be aided in the pursuit of an explanation for the lymphadenopathy by a careful medical history, physical examination, selected laboratory tests, and perhaps an excisional lymph node biopsy.

The *medical history* should reveal the setting in which lymphadenopathy is occurring. Symptoms such as sore throat, cough, fever, night sweats, fatigue, weight loss, or pain in the nodes should be sought. The patient's age, sex, occupation, exposure to pets, sexual behavior, and use of drugs such as diphenylhydantoin are other important historic points. For example, children and young adults usually have benign (i.e., nonmalignant) disorders, such as viral or bacterial upper respiratory infections, infectious mononucleosis, toxoplasmosis, and, in some countries, tuberculosis, which account for the observed lymphadenopathy. In contrast, after age 50 the incidence of malignant disorders increases and that of benign disorders decreases.

The *physical examination* can provide useful clues such as the extent of lymphadenopathy (localized or generalized), size of nodes, texture, presence or absence of nodal tenderness, signs of inflammation over the node, skin lesions, and splenomegaly. A thorough ear, nose, and throat (ENT) examination is indicated in adult patients with cervical adenopathy and a history of tobacco use. Localized or regional adenopathy implies involvement of a single anatomic area. Generalized adenopathy has been defined as involvement of three or more noncontiguous lymph node areas. Many of the causes of lymphadenopathy (Table 63-1) can produce localized *or* generalized adenopathy, so this distinction is of limited utility in the differential diagnosis. Nevertheless, generalized lymphadenopathy is frequently associated with nonmalignant disorders such as infectious mononucleosis [Epstein-Barr virus (EBV) or cytomegalovirus (CMV)], toxoplasmosis, AIDS, other viral infections, systemic lupus erythematosus (SLE), and mixed connective tissue disease. Acute and chronic lymphocytic leukemias and malignant lymphomas also produce generalized adenopathy in adults.

The site of localized or regional adenopathy may provide a useful clue about the cause. Occipital adenopathy often reflects an infection of the scalp, and preauricular adenopathy accompanies conjunctival infections and cat-scratch disease. The most frequent site of regional adenopathy is the neck, and most of the causes are benign -- upper respiratory infections, oral and dental lesions, infectious mononucleosis, other viral illnesses. The chief malignant causes include metastatic cancer from head and neck, breast, lung, and thyroid primaries. Enlargement of supraclavicular and scalene nodes is always abnormal. Because these nodes drain regions of the lung and retroperitoneal space, they can reflect either lymphomas, other cancers, or infectious processes arising in these areas. Virchow's node is an enlarged left supraclavicular node infiltrated with metastatic cancer from a gastrointestinal primary. Metastases to supraclavicular nodes also occur from lung, breast, testis, or ovarian cancers. Tuberculosis, sarcoidosis, and toxoplasmosis are nonneoplastic causes of supraclavicular adenopathy. Axillary adenopathy is usually due to injuries or localized infections of the ipsilateral upper extremity. Malignant causes include melanoma or lymphoma and, in women, breast cancer. Inguinal lymphadenopathy is usually secondary to infections or trauma of the lower extremities and may accompany sexually transmitted diseases such as lymphogranuloma venereum, primary syphilis, genital herpes, or chancroid. These nodes may also be involved by lymphomas and metastatic cancer from primary lesions of the rectum, genitalia, or lower extremities (melanoma).

The size and texture of the lymph node(s) and the presence of pain are useful parameters in evaluating a patient with lymphadenopathy. Nodes <1.0 cm^2 in area (1.0 ´ 1.0 cm or less) are almost always secondary to benign, nonspecific reactive causes. In one retrospective analysis of younger patients (9 to 25 years) who had a lymph node biopsy, a maximum diameter of >2 cm served as one discriminant for predicting that the biopsy would reveal malignant or granulomatous disease. Another study showed that a lymph node size of 2.25 cm^2 (1.5 cm ´ 1.5 cm) was the best discriminating limit for distinguishing malignant or granulomatous lymphadenopathy from other causes of lymphadenopathy. Patients with node(s) £1.0 cm^2should be observed after excluding infectious mononucleosis and/or toxoplasmosis unless there are symptoms and signs of an underlying systemic illness.

The texture of lymph nodes may be described as soft, firm, rubbery, hard, discrete, matted, tender, movable, or fixed. Tenderness is found when the capsule is stretched during rapid enlargement, usually secondary to an inflammatory process. Some malignant diseases such as acute leukemia may produce rapid enlargement and pain in the nodes. Nodes involved by lymphoma tend to be large, discrete, symmetric, rubbery, firm, mobile, and nontender. Nodes containing metastatic cancer are often hard, nontender, and nonmovable because of fixation to surrounding tissues. The coexistence of splenomegaly in the patient with lymphadenopathy implies a systemic illness such as infectious mononucleosis, lymphoma, acute or chronic leukemia,SLE, sarcoidosis, toxoplasmosis, cat-scratch disease, or other less common hematologic disorders. The patient's story should provide helpful clues about the underlying systemic illness.

Nonsuperficial presentations (thoracic or abdominal) of adenopathy are usually detected as the result of a symptom-directed diagnostic workup. Thoracic adenopathy may be detected by routine chest roentgenography or during the workup for superficial adenopathy. It may also be found because the patient complains of a cough or wheezing from airway compression; hoarseness from recurrent laryngeal nerve involvement; dysphagia from esophageal compression; or swelling of the neck, face, or arms secondary to compression of the superior vena cava or subclavian vein. The differential diagnosis of mediastinal and hilar adenopathy includes primary lung disorders and systemic illnesses that characteristically involve mediastinal or hilar nodes. In the young, mediastinal adenopathy is associated with infectious mononucleosis and sarcoidosis. In endemic regions, histoplasmosis can cause unilateral paratracheal lymph node involvement that mimics lymphoma. Tuberculosis can also cause unilateral adenopathy. In older patients, the differential diagnosis includes primary lung cancer (especially among smokers), lymphomas, metastatic carcinoma (usually lung), tuberculosis, fungal infection, and sarcoidosis.

Enlarged intraabdominal or retroperitoneal nodes are usually malignant. Although tuberculosis may present as mesenteric lymphadenitis, these masses usually contain lymphomas or, in young men, germ cell tumors.

Laboratory Investigation The laboratory investigation of patients with lymphadenopathy must be tailored to elucidate the etiology suspected from the patient's history and physical findings. One study from a family practice clinic evaluated 249 younger patients with "enlarged lymph nodes, not infected" or "lymphadenitis." No laboratory studies were obtained in 51%. When studies were performed, the most common were a complete blood count (33%), throat culture (16%), chest x-ray (12%), or monospot test (10%). Only eight patients (3%) had a node biopsy, and half of those were normal or reactive. The complete blood count can provide useful data for the diagnosis of acute or chronic leukemias,EBV orCMVmononucleosis, lymphoma with a leukemic component, pyogenic infections, or immune cytopenias in illnesses such asSLE. Serologic studies may demonstrate antibodies specific to components of EBV, CMV, HIV, and other viruses; *Toxoplasma gondii*; *Brucella*; etc. If SLE is suspected, then antinuclear and anti-DNA antibody studies are warranted.

The chest x-ray is usually negative, but the presence of a pulmonary infiltrate or mediastinal lymphadenopathy would suggest tuberculosis, histoplasmosis, sarcoidosis, lymphoma, primary lung cancer, or metastatic cancer and demands further

investigation.

A variety of imaging techniques [computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, color Doppler ultrasonography] have been employed to differentiate benign from malignant lymph nodes, especially in patients with head and neck cancer. CT and MRI are comparably accurate (65 to 90%) in the diagnosis of metastases to cervical lymph nodes. Ultrasonography has been used to determine the long (L) axis, short (S) axis, and a ratio of long to short axis in cervical nodes. An L/S ratio of <2.0 has a sensitivity and a specificity of 95% for distinguishing benign and malignant nodes in patients with head and neck cancer. This ratio has greater specificity and sensitivity than palpation or measurement of either the long or the short axis alone.

The indications for lymph node biopsy are imprecise, yet it is a valuable diagnostic tool. The decision to biopsy may be made early in a patient's evaluation or delayed for up to 2 weeks. Prompt biopsy should occur if the patient's history and physical findings suggest a malignancy; examples include a solitary, hard, nontender cervical node in an older patient who is a chronic user of tobacco; supraclavicular adenopathy; and solitary or generalized adenopathy that is firm, movable, and suggestive of lymphoma. If a primary head and neck cancer is suspected as the basis of a solitary, hard cervical node, then a carefulENTexamination should be performed. Any mucosal lesion that is suspicious for a primary neoplastic process should be biopsied first. If no mucosal lesion is detected, an excisional biopsy of the largest node should be performed. Fine-needle aspiration should not be performed as the first diagnostic procedure. Most diagnoses require more tissue than such aspiration can provide and it often delays a definitive diagnosis. Fine-needle aspiration should be reserved for thyroid nodules and for confirmation of relapse in patients whose primary diagnosis is known. If the primary physician is uncertain about whether to proceed to biopsy, consultation with a hematologist or medical oncologist should be helpful. In primary care practices, fewer than 5% of lymphadenopathy patients will require a biopsy. That percentage will be considerably larger in referral practices, i.e., hematology, oncology, or otolaryngology (ENT).

Two groups have reported algorithms that they claim will identify more precisely those lymphadenopathy patients who should have a biopsy. Both reports were retrospective analyses in referral practices. The first study involved patients 9 to 25 years of age who had a node biopsy performed. Three variables were identified that predicted those young patients with peripheral lymphadenopathy who should undergo biopsy; lymph node size >2 cm in diameter and abnormal chest x-ray had positive predictive value, whereas recentENTsymptoms had negative predictive values. The second study evaluated 220 lymphadenopathy patients in a hematology unit and identified five variables [lymph node size, location (supraclavicular or non-supraclavicular), age (>40 years or <40 years), texture (nonhard or hard), and tenderness] that were utilized in a mathematical model to identify those patients requiring a biopsy. Positive predictive value was found for age >40 years, supraclavicular location, node size >2.25 cm_2, hard texture, and lack of pain or tenderness. Negative predictive value was evident for age <40 years, node size<1.0 cm_2, nonhard texture, and tender or painful nodes. Ninety-one percent of those who required biopsy were correctly classified by this model. Since both of these studies were retrospective analyses and one was limited to young patients, it is not known how useful these models would be if applied prospectively in a primary care

setting.

Most lymphadenopathy patients do not require a biopsy, and at least half require no laboratory studies. If the patient's history and physical findings point to a benign cause for lymphadenopathy, then careful follow-up at a 2- to 4-week interval can be employed. The patient should be instructed to return for reevaluation if the node(s) increase in size. Antibiotics are not indicated for lymphadenopathy unless there is strong evidence of a bacterial infection. Glucocorticoids should not be used to treat lymphadenopathy because their lympholytic effect obscures some diagnoses (lymphoma, leukemia, Castleman's disease) and they contribute to delayed healing or activation of underlying infections. An exception to this statement is the life-threatening pharyngeal obstruction by enlarged lymphoid tissue in Waldeyer's ring that is occasionally seen in infectious mononucleosis.

SPLENOMEGALY

STRUCTURE AND FUNCTION OF THE SPLEEN

The spleen is a reticuloendothelial organ that has its embryologic origin in the dorsal mesogastrium at about 5 weeks' gestation. It arises in a series of hillocks, migrates to its normal adult location in the left upper quadrant (LUQ), and is attached to the stomach via the gastrolienal ligament and to the kidney via the lienorenal ligament. When the hillocks fail to unify into a single tissue mass, accessory spleens may develop in around 20% of persons. The function of the spleen has been elusive. Galen believed it was the source of "black bile" or melancholia, and the word *hypochondria* (literally, beneath the ribs) and the idiom "to vent one's spleen" attest to the beliefs that the spleen had an important influence on the psyche and emotions. In humans, its normal physiologic roles seem to be the following:

1. Maintenance of quality control over erythrocytes in the red pulp by removal of senescent and defective red blood cells. The spleen accomplishes this function through a unique organization of its parenchyma and vasculature (Fig. 63-1).

2. Synthesis of antibodies in the white pulp.

3. The removal of antibody-coated bacteria and antibody-coated blood cells from the circulation.

An increase in these normal functions may result in splenomegaly.

The spleen is composed of red pulp and white pulp, which are Malpighi's terms for the red blood-filled sinuses and reticuloendothelial cell-lined cords and the white lymphoid follicles arrayed within the red pulp matrix. The spleen is in the portal circulation. The reason for this is unknown but may relate to the fact that lower blood pressure allows less rapid flow and minimizes damage to normal erythrocytes. Blood flows into the spleen at a rate of about 150 mL/min through the splenic artery, which ultimately ramifies into central arterioles. Some blood goes from the arterioles to capillaries and then to splenic veins and out of the spleen, but the majority of blood from central arterioles flows into the macrophage-lined sinuses and cords. The blood entering the

sinuses reenters the circulation through the splenic venules, but the blood entering the cords is subjected to an inspection of sorts. In order to return to the circulation, the blood cells in the cords must squeeze through slits in the cord lining to enter the sinuses that lead to the venules. Old and damaged erythrocytes are less deformable and are retained in the cords, where they are destroyed and their components recycled. Red cell inclusion bodies such as parasites, nuclear residua (Howell-Jolly bodies), or denatured hemoglobin (Heinz bodies) are pinched off in the process of passing through the slits, a process called *pitting*. The culling of dead and damaged cells and the pitting of cells with inclusions appear to occur without significant delay since the blood transit time through the spleen is only slightly slower than in other organs.

The spleen is also capable of assisting the host in adapting to its hostile environment. It has at least three adaptational functions: (1) clearance of bacteria and particulates from the blood, (2) the generation of immune responses to certain invading pathogens, and (3) the generation of cellular components of the blood under circumstances in which the marrow is unable to meet the needs (i.e., extramedullary hematopoiesis). The latter adaptation is a recapitulation of the blood-forming function the spleen plays during gestation. In some animals, the spleen also serves a role in the vascular adaptation to stress because it stores red blood cells (often hemoconcentrated to higher hematocrits than normal) under normal circumstances and contracts under the influence ofb-adrenergic stimulation to provide the animal with an autotransfusion and improved oxygen-carrying capacity. However, the normal human spleen does not sequester or store red blood cells and does not contract in response to sympathetic stimuli. The normal human spleen contains approximately one-third of the total body platelets and a significant number of marginated neutrophils. These sequestered cells are available when needed to respond to bleeding or infection.

Approach to the Patient

Clinical Assessment The most common *symptoms* produced by diseases involving the spleen are pain and a heavy sensation in theLUQ. Massive splenomegaly may cause early satiety. Pain may result from acute swelling of the spleen with stretching of the capsule, infarction, or inflammation of the capsule. For many years, it was believed that splenic infarction was clinically silent, which at times is true. However, Soma Weiss, in his classic 1942 report of the self-observations by a Harvard medical student on the clinical course of subacute bacterial endocarditis, documented that severe LUQ and pleuritic chest pain may accompany thromboembolic occlusion of splenic blood flow. Vascular occlusion, with infarction and pain, is commonly seen in children with sickle cell crises. Rupture of the spleen, either from trauma or infiltrative disease that breaks the capsule, may result in intraperitoneal bleeding, shock, and death. The rupture itself may be painless.

A palpable spleen is the major *physical sign* produced by diseases affecting the spleen and suggests enlargement of the organ. The normal spleen is said to weigh less than 250 g, decreases in size with age, normally lies entirely within the rib cage, has a maximum cephalocaudad diameter of 13 cm by ultrasonography or maximum length of 12 cm and/or width of 7 cm by radionuclide scan, and is usually not palpable. However, a palpable spleen was found in 3% of 2200 asymptomatic, male, freshman college students. Follow-up at 3 years revealed that 30% of those students still had a palpable

spleen without any increase in disease prevalence. Ten-year follow-up found no evidence for lymphoid malignancies. Furthermore, in some tropical countries (e.g., New Guinea) the incidence of splenomegaly may reach 60%. Thus, the presence of a palpable spleen does not always equate with presence of disease. Even when disease is present, splenomegaly may not reflect the primary disease, but rather a reaction to it. For example, in patients with Hodgkin's disease, only two-thirds of the palpable spleens show involvement by the cancer.

Physical examination of the spleen utilizes primarily the techniques of palpation and percussion. Inspection may reveal a fullness in theLUQ that descends on inspiration, a finding associated with a massively enlarged spleen. Auscultation may reveal a venous hum or a friction rub.

Palpation can be accomplished by bimanual palpation, ballotment, and palpation from above (Middleton maneuver). For bimanual palpation, which is at least as reliable as the other techniques, the patient is supine with flexed knees. The examiner's left hand is placed on the lower rib cage and pulls the skin toward the costal margin, allowing the fingertips of the right hand to feel the tip of the spleen as it descends while the patient inspires slowly, smoothly, and deeply. Palpation is begun with the right hand in the left lower quadrant with gradual movement toward the left costal margin, thereby identifying the lower edge of a massively enlarged spleen. When the spleen tip is felt, the finding is recorded as centimeters below the left costal margin at some arbitrary point, i.e., 10 to 15 cm, from the midpoint of the umbilicus or the xiphisternal junction. This allows other examiners to compare findings or the initial examiner to determine changes in size over time. Bimanual palpation in the right lateral decubitus position adds nothing to the supine examination.

Percussion for splenic dullness is accomplished with any of three techniques described by Nixon, Castell, or Barkun:

1. *Nixon's method*: The patient is placed on the right side so that the spleen lies above the colon and stomach. Percussion begins at the lower level of pulmonary resonance in the posterior axillary line and proceeds diagonally along a perpendicular line toward the lower midanterior costal margin. The upper border of dullness is normally 6 to 8 cm above the costal margin. Dullness greater than 8 cm in an adult is presumed to indicate splenic enlargement.

2. *Castell's method*: With the patient supine, percussion in the lowest intercostal space in the anterior axillary line (8th or 9th) produces a resonant note if the spleen is normal in size. This is true during expiration or full inspiration. A dull percussion note on full inspiration suggests splenomegaly.

3. *Percussion of Traube's semilunar space*: The borders of Traube's space are the sixth rib superiorly, the left midaxillary line laterally, and the left costal margin inferiorly. The patient is supine with the left arm slightly abducted. During normal breathing, this space is percussed from medial to lateral margins, yielding a normal resonant sound. A dull percussion note suggests splenomegaly.

Studies comparing methods of percussion and palpation with a standard of

ultrasonography or scintigraphy have revealed sensitivity of 56 to 71% for palpation and 59 to 82% for percussion. Reproducibility among examiners is better for palpation than percussion. Both techniques are less reliable in obese patients or patients who have just eaten. Thus, the physical examination techniques of palpation and percussion are imprecise at best. It has been suggested that the examiner perform percussion first and, if positive, proceed to palpation; if the spleen is palpable, then one can be reasonably confident that splenomegaly exists. However, not allLUQmasses are enlarged spleens; gastric or colon tumors and pancreatic or renal cysts or tumors can mimic splenomegaly.

The presence of an enlarged spleen can be more precisely determined, if necessary, by liver-spleen radionuclide scan,CT,MRI, or ultrasonography. The latter technique is the current procedure of choice for routine assessment of spleen size (normal = a maximum cephalocaudad diameter of 13 cm) because it has high sensitivity and specificity and is safe, noninvasive, quick, mobile, and less costly. Nuclear medicine scans are accurate, sensitive, and reliable but are costly, require greater time to generate data, and utilize immobile equipment. They have the advantage of demonstrating accessory splenic tissue. CT and MRI provide accurate determination of spleen size, but the equipment is immobile and the procedures are expensive. MRI appears to offer no advantage over CT. Changes in spleen structure such as mass lesions, infarcts, inhomogeneous infiltrates, and cysts are more readily assessed by CT, MRI, or ultrasonography. None of these techniques is very reliable in the detection of patchy infiltration (e.g., Hodgkin's disease).

Differential Diagnosis Many of the diseases associated with splenomegaly are listed in Table 63-2. They are grouped according to the presumed basic mechanisms responsible for organ enlargement:

1. Hyperplasia or hypertrophy related to a particular splenic function such as reticuloendothelial hyperplasia (work hypertrophy) in diseases such as hereditary spherocytosis or thalassemia syndromes that require removal of large numbers of defective red blood cells; immune hyperplasia in response to systemic infection (infectious mononucleosis, subacute bacterial endocarditis) or to immunologic diseases (immune thrombocytopenia,SLE, Felty's syndrome).

2. Passive congestion due to decreased blood flow from the spleen in conditions that produce portal hypertension (cirrhosis, Budd-Chiari syndrome, congestive heart failure).

3. Infiltrative diseases of the spleen (lymphomas, metastatic cancer, amyloidosis, Gaucher's disease, myeloproliferative disorders with extramedullary hematopoiesis).

The differential diagnostic possibilities are much fewer when the spleen is "massively enlarged," that is, it is palpable more than 8 cm below the left costal margin or its drained weight is ^{3}1000 g (Table 63-3). The vast majority of such patients will have non-Hodgkin's lymphoma, chronic lymphocytic leukemia, hairy cell leukemia, chronic myelogenous leukemia, myelofibrosis with myeloid metaplasia, or polycythemia vera.

Laboratory Assessment The major laboratory abnormalities accompanying splenomegaly are determined by the underlying systemic illness. Erythrocyte counts

may be normal, decreased (thalassemia major syndromes,SLE, cirrhosis with portal hypertension), or increased (polycythemia vera). Granulocyte counts may be normal, decreased (Felty's syndrome, congestive splenomegaly, leukemias), or increased (infections or inflammatory disease, myeloproliferative disorders). Similarly, the platelet count may be normal, decreased when there is enhanced sequestration or destruction of platelets in an enlarged spleen (congestive splenomegaly, Gaucher's disease, immune thrombocytopenia), or increased in the myeloproliferative disorders such as polycythemia vera.

The complete blood count may reveal cytopenia of one or more blood cell types, which should suggest *hypersplenism*. This condition is characterized by splenomegaly, cytopenia(s), normal or hyperplastic bone marrow, and a response to splenectomy. The latter characteristic is less precise because reversal of cytopenia, particularly granulocytopenia, is sometimes not sustained after splenectomy. The cytopenias result from increased destruction of the cellular elements secondary to reduced flow of blood through enlarged and congested cords (congestive splenomegaly) or to immune-mediated mechanisms. In hypersplenism, various cell types usually have normal morphology on the peripheral blood smear, although the red cells may be spherocytic due to loss of surface area during their longer transit through the enlarged spleen. The increased marrow production of red cells should be reflected as an increased reticulocyte production index, although the value may be less than expected due to increased sequestration of reticulocytes in the spleen.

The need for additional laboratory studies is dictated by the differential diagnosis of the underlying illness of which splenomegaly is a manifestation.

SPLENECTOMY

Splenectomy is infrequently performed for diagnostic purposes, especially in the absence of clinical illness or other diagnostic tests that suggest underlying disease. More often splenectomy is performed for staging the extent of disease in patients with Hodgkin's disease, for symptom control in patients with massive splenomegaly, for disease control in patients with traumatic splenic rupture, or for correction of cytopenias in patients with hypersplenism or immune-mediated destruction of one or more cellular blood elements. Splenectomy is necessary for routine staging of patients with Hodgkin's disease only in those with clinical stage I or II disease in whom radiation therapy alone is contemplated as the treatment. Noninvasive staging of the spleen in Hodgkin's disease is not a sufficiently reliable basis for treatment decisions because one-third of normal-sized spleens will be involved with Hodgkin's disease and one-third of enlarged spleens will be tumor-free. Although splenectomy in chronic myelogenous leukemia does not affect the natural history of disease, removal of the massive spleen usually makes patients significantly more comfortable and simplifies their management by significantly reducing transfusion requirements. Splenectomy is an effective secondary or tertiary treatment for two chronic B cell leukemias, hairy cell leukemia and prolymphocytic leukemia, and for the very rare splenic mantle cell or marginal zone lymphoma. Splenectomy in these diseases may be associated with significant tumor regression in bone marrow and other sites of disease. Similar regressions of systemic disease have been noted after splenic irradiation in some types of lymphoproliferative disease, especially chronic lymphocytic leukemia and prolymphocytic leukemia. This

has been termed the *abscopal effect*. Such systemic tumor responses to local therapy directed at the spleen suggest that there may be some hormone or growth factor produced by the spleen that affects tumor cell proliferation, but this conjecture is not yet substantiated. The most common indication for splenectomy is traumatic or iatrogenic splenic rupture. In a fraction of patients with splenic rupture, peritoneal seeding of splenic fragments can lead to splenosis -- the presence of multiple rests of spleen tissue not connected to the portal circulation. This ectopic spleen tissue may cause pain or gastrointestinal obstruction, as in endometriosis. A large number of hematologic, immunologic, and congestive causes of splenomegaly can lead to destruction of one or more cellular blood elements. In the majority of such cases, splenectomy can correct the cytopenias, particularly anemia and thrombocytopenia. Perhaps the only contraindication to splenectomy is the presence of marrow failure, in which the enlarged spleen is the only source of hematopoietic tissue.

The absence of the spleen has minimal long-term effects on the hematologic profile. In the immediate postsplenectomy period, there may be some leukocytosis (up to 25,000/uL) and thrombocytosis (up to 1×10^6/uL), but within 2 to 3 weeks, blood cell counts and survival of each cell lineage are usually normal. The chronic manifestations of splenectomy are marked variation in size and shape of erythrocytes (anisocytosis, poikilocytosis) and the presence of Howell-Jolly bodies (nuclear remnants), Heinz bodies (denatured hemoglobin), basophilic stippling, and an occasional nucleated erythrocyte in the peripheral blood. When such erythrocyte abnormalities appear in a patient whose spleen has not been removed, one should suspect splenic infiltration by tumor that has interfered with its normal culling and pitting function.

The most serious consequence of splenectomy is increased susceptibility to bacterial infections, particularly those with capsules such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and some gram-negative enteric organisms. Patients under age 20 years are particularly susceptible to overwhelming sepsis with *S. pneumoniae*, and the overall actuarial risk of sepsis in patients who have had their spleens removed is about 7% in 10 years. The case-fatality rate for pneumococcal sepsis in splenectomized patients is 50 to 80%. About 25% of patients without spleens will develop a serious infection at some time in their life. The frequency is highest within the first 3 years after splenectomy. About 15% of the infections are polymicrobial, and lung, skin, and blood are the most common sites. No increased risk of viral infection has been noted in patients who have no spleen. The susceptibility to bacterial infections relates to the inability to remove opsonized bacteria from the bloodstream and a defect in making antibodies to T cell-independent antigens such as the polysaccharide components of bacterial capsules. Pneumococcal vaccine (23-valent polysaccharide vaccine) should be administered to all patients 2 weeks before elective splenectomy. The Advisory Committee on Immunization Practices recommends that even splenectomized patients receive pneumococcal vaccine with a repeat vaccination 5 years later. Efficacy has not been proven in this setting, and the recommendation discounts the possibility that administration of the vaccine may actually lower the titer of specific pneumococcal antibodies. A more effective pneumococcal vaccine that involves T cells in the response is in development. The vaccine to *H. influenzae* should also be given to patients in whom elective splenectomy is planned. No other vaccines are routinely recommended in this setting.

Splenectomized patients should be educated to consider any unexplained fever as a medical emergency. Prompt medical attention with evaluation and treatment of suspected bacteremia may be life-saving. Routine chemoprophylaxis with oral penicillin can result in the emergence of drug-resistant strains and is not recommended.

In addition to an increased susceptibility to bacterial infections, splenectomized patients are also more susceptible to the parasitic disease babesiosis. The splenectomized patient should avoid areas where the parasite *Babesia* is endemic (e.g., Cape Cod, MA).

Surgical removal of the spleen is an obvious cause of *hyposplenism*. Patients with sickle cell disease often suffer from autosplenectomy as a result of splenic destruction by the numerous infarcts associated with sickle cell crises during childhood. Indeed, the presence of a palpable spleen in a patient with sickle cell disease after age 5 suggests a coexisting hemoglobinopathy, e.g., thalassemia or hemoglobin C. In addition, patients who receive splenic irradiation for a neoplastic or autoimmune disease are also functionally hyposplenic. The term *hyposplenism* is preferred to *asplenism* in referring to the physiologic consequences of splenectomy because asplenia is a rare, specific, and fatal congenital abnormality in which there is a failure of the left side of the coelomic cavity (which includes the splenic anlagen) to develop normally. Infants with asplenia have no spleens, but that is the least of their problems. The right side of the developing embryo is duplicated on the left so there is liver where the spleen should be, there are two right lungs, and the heart comprises two right atria and two right ventricles.

64. DISORDERS OF GRANULOCYTES AND MONOCYTES - *Steven M. Holland*, *John I. Gallin*

Leukocytes are the major cells comprising inflammatory and immune responses and include neutrophils, T and B lymphocytes, natural killer (NK) cells, monocytes, eosinophils, and basophils. These cells have specific functions, such as antibody production by B lymphocytes or destruction of bacteria by neutrophils, but in no single infectious disease is the exact role of the cell types completely established. Thus, whereas neutrophils are classically thought to be critical to host defense against bacteria, they may also play important roles in defense against viral infections.

The blood delivers leukocytes to the various tissues from the bone marrow, where they are produced. Normal blood leukocyte counts are given in the Appendix (Tables A-7 and A-8). The various leukocytes are derived from a common stem cell in the bone marrow. Three-fourths of the nucleated cells of bone marrow are committed to the production of leukocytes. Leukocyte maturation in the marrow is under the regulatory control of a number of different factors, known as colony stimulating factors and interleukins (Chap. 104). Because an alteration in the number and type of leukocytes is often associated with disease processes, total white blood count (WBC) (cells per microliter) and differential counts are informative. The lymphocytes and basophils are discussed inChaps. 305 and310, respectively. This chapter focuses on the neutrophils, monocytes, and eosinophils.

NEUTROPHILS

MATURATION

Important events in neutrophil life are summarized inFig. 64-1. In normal humans, neutrophils are produced only in the bone marrow. The minimum number of stem cells necessary to support hematopoiesis is estimated to be 400 to 500. Human blood monocytes, tissue macrophages, and stromal cells produce colony stimulating factors, hormones required for the growth of monocytes and neutrophils in the bone marrow. The hematopoietic system not only produces enough neutrophils (~1.3×10^{11}cells per 80-kg person per day) to carry out physiologic functions but also has a large reserve stored in the marrow which can be mobilized in response to inflammation or infection. An increase in the number of blood neutrophils is called neutrophilia, and the presence of immature cells is termed a shift to the left. A decrease in the number of blood neutrophils is called neutropenia.

Neutrophils and monocytes evolve from pluripotent stem cells under the influence of cytokines and colony stimulating factors (Fig. 64-2). The proliferation phase through the metamyelocyte takes about 1 week, while the maturation phase from metamyelocyte to mature neutrophil takes another week. The myeloblast is the first recognizable precursor cell and is followed by the *promyelocyte* (Plate V-23). The promyelocyte evolves when the classic lysosomal granules, called the *primary* or *azurophil granules*, are produced. The primary granules contain hydrolases, elastase, myeloperoxidase, cationic proteins, and bactericidal/permeability-increasing protein, which is important for killing gram-negative bacteria. Azurophil granules also contain *defensins*, a family of cysteine-rich polypeptides with broad antimicrobial activity against bacteria, fungi, and

certain enveloped viruses. The promyelocyte divides to produce the *myelocyte*, a cell responsible for the synthesis of the *specific* or *secondary granules* which contain unique (specific) constituents such as lactoferrin, vitamin B_{12}-binding proteins, membrane components of the nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase required for hydrogen peroxide production, histaminase, and receptors for certain chemoattractants and adherence-promoting factors (CR3) as well as receptors for the basement membrane component, laminin. The secondary granules do not contain acid hydrolases and therefore are not classic lysosomes. Packaging of secondary granule contents during myelopoiesis is controlled by CCAAT/enhancer binding protein-e. Secondary granule contents are readily released extracellularly, and their mobilization is important in modulating inflammation. During the final stages of maturation no cell division occurs, and the cell passes through the *metamyelocyte* stage and then to the *band* neutrophil with a sausage-shaped nucleus (Plate V-35). As the band cell matures, the nucleus assumes a lobulated configuration. The nucleus of neutrophils normally contains up to four segments. Excessive segmentation (more than five nuclear lobes) may be a manifestation of folate or vitamin B_{12}deficiency (Plate V-38). The Pelger-Huet anomaly (Plate V-34B), an infrequent dominant benign inherited trait, results in neutrophils with distinctive bilobed nuclei that must be distinguished from band forms. The physiologic role of the multilobed nucleus of neutrophils is unknown, but it may allow great deformation of neutrophils during migration into tissues at sites of inflammation.

In severe acute bacterial infection, prominent neutrophil cytoplasmic granules called *toxic granulations* are occasionally seen (Plate V-11). Toxic granulations are immature or abnormally staining azurophil granules. Cytoplasmic inclusions, also called *Dohle bodies* (Plate V-35), can be seen during infection and are fragments of ribosome-rich endoplasmic reticulum. Large neutrophil vacuoles are often present in acute bacterial infection and probably represent pinocytosed (internalized) membrane.

Neutrophils are heterogeneous in function. Monoclonal antibodies have been developed that recognize only a subset of mature neutrophils. The meaning of neutrophil heterogeneity is not known.

MARROW RELEASE AND CIRCULATING COMPARTMENTS

Specific signals, including interleukin (IL) 1, tumor necrosis factor-a (TNF-a), the colony stimulating factors, complement fragment C3e, and perhaps other cytokines mobilize leukocytes from the bone marrow and deliver them to the blood in an unstimulated state. Under normal conditions, about 90% of the neutrophil pool is in the bone marrow, 2 to 3% in the circulation, and the remainder in the tissues (Fig. 64-3).

The circulating pool exists in two dynamic compartments: one freely flowing and one marginated. The freely flowing pool is about one-half the neutrophils in the basal state and is composed of those cells that are in the blood and not in contact with the endothelium. Marginated leukocytes are those that are in close physical contact with the endothelium (Fig. 64-4). In the pulmonary circulation, where an extensive capillary bed (~1000 capillaries per alveolus) exists, margination occurs because the capillaries are about the same size as a mature neutrophil. Therefore, neutrophil fluidity and deformability are necessary to make the transit through the pulmonary bed. Increased

neutrophil rigidity and decreased deformability lead to augmented neutrophil trapping and margination in the lung. In contrast, in the systemic postcapillary venules, margination is mediated by the interaction of specific cell-surface molecules. *Selectins* are glycoproteins expressed on neutrophils and endothelial cells, among others, that cause a low-affinity interaction, resulting in "rolling" of the neutrophil along the endothelial surface. On neutrophils, the molecule L-selectin [cluster determinant (CD) 62L] binds to glycosylated proteins on endothelial cells [e.g., glycosylation-dependent cell adhesion molecule (GlyCAM1) and CD34]. Glycoproteins on neutrophils, most importantly sialyl-Lewis$_x$(SLe$_x$, CD15s), are targets for binding of selectins expressed on endothelial cells [E-selectin (CD62E) and P-selectin (CD62P)] and other leukocytes. In response to chemotactic stimuli from injured tissues (e.g., complement product C5a, leukotriene B$_4$,IL-8) or bacterial products [e.g., *N*-formylmethionylleucylphenylalanine (f-metleuphe)], neutrophil adhesiveness increases, and the cells "stick" to the endothelium through *integrins*. The integrins are leukocyte glycoproteins that exist as complexes of a common CD18 b-chain with CD11a (LFA-1), CD11b (also called either Mac-1, CR3, or the C3bi receptor), and CD11c (p150,95). CD11a/CD18 and CD11b/CD18 bind to specific endothelial receptors [intercellular adhesion molecules (ICAM) 1 and 2].

On cell stimulation, L-selectin is shed; receptors for chemoattractants and opsonins are mobilized; the phagocytes orient toward the chemoattractant source in the extravascular space, increase their motile activity (chemokinesis), and migrate directionally (chemotaxis) into tissues. The process of migration into tissues is called *diapedesis* and involves the crawling of neutrophils between postcapillary endothelial cells that open junctions between adjacent cells to permit leukocyte passage. Diapedesis involves platelet/endothelial cell adhesion molecule (PECAM) 1 (CD31), which is expressed on both the emigrating leukocyte and the endothelial cells. The endothelial responses (increased blood flow from increased vasodilation and permeability) are mediated by anaphylatoxins (e.g., C3a and C5a) as well as vasodilators such as histamine, bradykinin, serotonin, nitric oxide, vascular endothelial growth factor (VEGF), and prostaglandins E and I. Cytokines regulate some of these processes [e.g.,TNF-ainduction of VEGF, interferon (IFN) g inhibition of prostaglandin E].

In the healthy adult, most neutrophils leave the body by migration through the mucous membrane of the gastrointestinal tract. Normally, neutrophils spend a short time in the circulation (half-life, 6 to 7 h). Senescent neutrophils are cleared from the circulation by macrophages in the lung and spleen. Once in the tissues, neutrophils release enzymes, such as collagenase and elastase, that help establish abscess cavities. Neutrophils ingest pathogenic materials that have been opsonized by IgG and C3b. Fibronectin and the tetrapeptide tuftsin facilitate phagocytosis.

With phagocytosis comes a burst of oxygen consumption and activation of the hexose-monophosphate shunt. A membrane-associatedNADPHoxidase, consisting of membrane and cytosolic components, is assembled and catalyzes the reduction of oxygen to superoxide anion, which is then converted to hydrogen peroxide and other toxic oxygen products (e.g., hydroxyl radical). Hydrogen peroxide + chloride+ neutrophil myeloperoxidase generates hypochlorous acid (bleach), hypochlorite, and chlorine. These products oxidize and halogenate microorganisms and tumor cells and, when uncontrolled, can damage host tissue. Strongly cationic proteins, defensins, and

probably nitric oxide also participate in microbial killing. Other enzymes, such as lysozyme and acid proteases, help digest microbial debris. After 1 to 4 days in tissues neutrophils die. The apoptosis of neutrophils is also cytokine regulated; granulocyte colony stimulating factor (G-CSF) andIFN-gprevent their death. Under certain conditions, such as in delayed-type hypersensitivity, monocyte accumulation occurs within 6 to 12 h of initiation of inflammation. Neutrophils, monocytes, microorganisms in various states of digestion, and altered local tissue cells make up the inflammatory exudate, pus. Myeloperoxidase confers the characteristic green color to pus and may participate in turning off the inflammatory process by inactivating chemoattractants and immobilizing phagocytic cells.

Neutrophils respond to certain cytokines [IFN-g, granulocyte-macrophage colony stimulating factor (GM-CSF),IL-8] and produce cytokines and chemotactic signals [TNF-a, IL-8, macrophage inflammatory protein (MIP) 1] that modulate the inflammatory response. In the presence of fibrinogen, f-metleuphe or leukotriene B_4induces IL-8 production by neutrophils, providing autocrine amplification of inflammation. *Chemokines* (*chemo*attractant cyto*kines*) are small proteins produced by many different cell types, including endothelial cells, fibroblasts, epithelial cells, neutrophils, and monocytes, that regulate neutrophil and monocyte recruitment and activation. The chemokines transduce their signals through heterotrimeric G protein-linked receptors that have seven cell membrane-spanning domains, the same type of cell-surface receptor that mediates the response to the classical chemoattractants *N*-f-metleuphe and C5a. Four major groups of chemokines are recognized based on the cysteine structure near the N terminus: C, CC, CXC, and CXXXC. The CXC cytokines like IL-8 mainly attract neutrophils; CC chemokines likeMIP-1aattract lymphocytes, monocytes, eosinophils, and basophils; the C chemokine lymphotactin is T cell tropic; the CXXXC chemokine fractalkine attracts neutrophils, monocytes, and T cells. These molecules and their receptors not only regulate the trafficking and activation of inflammatory cells, but chemokine receptors serve as co-receptors for HIV infection (Chap. 309).

NEUTROPHIL ABNORMALITIES

A defect in the neutrophil life cycle can lead to dysfunction and compromised host defenses. Inflammation is often depressed, and the clinical result is often recurrent and severe bacterial and fungal infections. Aphthous ulcers of mucous membranes (gray ulcers without pus) and gingivitis and periodontal disease suggest a phagocytic cell disorder. Patients with congenital phagocyte defects can have infections within the first few days of life. Skin, ear, upper and lower respiratory tract, and bone infections are common. Sepsis and meningitis are rare. In some disorders the frequency of infection is variable, and patients can go for months or even years without major infection. Aggressive management of these congenital diseases has extended the life span of patients beyond 30 years.

Neutropenia The consequences of absent neutrophils are dramatic. Susceptibility to infectious diseases increases sharply when neutrophil counts fall below 1000 cells/uL. When the absolute neutrophil count (ANC; band forms and mature neutrophils combined) falls below 500 cells/uL, control of endogenous microbial flora (e.g., mouth, gut) is impaired; when the ANC is < 200/uL, the inflammatory process is absent. Neutropenia can be due to depressed production, increased peripheral destruction, or

excessive peripheral pooling. A falling neutrophil count or a significant decrease in the number of neutrophils below steady state levels, together with a failure to increase neutrophil counts in the setting of infection or other challenge, requires investigation. Acute neutropenia, such as that caused by cancer chemotherapy, is more likely to be associated with increased risk of infection than neutropenia of long duration (months to years) that reverses in response to infection or carefully controlled administration of endotoxin (see "Laboratory Diagnosis," below).

Some causes of inherited and acquired neutropenia are listed in Table 64-1. The most common neutropenias are iatrogenic, resulting from the use of cytotoxic or immunosuppressive therapies for malignancy or control of autoimmune disorders. These drugs cause neutropenia because they result in decreased production of rapidly growing progenitor (stem) cells of the marrow. Certain antibiotics such as chloramphenicol, trimethoprim-sulfamethoxazole, flucytosine, vidarabine, and the antiretroviral drug zidovudine may cause neutropenia by inhibiting proliferation of myeloid precursors. The marrow suppression is generally dose-related and dependent on continued administration of the drug. Recombinant humanG-CSFreverses this form of neutropenia.

Another important mechanism for iatrogenic neutropenia is the effect of drugs that serve as immune haptens and sensitize neutrophils or neutrophil precursors to immune-mediated peripheral destruction. This form of drug-induced neutropenia can be seen within 7 days of exposure to the drug; with previous drug exposure, resulting in preexisting antibodies, neutropenia may occur a few hours after administration of the drug. Although any drug can cause this form of neutropenia, the most frequent causes are commonly used antibiotics, such as sulfa-containing compounds, penicillins, and cephalosporins. Fever and eosinophilia also may be associated drug reactions, but often these signs are not present. Drug-induced neutropenia can be severe, but discontinuation of the sensitizing drug is sufficient for recovery, which is usually seen within 5 to 7 days and is complete by 10 days. Readministration of the sensitizing drug should be avoided, since abrupt neutropenia often will result. For this reason, diagnostic challenge should be avoided.

Autoimmune neutropenias caused by circulating antineutrophil antibodies are another form of acquired neutropenia that results in increased destruction of neutrophils. Acquired neutropenia also may be seen with viral infections, including infection with HIV. Acquired neutropenia may be cyclic in nature, occurring at intervals of several weeks. Acquired cyclic or stable neutropenia may be associated with an expansion of large granular lymphocytes (LGL), which may be T cells,NKcells, or NK-like cells. Patients with LGL lymphocytosis may have moderate blood and bone marrow lymphocytosis, neutropenia, polyclonal hypergammaglobulinemia, splenomegaly, rheumatoid arthritis, and absence of lymphadenopathy. Such patients may have a chronic and relatively stable course. Recurrent bacterial infections are frequent. Benign and malignant forms of this syndrome occur. In some patients, a spontaneous regression has occurred even after 11 years, suggesting an immunoregulatory defect as the basis for at least one form of the disorder. Glucocorticoids, cyclosporine,IFN-a, and nucleosides such as 2-chlorodeoxyadenosine each have induced remission.

Hereditary Neutropenias Hereditary neutropenias are rare and may manifest in early

childhood as a profound constant neutropenia or agranulocytosis. Congenital forms of neutropenia include Kostmann's syndrome (neutrophil count<100/uL), which is often fatal; more benign chronic idiopathic neutropenia (neutrophil count of 300 to 1500/uL); the cartilage-hair hypoplasia syndrome; Shwachman's syndrome associated with pancreatic insufficiency; myelokathexis, a congenital disorder characterized by neutrophil degeneration, hypersegmentation, and myeloid hyperplasia in the marrow associated with decreased expression of bcl-XL in myeloid precursors and accelerated apoptosis; and neutropenias associated with other immune defects (X-linked agammaglobulinemia, ataxia telangiectasia, IgA deficiency). Mutations in theG-CSFreceptor on chromosome 1 associated with poor response to G-CSF can occur with severe congenital neutropenia and predispose to myeloid malignancy. Hereditary cyclic neutropenia, an autosomal dominant trait, may occur in infancy and is characterized by a remarkably regular 3-week cycle. Hereditary cyclic neutropenia actually is cyclic hematopoiesis, due to mutations in the neutrophil elastase gene. Glucocorticoids and G-CSF blunt the cycling in some patients.

Maternal factors can be associated with neutropenia in the newborn. Transplacental transfer of IgG directed against antigens on fetal neutrophils can result in peripheral destruction. Drugs (e.g., thiazides) ingested during pregnancy can cause neutropenia in the newborn by either depressed production or peripheral destruction.

The presence of immunoglobulin directed toward neutrophils is seen in Felty's syndrome -- a triad of rheumatoid arthritis, splenomegaly, and neutropenia (Chap. 312). Patients with Felty's syndrome who respond to splenectomy with an increase in their neutrophil count also have lower postoperative serum neutrophil-binding IgG. Some of these patients have neutropenia associated with an increased number ofLGL. Splenomegaly with peripheral trapping and destruction of neutrophils is also seen in lysosomal storage diseases and in portal hypertension.

Neutrophilia Neutrophilia results from increased neutrophil production, increased marrow release, or defective margination (Table 64-2). The most important acute cause of neutrophilia is infection. Neutrophilia from acute infection represents both increased production and increased marrow release. Increased production is also associated with chronic inflammation and certain myeloproliferative diseases. Increased marrow release and mobilization of the marginated leukocyte pool are induced by glucocorticoids. Release of epinephrine, as with vigorous exercise, excitement, or stress, will demarginate neutrophils in the spleen and lungs and double the neutrophil count in minutes. Leukocytosis with cell counts of 10,000 to 25,000/uL occurs in response to infection and other forms of acute inflammation and results from both release of the marginated pool and mobilization of marrow reserves. Persistent neutrophilia with cell counts of 30,000 to 50,000/uL or higher is called a *leukemoid reaction*, a term often used to distinguish this degree of neutrophilia from leukemia. In a leukemoid reaction, the circulating neutrophils are usually mature and not clonally derived.

Abnormal Neutrophil Function Inherited and acquired abnormalities of phagocyte function are listed in Table 64-3. The resulting diseases are best considered in terms of the functional defects of adherence, chemotaxis, and microbicidal activity. The distinguishing features of the important inherited disorders of phagocyte function are shown in Table 64-4.

Disorders of Adhesion Two types of leukocyte adhesion deficiency (LAD) have been described. Both are autosomal recessive traits and result in the inability of neutrophils to exit the circulation to sites of infection, leading to leukocytosis and increased susceptibility to infection (Fig. 64-4). Patients with LAD 1 have mutations in CD18, the common component of the integrins LFA-1, Mac-1, and p150,95, leading to a defect in tight adhesion between neutrophils and the endothelium. The heterodimer formed by CD18/CD11b (Mac-1) is also the receptor for the complement-derived opsonin C3bi (CR3). The CD18 gene is located on distal chromosome 21q. Variable expression of the defect determines the severity of clinical disease. Complete lack of expression of the leukocyte adhesion proteins results in the severe phenotype in which inflammatory cytokines do not increase the expression of leukocyte adhesion proteins on neutrophils or activated T and B cells. Neutrophils (and monocytes) from patients with LAD 1 adhere poorly to endothelial cells and protein-coated surfaces and exhibit defective spreading, aggregation, and chemotaxis. Patients with LAD 1 have recurrent bacterial and fungal infections involving skin, oral and genital mucosa, and respiratory and intestinal tracts; persistent leukocytosis (neutrophil counts of 15,000 to 20,000/uL) because cells do not marginate; and, in severe cases, a history of delayed separation of the umbilical stump. Infections, especially of the skin, may become necrotic with progressively enlarging borders, slow healing, and development of dysplastic scars. The most common bacteria are *Staphylococcus aureus* and enteric gram-negative bacteria. LAD 2 is caused by an abnormality of SLe^x(CD15s), the ligand on neutrophils that interacts with selectins on endothelial cells.

Disorders of Neutrophil Granules The most common neutrophil defect is *myeloperoxidase deficiency*, a primary granule defect inherited as an autosomal recessive trait; the incidence is ~1 in 2000 persons. Isolated myeloperoxidase deficiency is not associated with clinically compromised defenses, because other defense systems such as hydrogen peroxide generation are amplified. Microbicidal activity of neutrophils is delayed but not absent. Myeloperoxidase deficiency may make other acquired host defense defects more serious. An acquired form of myeloperoxidase deficiency occurs in myelomonocytic leukemia and acute myeloid leukemia.

Chediak-Higashi syndrome (CHS) is a rare disease with autosomal recessive inheritance due to defects in the lysosomal transport protein LYST, encoded by the gene *CHS1* at 1q42. This protein is required for normal packaging and disbursement of granules. Neutrophils (and all cells containing lysosomes) from patients with CHS characteristically have large granules (Plate V-34A). Patients with CHS have an increased number of infections resulting from many agents. CHS neutrophils and monocytes have impaired chemotaxis and abnormal rates of microbial killing due to slow rates of fusion of the lysosomal granules with phagosomes.NK cell function is also impaired.

Specific granule deficiency is a rare autosomal recessive disease in which the production of secondary granules and their contents, as well as primary granule component defensins, is defective. The defect in bacterial killing leads to severe bacterial infections. One type of specific granule deficiency is due to a mutation in the CCAAT/enhancer binding protein-e, a regulator of expression of granule components.

Chronic granulomatous disease Chronic granulomatous disease (CGD) is a group of disorders of granulocyte and monocyte oxidative metabolism. Although CGD is rare, with an incidence of 1 in 200,000 individuals, it is an important model of defective neutrophil oxidative metabolism. Most often CGD is inherited as an X-linked recessive trait; 30% of patients inherit the disease in an autosomal recessive pattern. Mutations in the genes for the four proteins that assemble at the plasma membrane account for all patients with CGD. Two proteins (a 91-kDa protein, abnormal in X-linked CGD, and a 22-kDa protein, absent in one form of autosomal recessive CGD) form the heterodimer cytochrome b-558 in the plasma membrane. Two other proteins (47 and 67 kDa, abnormal in the other autosomal recessive forms of CGD) are cytoplasmic in origin and interact with the cytochrome after cell activation to formNADPHoxidase, required for hydrogen peroxide production. Leukocytes from patients with CGD have severely diminished hydrogen peroxide production. The genes involved in each of the defects have been cloned and sequenced and the chromosome locations identified. Patients with CGD characteristically have increased numbers of infections due to catalase-positive microorganisms (organisms that destroy their own hydrogen peroxide). When patients with CGD become infected, they often have extensive inflammatory reactions, and lymph node suppuration is common despite the administration of appropriate antibiotics. Aphthous ulcers and chronic inflammation of the nares are often present. Granulomas are frequent and can obstruct the gastrointestinal or genitourinary tracts. The excessive inflammation probably reflects failure to degrade chemoattractants and antigens, leading to persistent neutrophil accumulation. Impaired killing of intracellular microorganisms by macrophages may lead to persistent cell-mediated immunity and granuloma formation.

MONONUCLEAR PHAGOCYTES

The mononuclear phagocyte system is composed of monoblasts, promonocytes, and monocytes in addition to the structurally diverse tissue macrophages that make up what was previously referred to as the reticuloendothelial system. Macrophages are long-lived phagocytic cells capable of many of the functions of neutrophils. They are also secretory cells that participate in many immunologic and inflammatory processes distinct from neutrophils. Monocytes leave the circulation by diapedesis more slowly than neutrophils and have a half-life in the blood of 12 to 24 h.

After blood monocytes arrive in the tissues, they differentiate into macrophages ("big eaters") with specialized functions suited for specific anatomic locations. Macrophages are particularly abundant in capillary walls of the lung, spleen, liver, and bone marrow, where they function to remove microorganisms and other noxious elements from the blood. Alveolar macrophages, liver Kupffer cells, splenic macrophages, peritoneal macrophages, bone marrow macrophages, lymphatic macrophages, brain microglial cells, and dendritic macrophages all have specialized functions. Macrophage-secreted products include lysozyme, neutral proteases, acid hydrolases, arginase, complement components, enzyme inhibitors (plasmin,a_2-macroglobulin), binding proteins (transferrin, fibronectin, transcobalamin II), nucleosides, and cytokines (TNF-a;IL-1, -8, -12, and -18). IL-1 (Chaps. 17 and305) has many functions, including initiating fever in the hypothalamus, mobilizing leukocytes from the bone marrow, activating lymphocytes and neutrophils. TNF-a is a pyrogen that duplicates many of the actions of IL-1 and plays an important role in the pathogenesis of gram-negative shock (Chap. 124). TNF-a

stimulates production of hydrogen peroxide and related toxic oxygen species by macrophages and neutrophils. In addition, TNF-a induces catabolic changes that contribute to the profound wasting (cachexia) associated with many chronic diseases.

Other macrophage-secreted products include reactive oxygen and nitrogen metabolites, bioactive lipids (arachidonic acid metabolites and platelet-activating factors), chemokines, colony stimulating factors, and factors stimulating fibroblast and vessel proliferation. Macrophages help regulate the replication of lymphocytes and participate in the killing of tumors, viruses, and certain bacteria (*Mycobacterium tuberculosis* and *Listeria monocytogenes*). Macrophages are key effector cells in the elimination of intracellular microorganisms. Their ability to fuse to form giant cells that coalesce into granulomas in response to some inflammatory stimuli is important in the elimination of intracellular microbes and is under the control ofIFN-g. Nitric oxide induced by IFN-g is an important effector against intracellular parasites including tuberculosis and *Leishmania*.

Macrophages play an important role in the immune response (Chap. 305). They process and present antigen to lymphocytes and secrete cytokines that modulate and direct lymphocyte development and function. Macrophages participate in autoimmune phenomena by removing immune complexes and other substances from the circulation. Polymorphisms in macrophage receptors for immunoglobulin (FcgRII) determine suceptibility to some infections and autoimmune diseases. In wound healing, they dispose of senescent cells, and they contribute to atheroma development. Macrophage elastase mediates development of emphysema from cigarette smoking.

DISORDERS OF THE MONONUCLEAR PHAGOCYTE SYSTEM

Many disorders of neutrophils extend to mononuclear phagocytes. Thus, drugs that suppress neutrophil production in the bone marrow can cause monocytopenia. Transient monocytopenia occurs after stress or glucocorticoid administration. Monocytosis is associated with tuberculosis, brucellosis, subacute bacterial endocarditis, Rocky Mountain spotted fever, malaria, and visceral leishmaniasis (kala azar). Monocytosis also occurs with malignancies, leukemias, myeloproliferative syndromes, hemolytic anemias, chronic idiopathic neutropenias, and granulomatous diseases such as sarcoidosis, regional enteritis, and some collagen vascular diseases. Patients withLAD, hyperimmunoglobulin E-recurrent infection (Job's) syndrome,CHS, andCGD all have defects in the mononuclear phagocyte system.

Monocyte cytokine production is impaired in some patients with disseminated nontuberculous mycobacterial infection who are not infected with HIV. Genetic defects inIFN-greceptors 1 and 2 impair monocyte killing of intracellular parasites, as do lesions in the potent IFN-g inducer,IL-12 and its receptor (Fig. 64-5).

Certain viral infections impair mononuclear phagocyte function. For example, influenza virus infection causes abnormal monocyte chemotaxis. Mononuclear phagocytes can be infected by HIV using CCR5, the chemokine receptor that acts as a coreceptor with CD4 for HIV. T lymphocytes produceIFN-g, which induces FcR expression and phagocytosis and stimulates hydrogen peroxide production by mononuclear phagocytes and neutrophils. In certain diseases, such as AIDS, IFN-g production may be deficient, while

in other diseases, such as T cell lymphomas, excessive release of IFN-g may be associated with erythrophagocytosis by splenic macrophages.

Monocytopenia occurs with acute infections, with stress, and after treatment with glucocorticoids. Monocytopenia also occurs in aplastic anemia, hairy cell leukemia, acute myeloid leukemia, and as a direct result of myelotoxic drugs.

EOSINOPHILS

Eosinophils and neutrophils share similar morphology, many lysosomal constituents, phagocytic capacity, and oxidative metabolism. Eosinophils express a specific chemoattractant receptor and respond to a specific chemokine, eotaxin. Little is known about the role of eosinophils. Eosinophils are much longer lived than neutrophils, and unlike neutrophils, tissue eosinophils can recirculate. During most infections, eosinophils are not important. However, in invasive helminthic infections, such as hookworm, schistosomiasis, strongyloidiasis, toxocariasis, trichinosis, filariasis, echinococcosis, and cysticercosis, the eosinophil plays a central role in host defense. Eosinophils are associated with bronchial asthma, cutaneous allergic reactions, and other hypersensitivity states.

The distinctive feature of the red-staining (Wright's stain) eosinophil granules is its crystalline core consisting of an arginine-rich protein (major basic protein) with histaminase activity, important in host defense against parasites. Eosinophil granules also contain a unique eosinophil peroxidase that catalyzes the oxidation of many substances by hydrogen peroxide and may facilitate killing of microorganisms.

Eosinophil peroxidase, in the presence of hydrogen peroxide and halide, initiates mast cell secretion in vitro and thereby promotes inflammation. Eosinophils contain cationic proteins, some of which bind to heparin and reduce its anticoagulant activity. Eosinophil-derived neurotoxin and eosinophil cationic protein are ribonucleases that can kill respiratory syncytial virus. Eosinophil cytoplasm contains Charcot-Leyden crystal protein, a hexagonal bipyramidal crystal first observed in a patient with leukemia and then in sputum of patients with asthma; this protein is lysophospholipase and may function to detoxify certain lysophospholipids.

Several factors enhance the eosinophil's function in host defense. T cell-derived factors enhance the ability of eosinophils to kill parasites. Mast cell-derived eosinophil chemotactic factor of anaphylaxis (ECFa) increases the number of eosinophil complement receptors and enhances eosinophil killing of parasites. Eosinophil colony stimulating factors (e.g.,IL-5) produced by macrophages increase eosinophil production in the bone marrow and activate eosinophils to kill parasites.

EOSINOPHILIA

Eosinophilia is the presence of >500 eosinophils per microliter of blood and is common in many settings besides parasite infection. Significant tissue eosinophilia can occur without an elevated blood count. The most common cause of eosinophilia is allergic reactions to drugs (iodides, aspirin, sulfonamides, nitrofurantoin, penicillins, and cephalosporins). Allergies such as hay fever, asthma, eczema, serum sickness, allergic

vasculitis, and pemphigus are associated with eosinophilia. Eosinophilia also occurs in collagen vascular diseases (e.g., rheumatoid arthritis, eosinophilic fasciitis, allergic angiitis, and periarteritis nodosa) and malignancies (e.g., Hodgkin's disease; mycosis fungoides; chronic myelogenous leukemia; and cancer of the lung, stomach, pancreas, ovary, or uterus), as well as in Job's syndrome andCGD. Eosinophilia commonly is present in the helminthic infections.IL-5 is the dominant eosinophil growth factor. Therapeutic administration of the cytokines IL-2 andGM-CSFfrequently leads to transient eosinophilia. The most dramatic hypereosinophilic syndromes are Loeffler's syndrome, tropical pulmonary eosinophilia, Loeffler's endocarditis, eosinophilic leukemia, and idiopathic hypereosinophilic syndrome (50,000 to 100,000/uL).

The idiopathic hypereosinophilic syndrome represents a heterogeneous group of disorders with the common feature of prolonged eosinophilia of unknown cause and organ system dysfunction, including the heart, central nervous system, kidneys, lungs, gastrointestinal tract, and skin. The bone marrow is involved in all affected individuals, but the most severe complications involve the heart and central nervous system. Clinical manifestations and organ dysfunction are highly variable. Eosinophils are found in the involved tissues and likely cause tissue damage by local deposition of toxic eosinophil proteins such as eosinophil cationic protein and major basic protein. In the heart, the pathologic changes lead to thrombosis, endocardial fibrosis, and restrictive endomyocardiopathy. The damage to tissues in other organ systems is similar. The mechanism for the hypereosinophilia is not known. Glucocorticoids usually induce remission. In patients who do not respond to glucocorticoids, a cytotoxic agent such as hydroxyurea has been used successfully to lower the peripheral blood eosinophil counts and to improve markedly the prognosis.IFN-aalso is effective in some patients, including those unresponsive to hydroxyurea. Aggressive medical and surgical approaches are used to manage patients with cardiovascular complications.

The *eosinophilia-myalgia syndrome* is a multisystem disease with prominent cutaneous, hematologic, and visceral manifestations that frequently evolves into a chronic course and can occasionally be fatal. The syndrome is characterized by eosinophilia (eosinophil count >1000/uL) and generalized disabling myalgias without other recognized causes. Eosinophil fasciitis, pneumonitis, and myocarditis; neuropathy culminating in respiratory failure; and encephalopathy may occur. The disease is caused by ingesting contaminants in L-tryptophan-containing products. Eosinophils, lymphocytes, macrophages, and fibroblasts accumulate in the affected tissues, but their role in pathogenesis is unclear. Activation of eosinophils and fibroblasts and the deposition of eosinophil-derived toxic proteins in affected tissues may contribute.IL-5 and transforming growth factor b have been implicated as potential mediators. Treatment is withdrawal of L-tryptophan-containing products and the administration of glucocorticoids. Most patients recover fully, remain stable, or show slow recovery; but the disease can be fatal in up to 5% of patients.

EOSINOPENIA

Eosinopenia occurs with stress, such as acute bacterial infection, and after treatment with glucocorticoids. The mechanism of eosinopenia of acute bacterial infection is unknown but is independent of endogenous glucocorticoids, since it occurs in animals after total adrenalectomy. There is no known adverse effect of eosinopenia.

HYPERIMMUNOGLOBULIN E-RECURRENT INFECTION SYNDROME

The hyperimmunoglobulin E-recurrent infection (HIE) syndrome or *Job's syndrome* is a rare multisystem disease in which the immune system, bone, teeth, lung and skin are affected. Abnormal chemotaxis is a variable feature. The molecular basis for this syndrome is not known, but some cases show autosomal dominant transmission with linkage to 4q. Patients with this syndrome have characteristic facies with broad nose, kyphoscoliosis and osteoporosis, and eczema. The primary teeth erupt normally but do not deciduate, often requiring extraction. Patients develop recurrent sinopulmonary and cutaneous infections that tend to be much less inflamed than appropriate for the degree of infection and have been referred to as "cold abscesses." A high degree of suspicion is required to diagnose infections in these patients, who may appear well despite extensive disease. The cold abscesses have been considered a reflection of impaired chemotaxis with too few phagocytes arriving too late, perhaps due to a lymphocyte factor inhibiting chemotaxis. However, the chemotactic defect in these patients is variable, and the fundamental basis for the impaired defenses is complex and poorly defined.

LABORATORY DIAGNOSIS AND MANAGEMENT

Initial studies ofWBC and differential and often a bone marrow examination are followed by assessment of bone marrow reserves (steroid challenge test), marginated circulating pool of cells (epinephrine challenge test), and marginating ability (endotoxin challenge test) (Fig. 64-3). In vivo assessment of inflammation is possible with a Rebuck skin window test or an in vivo blister assay, which measures the ability of leukocytes and inflammatory mediators to accumulate locally in the skin. In vitro tests of phagocyte aggregation, adherence, chemotaxis, phagocytosis, degranulation, and microbicidal activity (for *S. aureus*) may help pinpoint cellular or humoral lesions. Deficiencies of oxidative metabolism are detected with the nitroblue tetrazolium (NBT) dye test, which is based on the ability of products of oxidative metabolism to reduce yellow, soluble NBT to blue-black formazan, an insoluble material that can be seen microscopically. Studies of superoxide and hydrogen peroxide production may further define neutrophil oxidative function.

Patients with leukopenias or leukocyte dysfunction often have delayed inflammatory responses. Therefore, clinical manifestations may be minimal despite overwhelming infection, and unusual infections must always be suspected. Early signs of infection demand prompt, aggressive culturing for microorganisms, use of antibiotics, and surgical drainage of abscesses. Prolonged antibiotics are often required. In patients withCGD, prophylactic antibiotics (trimethoprim-sulfamethoxazole) diminish the frequency of life-threatening infections. Short courses of glucocorticoids may relieve gastrointestinal or genitourinary tract obstruction by granulomas in patients with CGD. Recombinant humanIFN-g, which nonspecifically stimulates phagocytic cell function, reduces the frequency of infections in patients with CGD by 70% and reduces the severity of infection. This effect of IFN-g in CGD is additive to the effect of prophylactic antibiotics. The recommended dose is 50 ug/$m_2$subcutaneously three times weekly. IFN-g also has been used successfully in the treatment of leprosy, nontuberculous mycobacteria, and visceral leishmaniasis.

Rigorous oral hygiene reduces but does not eliminate the discomfort of gingivitis, periodontal disease, and aphthous ulcers; chlorhexidine mouthwash and tooth brushing with a hydrogen peroxide-sodium bicarbonate paste helps many patients. Oral antifungal agents (fluconazole) have reduced mucocutaneous candidiasis in patients with Job's syndrome. Androgens, glucocorticoids, lithium, and immunosuppressive therapy have been used to restore myelopoiesis in patients with neutropenia due to impaired production. RecombinantG-CSF is useful in the management of certain forms of neutropenia due to depressed neutrophil production, especially that related to cancer chemotherapy. Patients with chronic neutropenia with evidence of a good bone marrow reserve need not receive prophylactic antibiotics.

Patients with constant or cyclic neutrophil counts <500/uL may benefit from prophylactic antibiotics andG-CSFduring periods of neutropenia. Oral trimethoprim-sulfamethoxazole (160/800 mg) twice daily can prevent infection. Increased numbers of fungal infections are not seen in patients withCGD on this regimen. Oral quinolones such as norfloxacin and ciprofloxacin are alternatives.

In the setting of cytotoxic chemotherapy with severe, persistent neutropenia, trimethoprim-sulfamethoxazole prevents *Pneumocystis carinii* pneumonia. These patients, and patients with phagocytic cell dysfunction, should avoid heavy exposure to airborne soil, dust, or decaying matter (mulch, manure), which are often rich in spores of *Aspergillus* or other fungi. Restriction of activities or social contact has no proven role in reducing risk of infection.

Cure of some congenital phagocyte defects is possible by bone marrow transplantation (Chap. 115). However, complications of bone marrow transplantation are still serious, and with rigorous medical care many patients with phagocytic disorders can go for years without a life-threatening infection. The identification of specific gene defects in patients withLAD 1 and CGDhas led to gene therapy trials in a number of genetic white cell disorders.

PART THREE -GENETICS AND DISEASE

65. PRINCIPLES OF HUMAN GENETICS - *J. Larry Jameson*, *Peter Kopp*

IMPACT OF GENETICS ON MEDICAL PRACTICE

New insights into the genetic basis of disease are being generated at an ever-increasing rate. This explosion of information was ignited by technological advances, such as the polymerase chain reaction (PCR) and automated DNA sequencing, and is fueled by rapid progress in the Human Genome Project (HGP). Although its promise is great, the integration of genetics into the everyday practice of medicine remains challenging. To date, the most significant impact of genetics has been to enhance our understanding of disease etiology and pathogenesis. In the near term, we can expect an even greater role for genetics in the diagnosis, prevention, and treatment of disease (Chaps. 68 and69).

Genetic disorders are more common than generally appreciated. It is estimated, for example, that 3% of pregnancies result in a child with a genetic disease or birth defect. About 10% of all pediatric and adult hospitalization admissions involve genetic diseases. This number would increase substantially if one included complex, multifactorial genetic diseases, such as diabetes or cardiovascular disease. The prevalence of genetic diseases, combined with their severity and chronic nature, imposes a great financial, social, and emotional burden on society.

Genetics has historically focused on chromosomal and metabolic disorders, reflecting the long-standing availability of techniques to diagnose these conditions. For example, conditions such as trisomy 21 (Down syndrome) or monosomy X (Turner syndrome) can be diagnosed using cytogenetics (Chap. 66). Likewise, many metabolic disorders (e.g., phenylketonuria, familial hypercholesterolemia) have been diagnosed using biochemical analyses. Recent advances in DNA diagnostics have extended the field of genetics to include virtually all medical specialties. In cardiology, for example, the molecular basis of inherited cardiomyopathies and ion channel defects that predispose to arrhythmias is being defined (Chaps. 230 and238). In neurology, genetics has unmasked the pathophysiology of a startling number of neurodegenerative disorders (Chap. 359). Hematology has evolved dramatically, from its incipient genetic descriptions of hemoglobinopathies to the current understanding of the molecular basis of red cell membrane defects, clotting disorders, and thrombotic disorders (Chaps. 106 and117). It is now abundantly clear that neoplasia and the acquisition of metastatic potential can be described in genetic terms (Chaps. 81,82, and83).

New concepts derived from genetic studies can sometimes clarify topics that were previously opaque. For example, although many different genetic defects can cause peripheral neuropathies, disruption of the normal folding of the myelin sheaths is frequently a common finalpathway (Chap. 379). Several genetic causes of obesity appear to converge on a physiologic pathway that involves products of the proopiomelanocortin polypeptide and the MC4R receptor, thus identifying a key mechanism for appetite control (Chap. 77). A similar situation is emerging for genetically distinct forms of Alzheimer disease, several of which lead to the formation of neurofibrillary tangles (Chap. 362). Increasingly, the identification of defective genes can

pinpoint cellular pathways involved in key physiologic processes. Examples include identification of the cystic fibrosis conductance regulator (*CFTR*) gene, the Duchenne's muscular dystrophy (*DMD*) gene, which encodes dystrophin, and the fibroblast growth factor receptor-3 (*FGFR3*) gene, which is responsible for achondroplastic dwarfism. Similarly, transgenic and gene "knockout" models can help to unravel the physiologic function of genes. Genetic approaches have proven invaluable for the detection of infectious pathogens and are used clinically to identify agents that are difficult to culture such as mycobacteria, viruses, and parasites (Chap. 121). In many cases, molecular genetics has improved the feasibility and accuracy of diagnostic testing, enhanced our understanding of pathophysiology, and is beginning to open new avenues for therapy, including gene therapy (Chap. 69).

It is increasingly apparent that genetic background plays some role in virtually every medical condition. This is particularly true when one considers disease susceptibility, the interaction of genetic background with the environment, host responses to illness and to pharmaceutical agents, or the metabolism of drugs. Although genetics has traditionally been viewed through the window of relatively rare single-gene diseases, many disorders such as hypertension, asthma, diabetes, susceptibility to cardiovascular disease, and mental illness are also affected by genetic background, as often evident from a patient's family history. These complex genetic traits involve the contributions of many different genes, as well as environmental factors that can modify disease risk (Chap. 68).

The astounding rate at which new genetic information is being generated creates a major challenge for physicians and other health care providers. The terminology and techniques used for discovery evolve continuously. Much genetic information presently resides in computer databases or is being published in basic science journals. The ongoing development of bioinformatics promises to simplify this seemingly daunting onslaught of new information. It is now possible, for example, to search for genetic testing centers through a web site (http://www.genlink.wustl.edu) that can be accessed conveniently by organ system, disease state, or gene. Monogenic disorders are summarized in a large, continuously evolving compendium, referred to as the *Online Mendelian Inheritance in Man* (OMIM;http://www.ncbi.nlm.nih.gov/omim/). These and other databases (http://www.genebank.com) will expand rapidly in conjunction with advances in theHGP.

CHROMOSOMES AND DNA REPLICATION

ORGANIZATION OF DNA INTO CHROMOSOMES

Size of the Human Genome The human genome is divided into 23 different chromosomes, including 22 autosomes (numbered 1 to 22) and the X and Y sex chromosomes. Adult cells are diploid, meaning they contain two homologous sets of 22 autosomes and a pair of sex chromosomes. Females have two X chromosomes (XX), whereas males have one X and one Y chromosome (XY). As a consequence of meiosis, germ cells (sperm or oocytes) are haploid and contain one set of 22 autosomes and one of the sex chromosomes. At the time of fertilization, the diploid genome is reconstituted by pairing of the homologous chromosomes from the mother and father. With each cell division (mitosis), chromosomes are replicated, paired, segregated, and

divided into two daughter cells (Chap. 66).

The genome is estimated to contain about 100,000 genes that are divided among the 23 chromosomes. A *gene* is a functional unit that is regulated by transcription (see below) and encodes a product, either RNA or protein, that exerts activity within the cell. Historically, genes were identified because they conferred specific traits that are transmitted from one generation to the next.

Human DNA is estimated to consist of about 3 billion base pairs (bp) of DNA per haploid genome. DNA length is normally measured in units of 1000 bp (kilobases, kb) or 1,000,000 bp (megabases, Mb). Not all DNA encodes genes. In fact, genes account for only about 10 to 15% of DNA. Much of the remaining DNA consists of highly repetitive sequences, the function of which is poorly understood. These repetitive DNA regions, along with nonrepetitive sequences that do not encode genes, may serve a structural role in the packaging of DNA into chromatin (DNA bound to histone proteins) and chromosomes (Fig. 65-1). If only 10% of DNA is expressed and there are 100,000 genes, the average gene would be about 3 kb in length. Although many genes are about this size, the range is quite broad. For example, some genes are only a few hundred bp, whereas others, like the *DMD* gene, are extraordinarily large (2 million bp).

Structure of DNA Each gene is composed of a linear polymer of DNA. DNA is a double-stranded helix composed of four different bases: adenine (A), thymidine (T), guanine (G), and cytosine (C). Adenine is paired to thymidine, and guanine is paired to cytosine, by hydrogen bond interactions that span the double helix. DNA has several remarkable features that make it ideal for the transmission of genetic information. It is relatively stable, at least in comparison to RNA or proteins. The double-stranded nature of DNA and its feature of strict base-pair complementarity permit faithful replication during cell division. As described below, complementarity also allows the transmission of genetic information from DNA ® RNA ® protein (Fig. 65-2). Messenger RNA (mRNA) is encoded by the so-called sense strand of the DNA double helix and is translated into proteins by ribosomes.

The presence of four different bases provides surprising genetic diversity. In the protein-coding regions of genes, the DNA bases are arranged into codons, a triplet of bases that specifies a particular amino acid. It is possible to arrange the four bases into 64 different triplet codons (4_3). Each codon specifies 1 of the 20 different amino acids, or a regulatory signal, such as stop translation. Because there are more codons than amino acids, the genetic code is degenerate; that is, most amino acids can be specified by several different codons. By arranging the codons in different combinations and in various lengths, it is possible to generate the tremendous diversity of primary protein structure.

REPLICATION OF DNA AND MITOSIS

Genetic information in DNA is transmitted to daughter cells under two different circumstances: (1) somatic cells divide by mitosis, allowing the diploid (2*n*) genome to replicate itself completely in conjunction with cell division; and (2) germ cells (sperm and ova) undergo meiosis, a process that enables the reduction of the diploid (2*n*) set of chromosomes to the haploid state (1*n*) (Chap. 66).

Prior to mitosis, cells exit the resting, or G_0 state, and enter the cell cycle (Chap. 82). After traversing a critical checkpoint in G_1, cells undergo DNA synthesis (S phase), during which the DNA in each chromosome is replicated, yielding two pairs of sister chromatids (2*n*® 4*n*). The process of DNA synthesis requires stringent fidelity in order to avoid transmitting errors to subsequent generations of cells. Genetic abnormalities of DNA mismatch/repair include xeroderma pigmentosum, Bloom syndrome, ataxia telangiectasia, and hereditary nonpolyposis colon cancer (HNPCC), among others. Many of these disorders strongly redispose to neoplasia because of the rapid acquisition of additional mutations (Chap. 81). After completion of DNA synthesis, cells enter G_2 and progress through a second checkpoint before entering mitosis. At this stage, the chromosomes condense and are aligned along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, divide and migrate to opposite poles of the cell (Fig. 66-3). After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two daughter cells are formed, thus restoring the diploid (2*n*) state.

ASSORTMENT AND SEGREGATION OF GENES DURING MEIOSIS

Meiosis occurs only in germ cells of the gonads. It shares certain features with mitosis but involves two distinct steps of cell division that reduce the chromosome number to the haploid state. In addition, there is active recombination that generates genetic diversity. During the first cell division, two sister chromatids (2*n*® 4*n*) are formed for each chromosome pair and there is an exchange of DNA between homologous paternal and maternal chromosomes. This process involves the formation of *chiasmata*, structures that correspond to the DNA segments that cross over between the maternal and paternal homologues (Fig. 65-3). Usually there is at least one crossover on each chromosomal arm; recombination occurs more frequently in female meiosis than in male meiosis. Subsequently, the chromosomes segregate randomly. Because there are 23 chromosomes, there exist 2_{23} (>8 million) possible combinations of chromosomes. Together with the genetic exchanges that occur during recombination, chromosomal segregation generates tremendous diversity, and each gamete is genetically unique. The process of recombination, and the independent segregation of chromosomes, provide the foundation for performing linkage analyses, whereby one attempts to correlate the inheritance of certain chromosomal regions (or linked genes) with the presence of a disease or genetic trait (see below).

After the first meiotic division, which results in two daughter cells (2*n*), the two chromatids of each chromosome separate during a second meiotic division to yield four gametes with a haploid state (1*n*). When the egg is fertilized by sperm, the two haploid sets are combined, thereby restoring the diploid state (2*n*) in the zygote.

REGULATION OF GENE EXPRESSION

Mechanisms that regulate gene expression play a critical role in the function of genes. The new field of *functional genomics* is based on the concept that understanding gene regulation and function will provide a better understanding of physiology and offer novel therapeutic opportunities. The transcription of genes is controlled primarily by *transcription factors* that bind to DNA sequences in the regulatory regions of genes. As

described below, mutations in transcription factors cause an unexpectedly large number of genetic disorders. Gene expression is also influenced by *epigenetic events*, such as X-inactivation and imprinting, processes in which DNA methylation is associated with the silencing (i.e., suppression) of expression. Several genetic disorders, such as Prader-Willi syndrome (neonatal hypotonia, developmental delay, obesity, short stature, and hypogonadism) and Albright hereditary osteodystrophy (resistance to parathyroid hormone, short stature, brachydactyly, resistance to other hormones in certain subtypes), exhibit the consequences of genomic imprinting. Most studies of gene expression have focused on the regulatory DNA elements of genes that control transcription. However, it should be emphasized that gene expression requires a series of steps including mRNA processing, protein translation, and posttranslational modifications, all of which are actively regulated (Fig. 65-2).

STRUCTURE OF GENES

A gene product is usually a protein but can occasionally consist of RNA that is not translated. *Exons* refer to the portion of genes that are eventually spliced together to form mRNA. *Introns* refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing (Fig. 65-2).

The gene locus also includes regions that are necessary to control its expression. The regulatory regions most commonly involve sequences upstream (5¢) of the transcription start site, although there are also examples of control elements within introns or downstream of the coding regions of a gene. The upstream regulatory regions are also referred to as the *promoter*. The minimal promoter usually consists of a TATA box (which binds TATA-binding protein, TBP) and initiator sequences that enhance the formation of an active transcription complex. Transcriptional termination signals reside downstream, or 3¢, of a gene. Specific sequences, such as the AAUAAA sequence at the 3¢ end of the mRNA, designate the site for polyadenylation (poly-A tail), a process that influences mRNA transport to the cytoplasm, stability, and translation efficiency. A rigorous test of the regulatory region boundaries involves expressing a gene in a transgenic animal to determine whether the isolated DNA flanking sequences are sufficient to recapitulate the normal developmental, tissue-specific, and signal-responsive features of the endogenous gene. This has been accomplished for only a few genes; there are many examples in which large genomic fragments only partially reconstitute normal gene regulation in vivo, implying the presence of distant regulatory sequences. This approach is critical to our understanding of mechanisms that regulate genes and is also relevant for gene therapy strategies that require normal gene regulation (Chap. 69).

As genes are dissected with greater resolution, the number of DNA sequences and transcription factors that regulate transcription is much greater than originally anticipated. Most genes contain at least 15 to 20 discrete regulatory elements within 300 bp of the transcription start site. This densely packed promoter region often contains binding sites for ubiquitous transcription factors such as CAAT box/enhancer binding protein (C/EBP), cyclic AMP response element binding (CREB) protein, selective promoter factor 1 (Sp-1), or activator protein 1 (AP-1). However, factors involved in cell-specific expression may also bind to these sequences. For example, basic helix-loop-helix (bHLH) proteins bind to E-boxes in the promoters of myogenic

genes, and steroidogenic factor 1 (SF-1) binds to a specific recognition site in the regulatory region of multiple steroidogenic enzyme genes. Key regulatory elements may also reside at some distance from the proximal promoter. The globin and the immunoglobulin genes, for example, contain *locus control regions* that are several kilobases away from the structural sequences of the gene. Specific groups of transcription factors that bind to these promoter and enhancer sequences provide a combinatorial code for regulating transcription. In this manner, relatively ubiquitous factors interact with more restricted factors to allow each gene to be expressed and regulated in a unique manner. As described below, the transcription factors that bind to DNA actually represent only the first level of regulatory control. Other proteins -- *coactivators* and *corepressors* -- interact with the DNA-binding transcription factors to generate large regulatory complexes. These complexes are subject to control by numerous cell-signaling pathways, including phosphorylation and acetylation. Ultimately, the recruited transcription factors interact with, and stabilize, components of the basal transcription complex that assembles at the site of the TATA box and initiator region. This basal transcription factor complex consists of >30 different proteins. Gene transcription occurs when RNA polymerase begins to synthesize RNA from the DNA template.

TRANSCRIPTIONAL ACTIVATION AND REPRESSION

Every gene is controlled uniquely, whether in its spatial or temporal pattern of expression or in its response to extracellular signals. It is estimated that transcription factors account for about 30% of expressed genes. A growing number of identified genetic diseases involve transcription factors (Table 65-1). The MODY (maturity-onset diabetes of the young) disorders are representative of this group of diseases; mutations in several different islet cell-specific transcription factors cause various forms of MODY (Chap. 333).

Transcriptional activation can be divided into three main mechanisms:

1. Events that alter chromatin structure can enhance the access of transcription factors to DNA. For example, histone acetylation opens chromatin structure and is correlated with transcriptional activation.

2. Posttranslational modifications of transcription factors, such as phosphorylation, can induce the assembly of active transcription complexes. As an example, phosphorylation ofCREBprotein on serine 133 induces a conformational change that allows the recruitment of CREB-binding protein (CBP), a factor that integrates the actions of many transcription factors, including proteins, with histone acetyltransferase activity.

3. Transcriptional activators can displace a repressor protein. This mechanism is particularly common during development when the pattern of transcription factor expression changes dynamically.

Of course, these mechanisms are not mutually exclusive, and most genes are activated by some combination of these events.

In general, mechanisms of transcriptional repression have not been studied to the same

extent as mechanisms of transcriptional activation. Nonetheless, suppression of gene expression is as important as gene activation. Some mechanisms of repression are the corollary of activation. For example, repression is often associated with histone deacetylation or protein dephosphorylation. For nuclear hormone receptors, transcriptional silencing involves the recruitment of repression complexes that contain histone deacetylase activity. Aberrant expression of repressor proteins is sometimes associated with neoplasia. The t(15;17) chromosomal translocation that occurs in promyelocytic leukemia fuses the *PML* gene to a portion of the retinoic acid receptor*a* (*RAR a*) gene (Table 65-1). This event causes unregulated transcriptional repression in a manner that precludes normal cellular differentiation. The addition of the RAR ligand, retinoic acid, activates the receptor, thereby relieving repression and allowing cells to differentiate and ultimately undergo apoptosis. This mechanism has therapeutic importance as the addition of retinoic acid to treatment regimens induces a higher remission rate in patients with promyelocytic leukemia (Chap. 111).

CLONING AND SEQUENCING DNA

Since the mid-1970s, eight Nobel prizes have been awarded for research that led, directly or indirectly, to major methodological advances as well as to profound insights into genetics. Examples include the discoveries of reverse transcriptase, restriction enzymes, plasmid cloning vectors, DNA sequencing, andPCR. A description of recombinant DNA techniques, the methodology used for the manipulation, analysis, and characterization of DNA segments, is beyond the scope of this chapter. As these methods are widely used in genetics and molecular diagnostics, however, it is useful to review briefly some of the fundamental principles of cloning and DNA sequencing.

CLONING OF GENES

Cloning refers to the creation of a recombinant DNA molecule that can be propagated indefinitely. The ability to clone genes and cDNAs therefore provides a permanent and renewable source of these reagents. Cloning is essential for DNA sequencing, nucleic acid hybridization studies, expression of recombinant proteins, and other recombinant DNA procedures.

The cloning of DNA involves the insertion of a DNA fragment into a cloning vector, followed by the propagation of the recombinant DNA in a host cell. The most straightforward cloning strategy involves inserting a DNA fragment into bacterial plasmids. Plasmids are small, autonomously replicating, circular DNA molecules that propagate separately from the chromosome in bacterial cells. The process of DNA insertion relies heavily on the use of restriction enzymes, which cleave DNA at highly specific sequences (usually 4 to 6 bp in length). Restriction enzymes generate complementary, cohesive sequences at theends of the DNA fragment, which allow them to be efficiently ligated to the plasmid vector. Because plasmids contain genes that confer resistance to antibiotics, their presence in the host cell can be used for selection and DNA amplification.

A variety of vectors and appropriate hosts are now used for cloning (Table 65-2). Many of these are used for creating *libraries*, a term that refers to a collection of DNA clones. A genomic library represents an array of clones derived from genomic DNA. These

overlapping DNA fragments represent the entire genome and can ultimately be arranged according to their linear order. Genomic libraries are propagated using a variety of vectors, such as lambda (l) phage, cosmids, bacterial artificial chromosomes (BACs), and yeast artificial chromosomes (YACs). Phage libraries have been used extensively to isolate specific genes. Cosmids, BACs, and YACs are particularly useful for studying large genes and for defining the order of genes along the chromosomes (Fig. 65-4). cDNA libraries reflect clones derived from mRNA, typically from a particular tissue source. Thus, a cDNA library from the heart contains copies of mRNA expressed specifically in cardiac myocytes, in addition to those that are expressed ubiquitously. For this reason, a heart cDNA library will be enriched with cardiac-specific gene products and will differ from cDNA libraries generated from liver or pituitary mRNAs. As an example of the complexity of a genomic library, consider that the human genome contains 3×10^9 bp and the average genomic insert in a l phage library is about 10^4 bp. Therefore, it requires at least 3×10^5 clones to represent all of the genomic DNA. Specific clones are isolated from the several hundred thousand clones by using DNA hybridization.

With completion of the HGP, all human genes have been cloned and sequenced. As a result, many of these cloning procedures will be unnecessary or greatly facilitated by the extensive information concerning DNA markers and the sequence of DNA (see below).

NUCLEIC ACID HYBRIDIZATION

Nucleic acid *hybridization* is a fundamental principle in molecular biology that takes advantage of the fact that the two complementary strands of nucleic acids bind, or *hybridize*, to one another with very high specificity. The goal of hybridization is to detect specific nucleic acid (DNA or RNA) sequences in a complex background of other sequences. This technique is used for Southern blotting, northern blotting, and for screening libraries (see above). Further adaptation of hybridization techniques has led to the development of microarray DNA chips.

Southern Blot Southern blotting is used to analyze whether genes have been deleted or rearranged. It is also used to detect restriction fragment length polymorphisms (RFLPs). Genomic DNA is digested with restriction endonucleases and separated by gel electrophoresis. Individual fragments can then be transferred to a membrane and detected after hybridization with specific radioactive DNA probes. Because single base-pair mismatches can disrupt the hybridization of short DNA probes (oligonucleotides), a variation of the Southern blot, termed *oligonucleotide-specific hybridization* (OSH), uses short oligonucleotides to distinguish normal from mutant genes.

Northern Blot Northern blots are used to analyze patterns and levels of gene expression in different tissues. In a northern blot, mRNA is separated on a gel and transferred to a membrane, and specific transcripts are detected using radiolabeled DNA as a probe. This technique is rapidly being supplanted by more sensitive and comprehensive methods such as reverse transcriptase (RT)-PCR and gene expression arrays on DNA chips (see below).

Microarray Technology A rapidly evolving approach to genome-scale studies consists

of *microarrays*, or *DNA chips*. These approaches consist of thousands of synthetic nucleic acid sequences aligned on thin glass or silicon surfaces. Fluorescently labeled test sample DNA or RNA is hybridized to the chip, and a computerized scanner detects sequence matches. Microarrays allow the detection of variations in DNA sequence and are used for mutational analysis and genotyping. Alternatively, the expression pattern of large numbers of mRNA transcripts can be determined by hybridization of RNA samples to cDNA or genomic microarrays. This method has tremendous potential in the era of functional genomics. As one example, microarrays can be used to develop genetic fingerprints of different types of lymphomas, providing information useful for classification, pathophysiology, prognosis, and treatment.

THE POLYMERASE CHAIN REACTION

ThePCR, introduced in 1985, has revolutionized the way DNA analyses are performed and has become a cornerstone of molecular biology and genetic analysis. In essence, PCR provides a rapid way of cloning (amplifying) specific DNA fragments in vitro (Fig. 65-5). Exquisite specificity is conferred by the use of PCR primers, which are designed for a given DNA sequence. The geometric amplification of the DNA after multiple cycles yields remarkable sensitivity. As a result, PCR can be used to amplify DNA from very small samples, including single cells. These properties also allow DNA amplification from a variety of tissue sources including blood samples, biopsies, surgical or autopsy specimens, or cells from hair or saliva. PCR can also be used to study mRNA. In this case, the enzymeRT is first used to convert the RNA to DNA, which can then be amplified by PCR. This procedure, commonly known as *RT-PCR*, is useful as a quantitative measure of gene expression.

PCRprovides a key component of molecular diagnostics. It provides a strategy for the rapid amplification of DNA (or mRNA) to search for mutations by a wide array of techniques, including DNA sequencing. PCR is also used for the amplification of highly polymorphic di- or trinucleotide repeat sequences, which allow various polymorphic alleles to be traced in genetic linkage or association studies. PCR is increasingly used to diagnose various microbial pathogens (Chap. 121).

DNA SEQUENCING

DNA sequencing is now an automated procedure. Although many protocols exist, the most commonly used strategy is based on the Sanger method in which dideoxynucleotides are used to randomly terminate DNA polymerization at each of the four bases (A,G,T,C). After separating the array of terminated DNA fragments using high-resolution gel or capillary electrophoresis, it is possible to deduce the DNA sequence by examining the progression of fragment lengths generated in each of the four nucleotide reactions. The use of fluorescently labeled dideoxynucleotides allows automated detection of the different bases and direct computer analysis of the DNA sequence. Efforts are underway to develop faster, more cost-effective DNA sequencing technologies. These include the use of mass spectrometry; detection of fluorescently labeled bases in flow cytometry; direct reading of the DNA sequence by scanning, tunneling, or atomic force microscopy; and sequence analysis using DNA chips.

TRANSGENIC MICE AS MODELS OF GENETIC DISEASE

Several organisms have been studied extensively as genetic models, including *Mus musculus* (mouse), *Drosophila melanogaster* (fruit fly), *Caenorhabditis elegans* (nematode), *Saccharomyces cerevisiae* (baker's yeast), and *Eschericia coli* (colonic bacterium). The ability to use these evolutionarily distant organisms as genetic models that are relevant to human physiology reflects a surprising conservation of genetic pathways and gene function. Transgenic mouse models have been particularly valuable, because many human and mouse genes exhibit similar structure and function and because manipulation of the mouse genome is relatively straightforward compared to those of other mammalian species.

Transgenic strategies in mice can be divided into two main approaches: (1) overexpression of a gene by random insertion into the genome, and (2) deletion or targeted mutagenesis of a gene by homologous recombination with the native endogenous gene (Fig. 65-6). Many variations of these basic approaches now exist that allow genes to be expressed in specific cell types, at different times during development, or at varying levels. Consequently, transgenic technology has emerged as a powerful strategy for defining the physiologic effects of deleting or overexpressing a gene, as well as providing unique genetic models for dissecting pathophysiology or testing therapies.

Examples of transgenic models relevant to human genetic disorders are listed inTable 65-3. Transgenic overexpression of genes is useful for studying disorders that are sensitive to gene dosage. Overexpression of *PMP22*, for example, mimics a common duplication of this gene in type IA Charcot-Marie-Tooth disease (Chap. 379). Duplication of the *PMP22* gene results in high levels of expression of peripheral myelin protein 22, and this dosage effect is responsible for the demyelinating neuropathy. Expression of the Y chromosome-specific gene, *SRY*, in XX females demonstrates that *SRY* is sufficient to induce the formation of testes. This finding confirms the pathogenic role of *SRY* translocations to the X chromosome in sex-reversed XX females. Huntington disease is an autosomal dominant disorder caused by expansion of a CAG trinucleotide repeat that encodes a polyglutamine tract. Targeted deletion of the Huntington disease (*HD*) gene does not induce the neurologic disorder. On the other hand, transgenic expression of the entire gene or of the first exon containing the expanded polyGlu repeat is sufficient to cause many features of the neurologic disorder, indicating a gain-of-function property for the expanded polyGlu-containing protein. Transgenic strategies can also be used as a precursor to gene therapy. Expression of dystrophin, the protein that is deleted in Duchenne muscular dystrophy, partially corrects the disorder in a mouse model of Duchenne's. Targeted expression of oncogenes has been valuable to study mechanisms of neoplasia and to generate immortalized cell lines. For example, expression of the simian virus 40 (SV40) large T antigen under the direction of the insulin promoter induces the formation of islet cell tumors.

Targeted deletion mutagenesis, commonly known as *gene knockout*, is performed using a targeting vector that carries a mutant version of the gene. After homologous recombination in embryonic stem (ES) cells, chimeric animals are produced by injection of ES cells into blastocysts. Subsequently, animals are bred to be heterozygous or homozygous for the mutation. In addition to their use in examining gene function, gene knockouts provide valuable animal models for many loss-of-function mutations. A

variation of this strategy is to use cre recombinase to induce genetic recombination in vivo. Cre recombinase will delete genes that have been flanked by its recognition sequences, called *loxP* sites. One advantage to this approach is that transgenic expression of cre in specific tissues can be used to delete a gene in a tissue-specific or developmentally staged manner. This is particularly useful for genes that would be lethal if deleted universally or during early development.

The list of genes that have been knocked out in mice is already very large. Many of these knockouts do not have an apparent phenotype, either because of redundant functions of the other genes or because the phenotype is subtle. For example, deletion of the hypoxanthine phosphoribosyltransferase (HPRT) gene (*Hprt*) does not cause characteristic features of Lesch-Nyhan syndrome in mice because of their reliance on adenine phosphoribosyltransferase (APRT) in the purine salvage pathway. The administration of an APRT inhibitor to HPRT-deficient mice, however, results in the typical self-injurious behavior seen in patients with Lesch-Nyhan syndrome. The phenotypes of some knockouts are quite different from their human disease counterparts. For example, deletion of the retinoblastoma (*Rb*) gene does not lead to retinoblastoma or other tumors that characterize the human syndrome. These examples underscore the fact that the functions of genes, and their interactions with genetic background and the environment, cannot be assumed to be identical in mice and humans. On the other hand, the deletion of many genes provides a remarkably faithful model of human disorders (Table 65-3). In addition to clarifying pathophysiology, these models facilitate the development of therapies, both genetic and pharmaceutical.

In addition to transgenic animal models, naturally occurring mutations in mice and other species continue to provide fundamental insights into human disease. A compendium of natural and transgenic animal models is provided in continuously evolving databases (Online Mendelian Inheritance in Animals OMIA:http://www.angis.su.oz.au/Databases/BIRX/omia/; The Jackson Library:http://www.jax.org/).

Human pluripotential *stem cells* have recently been developed, and, consistent with their potential for self-renewal, these cell lines express high levels of telomerase, an enzyme that is essential for allowing repeated replication of the ends of eukaryotic chromosomes. Although much remains to be learned about the properties of pluripotential stem cells, they may prove useful for transplantation, drug testing, or for other purposes.

THE HUMAN GENOME PROJECT

TheHGP was initiated in the mid-1980s as an ambitious effort to characterize the human genome, culminating in a complete DNA sequence. In the United States, the National Institutes of Health (NIH) and the Department of Energy (DOE) officially launched the genome project in 1990; the project has evolved as an international effort and has also included important contributions from the private sector. The main goals include: (1) creation of genetic maps, (2) development of physical maps, and (3) determination of the complete human DNA sequence.

Some analogies help in appreciating the scope of theHGP. The 23 pairs of human

chromosomes are thought to encode approximately 100,000 genes. The total length of DNA is about 3 billion bp, which is nearly 1000-fold greater than the *E. coli* genome. If the human DNA sequence were printed out, it would correspond to about 120 volumes of *Harrison's Principles of Internal Medicine*.

THE GENETIC MAP

Given the size and complexity of the human genome, genetic maps have been developed to provide orientation and to delimit where a gene of interest may be located. A *genetic map* describes the order of genes and defines the position of a gene relative to other loci on the same chromosome. It is constructed by assessing how frequently two markers are inherited together by linkage studies. Distances of the genetic map are expressed in recombination units, or centimorgans (cM). One cM corresponds to a recombination frequency of 1% between two polymorphic markers; 1 cM corresponds to approximately 1 Mb of DNA (Fig. 65-3). Any polymorphic sequence variation can be useful for mapping purposes. Examples of polymorphic markers include variable number of tandem repeats (VNTRs),RFLPs, microsatellite repeats, and single nucleotide polymorphisms (SNPs); the latter two methods are now used predominantly because of the high density of markers and because they are amenable to automated procedures.

The current genetic map exists at about 1 cM resolution. A goal for the near term is to add about 100,000SNPs to these maps. This would provide 1 SNP approximately every 100,000 bp. The addition of SNPs will facilitate automation using DNA chips and will enhance the ability to perform linkage studies of complex genetic diseases.

THE PHYSICAL MAP

Cytogenetics and chromosomal banding techniques provide a relatively low-resolution microscopic view of genetic loci. Physical maps indicate the position of a locus or gene in absolute values. Sequence-tagged sites (STSs) are used as a standard unit for physical mapping and serve as sequence-specific landmarks for arranging overlapping cloned fragments in the same order as they occur in the genome. These overlapping clones, usually inYACs orBACs, allow the characterization of contiguous DNA sequences, commonly referred to as *contigs* (Fig. 65-4). The STSs consist of 200 to 500 bp, which can be retrieved from computer databases; >50,000 STSs have been mapped. The goal of achieving a high-resolution physical map of the human genome has essentially been achieved as all of the genome has been cloned into overlapping fragments. The highest resolution physical map will provide the complete DNA sequence of each chromosome in the human genome.

STATUS OF DNA SEQUENCING

The primary focus of the genome project is to obtain DNA sequence for the entire human genome as well as model organisms. The sequences of *E. coli* and many other bacteria, *S. cerevisiae*, *C. elegans*, and *D. melanogaster* have already been completed. Sequencing of the laboratory mouse genome is in progress. Although the prospect of determining the complete sequence of the human genome was a daunting prospect several years ago, technical advances in DNA sequencing and bioinformatics have led

to the completion of a draft human sequence in June 2000, well in advance of the original goal of the year 2003. The current standard is to achieve 99.99% (1 error in 10,000 bp) accuracy. This level of accuracy is important for many reasons, including efforts to determine the degree of DNA sequence variation in the population. Comparisons of the DNA sequence from multiple individuals or populations will allow assessments of genetic variance in the human population. Another goal is to develop a complete set of full-length human cDNAs and to define their locations on the physical map.

ETHICAL ISSUES

Implicit in theHGP is the idea and hope that identifying disease-causing genes can lead to improvements in diagnosis, prognosis, and treatment. It is estimated that most individuals harbor several serious recessive genes. However, completion of the human genome sequence, determination of the association of genetic defects with disease, and studies of genetic variation raise many new issues with implications for the individual and mankind. The controversies concerning the cloning of mammals and the establishment of human embryonic stem cells underscore the relevance of these questions. Moreover, the information gleaned from genotypic results can have quite different impacts, depending on the availability of strategies to modify the course of disease. For example, the identification of mutations that cause multiple endocrine neoplasia (MEN) type 2 or hemochromatosis allows specific interventions for affected family members. On the other hand, at present the identification of an Alzheimer or Huntington disease gene does not alter therapy. Genetic test results can generate anxiety in affected individuals and family members, and there is the possibility of discrimination on the basis of the test results. Most genetic disorders are likely to fall into an intermediate category where the opportunity for prevention or treatment is significant but limited (Chap. 68). For these reasons, the scientific components of the HGP have been paralleled by efforts to examine ethical and legal implications as new issues arise.

Many issues raised by the genome project are familiar, in principle, to medical practitioners. For example, an asymptomatic patient with increased low-density lipoprotein (LDL) cholesterol, high blood pressure, or a strong family history of early myocardial infarction, is known to be at increased risk of coronary heart disease. In such cases, it is clear that the identification of risk factors and an appropriate intervention are beneficial. Likewise, patients with phenylketonuria, cystic fibrosis, or sickle cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information. We can anticipate similar efforts, whether based on genotypes or other markers of genetic predisposition, to be applied to many disorders. One confounding aspect of the rapid expansion of information is that our ability to make clinical predictions often lags behind genetic advances. For example, when genes that predispose to breast cancer, such as *BRCA1*, are described, they generate tremendous public interest in the potential to predict disease, but many years of clinical research are still required to rigorously establish genotype and phenotype correlations.

Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or their families, there is a great need for more

information about fundamental principles of genetics. The pervasive nature of the role of genetics in medicine makes it imperative for physicians and other health care professionals to become more informed about genetics and to provide advice and counseling in conjunction with trained genetic counselors (Chap. 68). The application of screening and prevention strategies will therefore require intensive patient and physician education, changes in health care financing, and legislation to protect patient's rights.

TRANSMISSION OF GENETIC DISEASE

ORIGINS AND TYPES OF MUTATIONS

A *mutation* can be defined as any change in the primary nucleotide sequence of DNA regardless of its functional consequences. Some mutations may be lethal, others are less deleterious, and some may confer an evolutionary advantage. Mutations can occur in the germline (sperm or oocytes); these can be transmitted to progeny. Alternatively, mutations can occur during embryogenesis or in somatic tissues. Mutations that occur during development lead to *mosaicism*, a situation in which tissues are composed of cells with different genetic constitutions. If the germline is mosaic, a mutation can be transmitted to some progeny but not others, which sometimes leads to confusion in assessing the pattern of inheritance. Somatic mutations that do not affect cell survival can sometimes be detected because of variable phenotypic effects in tissues (e.g., pigmented lesions in McCune-Albright syndrome). Other somatic mutations are associated with neoplasia because they confer a growth advantage to cells. Epigenetic events such as altered DNA methylation may also influence gene expression. With the exception of triplet nucleotide repeats, which can expand (see below), mutations are usually stable.

Mutations are structurally diverse -- they can involve the entire genome, as in triploidy (one extra set of chromosomes), or gross numerical or structural alterations in chromosomes or individual genes (Chap. 66). Large deletions may affect a portion of a gene or an entire gene, or, if several genes are involved, they may lead to a *contiguous gene syndrome*. Unequal crossing-over between homologous genes can result in fusion gene mutations, as illustrated by color blindness (Chap. 28). Mutations involving single nucleotides are referred to as *point mutations*. Substitutions are called *transitions* if a purine is replaced by another purine base (A« G) or if a pyrimidine is replaced by another pyrimidine (C « T). Changes from a purine to a pyrimidine, or vice versa, are referred to as *transversions*. If the DNA sequence change occurs in a coding region and alters an amino acid, it is called a *missense mutation*. Depending on the functional consequences of such a missense mutation, amino acid substitutions in different regions of the protein can lead to distinct phenotypes. *Polymorphisms* are sequence variations that have a frequency of at least 1%. Usually, they do not result in a perceptible phenotype. Often they consist of single base-pair substitutions that do not alter the protein coding sequence because of the degenerate nature of the genetic code, although it is possible that some might alter mRNA stability, translation, or the amino acid sequence. These types of silent base substitutions andSNPs are encountered frequently during genetic testing and must be distinguished from true mutations that alter protein expression or function. Small nucleotide deletions or insertions cause a shift of the codon reading frame. Most commonly, reading frame

alterations result in an abnormal protein segment of variable length before termination of translation occurs at a stop codon (*nonsense mutation*). Mutations in intronic sequences or in exon junctions may destroy or create splice donor or splice acceptor sites. Mutations may also be found in the regulatory sequences of genes, resulting in reduced gene transcription.

Mutation Rates As noted before, mutations represent an important cause of genetic diversity as well as disease. Mutation rates are difficult to determine in humans because many mutations are silent and because testing is often not adequate to detect the phenotypic consequences. Mutation rates vary in different genes but are estimated to occur at a rate of about 10^{-10}/bp per cell division. Germline mutation rates (as opposed to somatic mutations) are relevant in the transmission of genetic disease. Because the population of oocytes is established very early in development, only about 20 cell divisions are required for completed oogenesis, whereas spermatogenesis involves about 30 divisions by the time of puberty and 20 cell divisions each year thereafter. Consequently, the probability of acquiring new point mutations is much greater in the male germline than the female germline, in which rates of aneuploidy are increased (Chap. 66). Thus, the incidence of new point mutations in spermatogonia increases with paternal age (e.g., achondrodysplasia, Marfan syndrome, neurofibromatosis). It is estimated that about 1 in 10 sperm carries a new deleterious mutation. The rates for new mutations are calculated most readily for autosomal dominant and X-linked disorders and are ~$10^{-5}$to 10^{-6}/locus per generation. Because most monogenic diseases are relatively rare, new mutations account for a significant fraction of cases. This is important in the context of genetic counseling, as a new mutation can be transmitted to the affected individual but does not necessarily imply that the parents are at risk to transmit the disease to other children. An exception to this is when the new mutation occurs early in germline development, leading to *gonadal mosaicism*.

Unequal Crossing-Over Normally, DNA recombination in germ cells occurs with remarkable fidelity to maintain the precise junction sites for the exchanged DNA sequences (Fig. 65-2). However, mispairing of homologous sequences leads to unequal crossover, with gene duplication on one of the chromosomes and gene deletion on the other chromosome. A significant fraction of growth hormone (*GH*) gene deletions, for example, involve unequal crossing-over (Chap. 328). The *GH* gene is a member of a large gene cluster that includes a growth hormone variant gene as well as several structurally related chorionic somatomammotropin genes and pseudogenes (highly homologous but functionally inactive relatives of a normal gene). Because such gene clusters contain multiple homologous DNA sequences arranged in tandem, they are particularly prone to undergo recombination and, consequently, gene duplication or deletion. On the other hand, duplication of the *PMP22* gene as a result of unequal crossing-over results in increased gene dosage and type IA Charcot-Marie-Tooth disease (Chap. 379). Unequal crossing-over resulting in deletion of *PMP22* results in a distinct neuropathy called *hereditary liability to pressure palsy* (Chap. 379).

Glucocorticoid-remediable aldosteronism (GRA) is caused by a rearrangement involving the genes that encode aldosterone synthase (*CYP11B2*) and steroid 11b-hydroxylase (*CYP11B1*), normally arranged in tandem on chromosome 8q. These two genes are 95% identical, predisposing to gene duplication and deletion by unequal crossing-over. The rearranged gene product contains the regulatory regions of 11b-hydroxylase fused

to the coding sequence of aldosterone synthetase. Consequently, the latter enzyme is expressed in the adrenocorticotropic hormone (ACTH)-dependent zone of the adrenal gland, resulting in overproduction of mineralocorticoids and hypertension (Chap. 331).

Gene conversion refers to a nonreciprocal exchange of homologous genetic information; it is probably more common than generally recognized. In human genetics, gene conversion has been used to explain how an internal portion of a gene is replaced by a homologous segment copied from another allele or locus; these genetic alterations may range from a few nucleotides to a few thousand nucleotides. As a result of gene conversion, it is possible for short DNA segments of two chromosomes to be identical, even though these sequences are distinct in the parents. A practical consequence of this phenomenon is that nucleotide substitutions can occur during gene conversion between related genes, often altering the function of the gene. In disease states, gene conversion often involves intergenic exchange of DNA between a gene and a related pseudogene. For example, the 21-hydroxylase gene (*CYP21A*) is adjacent to a nonfunctional pseudogene. Many of the nucleotide substitutions that are found in the *CYP21A* gene in patients with congenital adrenal hyperplasia correspond to sequences that are present in the pseudogene, suggesting gene conversion as a mechanism of mutagenesis. In addition, mitotic gene conversion has been suggested as a mechanism to explain revertant mosaicism in which an inherited mutation is "corrected" in certain cells. For example, patients with autosomal recessive generalized atrophic benign epidermolysis bullosa have acquired reverse mutations in one of the two mutated *COL17A1* alleles, leading to clinically unaffected patches of skin.

Insertions and Deletions Though many instances of insertions and deletions occur as a consequence of unequal crossing-over, there is also evidence for internal duplication, inversion, or deletion of DNA sequences. The fact that certain deletions or insertions appear to occur repeatedly as independent events suggests that specific regions within the DNA sequence predispose to these errors. For example, certain regions of the *DMD* gene appear to be hot spots for deletions.

Errors in DNA Repair Because mutations caused by defects in DNA repair accumulate as somatic cells divide, these types of mutations are particularly important in the context of neoplastic disorders (Chap. 82). Several genetic disorders involving DNA repair enzymes underscore their importance. Patients with xeroderma pigmentosum have defects in DNA damage recognition or in the nucleotide excision and repair pathway (Chap. 86). Exposed skin is dry and pigmented and is extraordinarily sensitive to the mutagenic effects of ultraviolet irradiation. More than 10 different genes have been shown to cause the different forms of xeroderma pigmentosum. This finding is consistent with the earlier classification of this disease into different complementation groups (Table 65-4) in which normal function is rescued by the fusion of cells derived from two different forms of xeroderma pigmentosum.

Ataxia telangiectasia causes large telangiectatic lesions of the face, cerebellar ataxia, immunologic defects, and hypersensitivity to ionizing radiation (Chap. 364). The discovery of the ataxia telangiectasia mutated (*ATM*) gene reveals that it is homologous to genes involved in DNA repair and control of cell cycle checkpoints. Mutations in the *ATM* gene give rise to defects in meiosis as well as increasing susceptibility to damage from ionizing radiation. Fanconi's anemia is also associated with an increased risk of

multiple acquired genetic abnormalities. It is characterized by diverse congenital anomalies and a strong predisposition to develop aplastic anemia and acute myelogenous leukemia (Chap. 111). Cells from these patients are susceptible to chromosomal breaks caused by a defect in genetic recombination. At least eight different complementation groups have been identified, and several loci and genes associated with Fanconi's anemia have been mapped or cloned (Table 65-4).

HNPCCis caused by mutations in one of several different mismatch repair (MMR) genes including MutS homologue 2 (*MSH2*) and MutL homologue 1 (*MLH1*) (Chap. 90). These enzymes are involved in the detection of nucleotide mismatches and in the recognition of slipped-strand trinucleotide repeats. Germline mutations in these genes lead to microsatellite instability and a high mutation rate in colon cancer. This syndrome is characterized by autosomal dominant transmission of colon cancer, young age (<50 years) of presentation, predisposition to lesions in the proximal large bowel, and associated malignancies such as uterine cancer and ovarian cancer. Genetic screening tests for this disorder are now being used for families considered to be at risk (Chap. 68). Recognition of HNPCC allows early screening with colonoscopy and the implementation of prevention strategies using nonsteroidal anti-inflammatory drugs.

CpG and Dipyrimidine Sequences Certain DNA sequences are particularly susceptible to mutagenesis. Successive pyrimidine residues (e.g., T-T or C-C) are subject to the formation of ultraviolet light-induced photoadducts. If these pyrimidine dimers are not repaired by the nucleotide excision repair pathway, mutations will be introduced after DNA synthesis. The dinucleotide C-G, or CpG, is also a hot spot for a specific type of mutation. In this case, methylation of the cytosine is associated with an enhanced rate of deamination to uracil, which is then replaced with thymine. This C ® T transition (or G ® A on the opposite strand) accounts for at least one-third of point mutations associated with polymorphisms and mutations. Many of the *MSH2* mutations inHNPCC, for example, involve CpG sequences.

Certain types of mutations (C ® T or G® A) are relatively common. Moreover, the redundant nature of the genetic code results in overrepresentation of certain amino acid substitutions. For example, arginine codons are most likely to be converted to cysteine, tryptophan, or a stop codon when a C® T transition occurs, and to histidine or glutamine when a G ® A transition occurs.

Unstable DNA Sequences *Trinucleotide repeats* may be unstable and expand beyond a critical number. Mechanistically, the expansion is thought to be caused by unequal recombination and slipped mispairing. A premutation represents a small increase in trinucleotide copy number. In subsequent generations, the expanded repeat may increase further in length and result in an increasingly severe phenotype, a process called *dynamic mutation* (see below for discussion of anticipation). Trinucleotide expansion was first recognized as a cause of the fragile X syndrome, one of the most common causes of mental retardation (Chap. 359). Other disorders arising from a similar mechanism include Huntington disease (Chap. 362), X-linked spinobulbar muscular atrophy (Chap. 365), and myotonic dystrophy (Chap. 383) (Tables 65-5 and65-6). Malignant cells are also characterized by genetic instability, indicating a breakdown in mechanisms that regulate DNA repair and the cell cycle.

FUNCTIONAL CONSEQUENCES OF MUTATIONS

Functionally, mutations can be broadly classified as gain-of-function and loss-of-function mutations. Gain-of-function mutations are typically dominant; that is, they result in phenotypic alterations when a single allele is affected. Inactivating mutations are usually recessive, and an affected individual is homozygous or compound heterozygous (i.e., carrying two different mutant alleles) for the disease-causing mutations. Alternatively, mutation in a single allele can result in *haploinsufficiency*, a situation in which one normal allele is not sufficient for a normal phenotype. This phenomenon applies, for example, to expression of rate-limiting enzymes in heme synthesis that cause porphyrias (Chap. 346). An increase in dosage of a gene product may also result in disease, as illustrated by the duplication of the *DAX1* gene in dosage-sensitive sex-reversal (Chap. 338). Mutation in a single allele can also result in loss of function due to a dominant-negative effect. In this case, the mutated allele interferes with the function of the normal gene product by one of several different mechanisms: (1) a mutant protein may interfere with the function of a multimeric protein complex, as illustrated by mutations in type 1 collagen (*COL1A1*, *COL1A2*) genes in osteogenesis imperfecta (Chap. 351); (2) a mutant protein may occupy binding sites on proteins or promoter response elements, as illustrated by thyroid hormone resistance, a disorder in which inactivated thyroid hormone receptor binds to target genes and functions as an antagonist of normal receptors (Chap. 330); or (3) a mutant protein can be cytotoxic as in $a_1$antitrypsin deficiency (Chap. 258) or autosomal dominant neurohypophyseal diabetes insipidus (Chap. 329), in which the abnormally folded proteins are trapped within the endoplasmic reticulum and ultimately cause cellular damage.

GENOTYPE AND PHENOTYPE

Alleles, Genotypes, and Haplotypes An observed trait is referred to as a *phenotype*; the genetic information defining the phenotype is called the *genotype*. Alternative forms of a gene or a genetic marker are referred to as alleles. Alleles may be polymorphic variants of nucleic acids that have no apparent effect on gene expression or function. In other instances, these variants may have subtle effects on gene expression, thereby conferring the adaptive advantages associated with genetic diversity. On the other hand, allelic variants may reflect mutations in a gene that clearly alter its function. The common Glu ® Val sickle cell mutation (E6V) in the*b-globin* gene and theDF508 deletion of phenylalanine (F) in the *CFTR* gene are examples of allelic variants of these genes. Because each individual has two copies of each chromosome (one inherited from the mother and one inherited from the father), he or she can only have two alleles at a given locus. However, there can be many different alleles in the population. The normal or common allele is usually referred to as *wild type*. When alleles at a given locus are identical, the individual is *homozygous*. Inheriting such identical copies of a mutant allele occurs in many autosomal recessive disorders, particularly in circumstances of consanguinity. If the alleles are different, the individual is *heterozygous* at this locus. If two different mutant alleles are inherited at a given locus, the individual is said to be a *compound heterozygote*. *Hemizygous* is used to describe males with a mutation in an X chromosomal gene, or a female with a loss of one X chromosomal locus.

Genotypes describe the specific alleles at a particular locus. For example, there are

three common alleles (E2, E3, E4) of the apolipoprotein E (*APOE*) gene. The genotype of an individual can therefore be described as *APOE3/4* or *APOE4/4* or any other variant. These designations indicate which alleles are present on the two chromosomes in the *APOE* gene at locus 19q13.2. In other cases, the genotype might be assigned arbitrary numbers (e.g., 1/2) or letters (e.g., B/b) to distinguish different alleles.

A *haplotype* refers to a group of alleles that are closely linked together at a genomic locus. Haplotypes are useful for tracking the transmission of genomic segments within families and for detecting evidence of genetic recombination, if the crossover event occurs between the alleles (Fig. 65-3). As an example, various alleles at the histocompatibility locus antigen (HLA) on chromosome 6p are used to establish haplotypes associated with certain disease states. For example, 21-hydroxylase deficiency, complement deficiency, and hemochromatosis are each associated with specific HLA haplotypes. It is now recognized that these genes lie in close vicinity to the HLA locus, which explains why HLA associations were identified even before the disease genes were cloned and localized. In other cases, specific HLA associations with diseases such as ankylosing spondylitis (HLA-B27) or type 1 diabetes mellitus (HLA-DR4) reflect the role of specific HLA allelic variants in susceptibility to these autoimmune diseases.

Allelic Heterogeneity *Allelic heterogeneity* refers to the fact that different mutations in the same genetic locus can cause an identical or similar phenotype. For example, many different mutations of the b-globin locus can cause b-thalassemia (Fig. 65-7). In essence, allelic heterogeneity reflects the fact that many different mutations are capable of altering protein structure and function. For this reason, maps of inactivating mutations in genes usually show a near-random distribution. Exceptions include: (1) a founder effect, in which a particular mutation that does not affect reproductive capacity can be traced to a single individual; (2) "hot spots" for mutations, in which the nature of the DNA sequence predisposes to a recurring mutation; and (3) localization of mutations to certain domains that are particularly critical for protein function. Allelic heterogeneity creates a practical problem for genetic testing because one must often examine the entire genetic locus for mutations, as these can differ in each patient.

Phenotypic Heterogeneity *Phenotypic heterogeneity* occurs when more than one phenotype is caused by allelic mutations (e.g., different mutations in the same gene). For example, mutations in the *myosin VIIIA* gene can result in four distinct clinical disorders: (1) autosomal recessive deafness DFNB2, (2) autosomal dominant nonsyndromic deafness DFNA11, (3) Usher 1B syndrome [congenital deafness, retinitis pigmentosa (Plate IV-14)], and (4) an atypical variant of Usher's syndrome. Similarly, identical mutations in the *FGFR2* gene can result in very distinct phenotypes: Crouzon syndrome (craniofacial synostosis), or Pfeiffer syndrome (acrocephalopolysyndactyly).

Locus or Nonallelic Heterogeneity and Phenocopies *Nonallelic or locus heterogeneity* refers to the situation in which a similar disease phenotype results from mutations at different genetic loci (Table 65-4). This often occurs when more than one gene product produces different subunits of an interacting complex or when different genes are involved in the same genetic cascade or physiologic pathway. For example, osteogenesis imperfecta can arise from mutations in two different procollagen genes (*COL1A1* or *COL1A2*) that are located on different chromosomes (Chap. 351). The

effects of inactivating mutations in these two genes are similar because the protein products comprise different subunits of the helical collagen fiber. Similarly, muscular dystrophy syndromes can be caused by mutations in various genes, consistent with the fact that it can be transmitted in an X-linked (Duchenne or Becker), autosomal dominant (limb-girdle muscular dystrophy type 1), or autosomal recessive (limb-girdle muscular dystrophy type 2) manner (Chap. 383). Mutations in the X-linked *DMD* gene, which encodes dystrophin, are the most common cause of muscular dystrophy. This feature reflects the large size of the gene as well as the fact that the phenotype is expressed in hemizygous males because they only have a single copy of the X chromosome. Dystrophin is associated with a large group of additional proteins that form the membrane-associated cytoskeleton in muscle. Mutations in several components of this protein complex can also cause muscular dystrophy syndromes. Although the phenotypic features of some of these disorders are distinct, the phenotypic spectrum caused by mutations in different genes overlaps, thereby leading to nonallelic heterogeneity. It should be noted that mutations in dystrophin also cause allelic heterogeneity. For example, mutations in the *DMD* gene can cause either Duchenne or the less severe Becker muscular dystrophy, depending on the severity of the protein defect.

Recognition of nonallelic heterogeneity is important for several reasons: (1) the ability to identify disease loci in linkage studies is reduced by including patients with similar phenotypes but different genetic disorders; (2) genetic testing is more complex because several different genes need to be considered along with the possibility of different mutations in each of the candidate genes; and (3) novel information is gained about how genes or proteins interact, providing unique insights into molecular physiology.

Phenocopies refer to circumstances in which nongenetic conditions mimic a genetic disorder. For example, features of toxin- or drug-induced neurologic syndromes can resemble those seen in Huntington disease, and vascular causes of dementia share phenotypic features with familial forms of Alzheimer dementia (Chap. 362). Children born with activating mutations of the thyroid-stimulating hormone receptor (TSH-R) exhibit goiter and thyrotoxicosis similar to that seen in neonatal Graves' disease, which is caused by the transfer of maternal autoantibodies to the fetus (Chap. 330). As in nonallelic heterogeneity, the presence of phenocopies has the potential to confound linkage studies and genetic testing. Patient history and subtle differences in phenotype can often provide clues that distinguish these disorders from related genetic conditions.

Variable Expressivity and Incomplete Penetrance It is not uncommon for the same genetic mutation to cause a phenotypic spectrum illustrating the phenomenon of *variable expressivity*. This may include different manifestations of a complex disorder (e.g.,MEN), the severity of the disorder (e.g., sickle cell anemia), or the age of disease onset (e.g., Alzheimer dementia). MEN-1 illustrates several of these features. Families with this autosomal dominant disorder develop tumors of the parathyroid gland, endocrine pancreas, and the pituitary gland (Chap. 339). However, the pattern of tumors in the different glands, the age at which tumors develop, and the types of hormones produced vary among affected individuals, even within a given family. In this example, the phenotypic variability arises, in part, because of the requirement for a second mutation in the normal copy of the *MEN1* gene, as well as the large array of different cell types that are susceptible to the effects of *MEN1* gene mutations. In part, variable

expression reflects the influence of other genes, or genetic background, on the effects of a particular mutation. Even in identical twins, in whom the genetic constitution is the same, one can occasionally see variable expression of a genetic disease.

Interactions with the environment can also influence the course of a disease. For example, the manifestations and severity of hemochromatosis can be influenced by iron intake (Chap. 345), and the course of phenylketonuria is affected by exposure to phenylalanine in the diet (Chap. 352). Other metabolic disorders, such as hyperlipidemias and porphyria, also fall into this category. Many mechanisms, including genetic effects and environmental influences, can therefore lead to variable expressivity. In genetic counseling, it is particularly important to recognize this variability, as one cannot always predict the course of disease, even when the mutation is known.

Penetrance is the probability of expressing the phenotype given a defined genotype; it can be complete or incomplete. For example, hypertrophic obstructive cardiomyopathy (HOCM) caused by mutations in the *myosin heavy chain b*gene is a dominant disorder with clinical features in only a subset of patients who carry the mutation (Chap. 238). Patients who have the mutation but no evidence of the disease can still transmit the disorder to subsequent generations. In this situation, the disorder is said to be *nonpenetrant* or *incompletely penetrant*. This classification depends to some degree on the criteria and techniques used for diagnosis. For disorders such as Huntington disease or familial amyotrophic lateral sclerosis, which present late in life, the rate of penetrance is influenced by the age at which the clinical assessment is performed. *Imprinting* can also modify the penetrance of a disease (see below). For example, in patients with Albright hereditary osteodystrophy, mutations in the Gsa subunit (*GNAS1* gene) are expressed clinically only in individuals who inherit the mutation from their mother (Chap. 343).

Sex-Influenced Phenotypes Certain mutations affect males and females quite differently. In some instances, this is because the gene resides on the X or Y sex chromosomes (X-linked disorders and Y-linked disorders). As a result, the phenotype of mutated X-linked genes will be expressed fully in males but variably in heterozygous females, depending on the degree of X-inactivation and the function of the gene. For example, most heterozygous female carriers of factor VIII deficiency (hemophilia A) are asymptomatic because sufficient factor VIII is produced to prevent a defect in coagulation (Chap. 117). On the other hand, some females heterozygous for the X-linked lipid storage defect caused bya-galactosidase A deficiency (Fabry disease) experience mild manifestations of painful neuropathy, as well as other features of the disease (Chap. 349). Because only males have a Y chromosome, mutations in genes such as *SRY* (which causes male-to-female sex-reversal) or *DAZ* (which causes abnormalities of spermatogenesis) are unique to males (Chap. 338).

Other diseases are expressed in a sex-limited manner because of the differential function of the gene product in males and females. Activating mutations in the luteinizing hormone receptor cause dominant male-limited precocious puberty in boys (Chap. 335). The phenotype is unique to males because activation of the receptor induces testosterone production in the testis, whereas it is functionally silent in the immature ovary. Homozygous inactivating mutations of the follicle-stimulating hormone (FSH) receptor cause primary ovarian failure in females because the follicles do not

develop in the absence of FSH action. In contrast, affected males have a more subtle phenotype, because testosterone production is preserved (allowing sexual maturation) and spermatogenesis is only partially impaired (Chap. 335). In congenital adrenal hyperplasia, most commonly caused by 21-hydroxylase deficiency, cortisol production is impaired and ACTHstimulation of the adrenal gland leads to increased production of androgenic precursors (Chap. 331). In females, the increased androgen level causes ambiguous genitalia, which can be recognized at the time of birth. In males, the diagnosis may be made on the basis of adrenal insufficiency at birth, because the increased adrenal androgen level does not alter sexual differentiation, or later in childhood, because of the development of precocious puberty. Hemochromatosis is more common in males than in females, presumably because of differences in dietary iron intake and losses associated with menstruation and pregnancy in females (Chap. 345).

GENETIC LINKAGE

Genetic linkage refers to the fact that genes are physically connected, or linked, to one another along the chromosomes. Two fundamental principles are essential for understanding the concept of a genetic linkage: (1) When two genes are close together on a chromosome, they are usually transmitted together, unless a recombination event separates them (Fig. 65-3); and (2) the odds of a crossover, or recombination event, between two linked genes is proportional to the distance that separates them. Thus, genes that are further apart are more likely to undergo a recombination event than genes that are very close together. Linkage is used in genetic counseling to predict the odds of disease gene transmission.

Polymorphisms are essential for linkage studies because they provide a means to distinguish the maternal and paternal chromosomes in an individual. On average, 1 out of every 1000 bp varies from one person to the next. Although this degree of variation seems low (99.9% identical), it means that >3 million sequence differences exist between any two unrelated individuals. This sequence variation usually has no significant functional consequence and provides much of the basis for variation in genetic traits. Although many of these sequence variations areSNPs, other variants includeVNTRs or short tandem repeats (STRs). In VNTRs and STRs, the number of times a sequence is repeated is highly variable in the population. Consequently, the probability that sequences will differ on the two homologous chromosomes is high (often>70 to 90%). Most STRs, also called *polymorphic microsatellite markers*, consist of di-, tri-, or tetranucleotide repeats that can be measured readily usingPCR and primers that reside on either side of the repeat sequences (Fig. 65-8). Many other methods for analyzing polymorphic variation are also available. Historically,RFLPswere used to detect sequence variations that caused changes in the recognition sites for restriction enzymes. This procedure has been largely replaced by the use of STRs. Analyses of SNPs, using DNA chips, provide a promising means for rapid analysis of genetic variation and linkage.

In order to identify a chromosomal locus that segregates with a disease, it is necessary to determine the genotype or haplotype of DNA samples from one or several pedigrees. One can then assess whether certain marker alleles cosegregate with the disease. Markers that are closest to the disease gene are less likely to undergo recombination

events and therefore receive a higher linkage score. Linkage is expressed as a lod (logarithm of odds) score -- the ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of -2 is consistent with the absence of linkage.

An example of the use of linkage analysis is shown in Fig. 65-8. In this case, the gene for the autosomal dominant disorder,MEN-1, is known to be located on chromosome 11q13. Using positional cloning, the *MEN1* gene was identified and shown to encode menin, the function of which is poorly understood. However, the transmission of the disorder suggests that menin acts like a tumor-suppressor gene. Affected individuals inherit a mutant form of the *MEN1* gene, predisposing them to certain types of tumors (parathyroid, pituitary, pancreatic islet) (Chap. 339). In the tissues that develop a tumor, a "second hit" occurs in the normal copy of the *MEN1* gene. This somatic mutation may be a point mutation, a microdeletion, or loss of a chromosomal fragment (detected as loss of heterozygosity, LOH). Within a given family, linkage to the *MEN1* gene locus can be assessed without necessarily knowing the specific mutation in the *MEN1* gene. Using polymorphicSTRsthat are close to the *MEN1* gene, one can assess transmission of the different *MEN1* alleles and compare this pattern to development of the disorder to determine which allele is associated with risk of MEN-1. In the pedigree shown, the affected grandfather in generation I carries alleles 3 and 4 on the chromosome with the mutated *MEN1* gene and alleles 2 and 2 on his other chromosome 11. Consistent with linkage of the 3/4 genotype to the *MEN1* locus, his son in generation II is affected, whereas his daughter (who inherits the 2/2 genotype from her father) is unaffected. In the third generation, transmission of the 3/4 genotype indicates risk of developing MEN-1, assuming that no genetic recombination between the 3/4 alleles and the *MEN1* gene has occurred. After a specific mutation in the *MEN1* gene is identified within a family, it is possible to track transmission of the mutation itself, thereby eliminating uncertainty caused by recombination.

CHROMOSOMAL DISORDERS

Chromosomal or cytogenetic disorders are caused by numerical or structural aberrations in chromosomes. Deviations in chromosome number are common causes of abortions, developmental disorders, and malformations.**For discussion of disorders of chromosome number and structure, see Chap. 66.*

Contiguous Gene Syndromes Large deletions or duplications may affect a portion of a gene, an entire gene, or, if several genes are involved, cause a *contiguous gene syndrome*. Syndromes associated with chromosomal deletions or duplications have a wide phenotypic spectrum that is dependent on the number of involved gene loci. For example, the cri-du-chat syndrome, one of the most common deletion disorders, is associated with deletions on the short arm of chromosome 5 that vary in size from extremely small deletions within 5p15.2 to the loss of the entire short arm. Because of the variable size of the involved deletions, the phenotype encompasses a spectrum that ranges from severe mental retardation and microcephaly to an isolated catlike cry without morphologic or mental abnormalities.

Contiguous gene syndromes have been useful for identifying the location of new disease-causing genes. Because of the variable size of gene deletions in different

patients, a systemic comparison of phenotypes and locations of deletion breakpoints allows positions of particular genes to be mapped within the critical genomic region.

MONOGENIC MENDELIAN DISORDERS

Monogenic human diseases are frequently referred to as *Mendelian disorders* because they obey the principles of genetic transmission originally set forth in Gregor Mendel's classic work. The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. All affected and unaffected individuals in the family are recorded in a pedigree using standard symbols (Fig. 65-9). The principles of allelic segregation, and the transmission of alleles from parents to children, are illustrated inFig. 65-10. One dominant (A) allele and one recessive (a) allele can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-chromosomal. About 65% of human monogenic disorders are autosomal dominant, 25% are autosomal recessive, and 5% are X-linked (Table 65-5). Genetic testing is now available for many of these disorders and plays an increasingly important role in clinical medicine.

Autosomal Dominant Disorders Autosomal dominant disorders assume particular relevance because mutations in a single allele are sufficient to cause the disease. In contrast to recessive disorders, in which disease pathogenesis is relatively straightforward because there is loss of gene function, in dominant disorders there are various disease mechanisms, many of which are unique to the function of the genetic pathway involved.

In autosomal dominant disorders, individuals are affected in successive generations; the disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency because the defective gene resides on one of the 22 autosomes (Fig. 65-11*A*). Autosomal dominant mutations alter one of the two alleles at a given locus. Because the alleles segregate randomly at meiosis, the probability that an offspring will be affected is 50%. Unless there is a new germline mutation, an affected individual has an affected parent. Children with a normal genotype do not transmit the disorder. Due to differences in penetrance or expressivity (see above), the clinical manifestations of autosomal dominant disorders may be variable. Because of these variations, it is sometimes challenging to determine the pattern of inheritance.

It should be recognized, however, that some individuals acquire a mutated gene from an unaffected parent. De novo germline mutations occur more frequently during later cell divisions in gametogenesis, explaining why siblings are rarely affected. As noted before, new germline mutations occur more frequently in fathers of advanced age. For example, the average age of fathers with new germline mutations that cause Marfan's syndrome is approximately 37 years, whereas fathers who transmit the disease by inheritance have an average age of about 30 years.

Autosomal Recessive Disorders The clinical expression of autosomal recessive disorders is more uniform than in autosomal dominant disorders. Most mutated alleles lead to a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or proteins in signaling cascades. Though most recessive disorders are rare, the relatively high frequency of certain recessive disorders,

such as sickle cell anemia, cystic fibrosis, and thalassemia, is partially explained by a selective biologic advantage for the heterozygous state (see below).

In an autosomal recessive disease, the affected individual, who can be of either sex, is a homozygote or compound heterozygote for a single-gene defect. With a few important exceptions, autosomal recessive diseases are rare and often occur in the context of parental consanguinity. Though heterozygous carriers of a defective allele are usually clinically normal, they may display subtle differences in phenotype that only become apparent with more precise testing or in the context of certain environmental influences. In sickle cell anemia, for example, heterozygotes are normally asymptomatic. However, in situations of dehydration or diminished oxygen pressure, sickle cell crises can also occur in heterozygotes (Chap. 106).

In most instances, an affected individual is the offspring of heterozygous parents. In this situation, there is a 25% chance that the offspring will have a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of homozygosity for the recessive alleles (Fig. 65-11*B*). In the case of one unaffected heterozygous and one affected homozygous parent, the probability of disease increases to 50% for each child. In this instance, the pedigree analysis mimics an autosomal dominant mode of inheritance (*pseudodominance*). In contrast to autosomal dominant disorders, new mutations in recessive alleles are rarely manifest because they usually result in an asymptomatic carrier state.

X-Linked Disorders Males have only one X chromosome; consequently, a daughter always inherits her father's X chromosome in addition to one of her mother's two X chromosomes. A son inherits the Y chromosome from his father and one maternal X chromosome. Thus, the characteristic features of X-linked inheritance are (1) the absence of father-to-son transmission, and (2) the fact that all daughters of an affected male are obligate carriers of the mutant allele (Fig. 65-11*C*). The risk of developing disease due to a mutant X-chromosomal gene differs in the two sexes. Because males have only one X chromosome, they are hemizygous for the mutant allele; thus, they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. The terms *X-linked dominant* or *X-linked recessive* are therefore only applicable to expression of the mutant phenotype in women. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation (see below).

Y-Linked Disorders Only a few genes are known on the Y chromosome. One such gene, the sex-region determining Y factor (*SRY*), or testis-determining factor (*TDF*), is crucial for normal male development. Normally there is infrequent exchange of sequences on the Y chromosome with the X chromosome. Because the *SRY* region is closely adjacent to the pseudoautosomal region, a chromosomal segment on the X and Y chromosomes with a high degree of homology, a crossing-over occasionally involves the *SRY* region. Translocations can result in XY females with the Y chromosome lacking the *SRY* gene or XX males harboring the *SRY* gene on one of the X chromosomes (Chap. 338). Point mutations in the *SRY* gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur de novo. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of

the Y chromosome that involve one or more of the azoospermia factor (*AZF*) genes.

EXCEPTIONS TO SIMPLE MENDELIAN INHERITANCE PATTERNS

Mitochondrial Disorders Each mitochondrion contains several copies of a circular chromosome. Mitochondrial DNA predominantly encodes transfer RNAs and proteins that are components of the respiratory chain involved in oxidative phosphorylation and ATP generation. The mitochondrial genome is inherited through the maternal line because sperm does not contribute significant cytoplasmic components to the zygote. All children from an affected mother will inherit the disease, but it will not be transmitted from an affected father to his children. During cell replication, the proportion of wild-type and mutant mitochondria can drift; differences in the fraction of defective mitochondria are referred to as *heteroplasmia* and explain, in part, the phenotypic variability that is common in mitochondrial diseases.**For detailed discussion of mitochondrial disorders, see Chap. 67.*

Mosaicism Mosaicism refers to the presence of two or more genetically distinct cell lines in the tissues of an individual. It results from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the mutation arises will determine whether germ cells and/or somatic cells are involved. Chromosomal mosaicism results from non-disjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line, as exemplified by some patients with Turner syndrome (Chap. 338). Somatic mosaicism is characterized by a patchy distribution of genetically altered somatic cells. The McCune-Albright syndrome, for example, is caused by activating mutations in the stimulatory G protein a(G_sa) that occur early in development (Chap. 343). The clinical phenotype varies depending on the tissue distribution of the mutation; manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, cafe-au-lait skin pigmentation, growth hormone-secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules (Chap. 336).

X-Inactivation, Imprinting, and Uniparental Disomy According to traditional Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of the phenotype. Nonetheless, there are important exceptions to this rule. X-inactivation prevents the expression of most genes on one of the two X-chromosomes in every cell of a female. Gene inactivation also occurs on selected chromosomal regions of autosomes. This phenomenon, referred to as *genomic imprinting*, leads to preferential expression of an allele depending on its parental origin. It is of pathophysiologic importance in disorders where the transmission of disease is dependent on the sex of the transmitting parent and, thus, plays an important role in the expression of certain genetic disorders. Two classic examples are the Prader-Willi syndrome and Angelman syndrome (Chap. 66). Prader-Willi syndrome is characterized by diminished fetal activity, obesity, hypotonia, mental retardation, short stature, and hypogonadotropic hypogonadism. Deletions in the Prader-Willi syndrome occur exclusively on the paternal chromosome 15. In contrast, patients with Angelman syndrome, characterized by mental retardation, seizures, ataxia, and hypotonia, have deletions at the same site of chromosome 15; however, they are located on the maternal chromosome 15. These two syndromes may also result from *uniparental disomy*. In this case, the syndromes are not caused by deletions on chromosome 15 but

by the inheritance of either two paternal chromosomes (Prader-Willi syndrome), or two maternal chromosomes (Angelman syndrome).

Imprinting and the related phenomenon of allelic exclusion may be more common than currently documented, as it is difficult to examine levels of mRNA expression from the maternal and paternal alleles in specific tissues or in individual cells. Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies (Chap. 66). Hydatidiform mole contains a normal number of diploid chromosomes, but they are all of paternal origin. The opposite situation occurs in ovarian teratomata, with 46 chromosomes of maternal origin. Expression of the imprinted gene for insulin-like growth factor II (IGF-II) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS) (Chap. 81). These children show somatic overgrowth with organomegalies and hemihypertrophy, and they have an increased risk of embryonal malignancies such as Wilm's tumor. Normally only the paternally derived copy of the *IGF-II* gene is active and the maternal copy is inactive. Imprinting of the *IGF-II* gene is regulated by *H19*, which encodes an RNA transcript that is not translated into protein. Disruption or lack of *H19* methylation leads to a relaxation of *IGF-II* imprinting and expression of both alleles. Heritable changes in gene expression not associated with DNA sequence alterations are referred to as *epigenetic effects*; these changes are increasingly recognized to play a role in human diseases and possibly in aging as well (Chap. 9).

Somatic Mutations In many cancer syndromes, there is an inherited predisposition to tumor formation. However, the neoplastic process requires the acquisition of additional somatic mutations (Chap. 81). In retinoblastoma, the tumor develops when both copies of the retinoblastoma (*RB*) gene are inactivated through two somatic events (sporadic retinoblastoma) or through a somatic loss of the normal allele in an individual with a hereditary defect in the other allele (hereditary retinoblastoma). This "two-hit" model applies to other inherited cancer syndromes such asMEN-1 (Chap. 339) and neurofibromatosis type 2 (Chap. 370). The defective allele is transmitted in a dominant pattern, though tumorigenesis results from a recessive loss of the tumor suppressor gene in an affected tissue. In other instances, the development of cancer typically requires somatic defects in multiple genes, a process termed *multistep carcinogenesis* (Chap. 82).

Nucleotide Repeat Expansion Disorders Several diseases are associated with an increase in the number of nucleotide repeats above a certain threshold (Table 65-6). The repeats are sometimes located within the coding region of the genes, as in Huntington disease or the X-linked form of spinal and bulbar muscular atrophy (SBMA, Kennedy syndrome). In other instances, the repeats probably alter gene regulatory sequences. If an expansion is present, the DNA fragment is unstable and tends to expand further during cell division. The length of the nucleotide repeat often correlates with the severity of the disease. When repeat length increases from one generation to the next, disease manifestations may worsen or be observed at an earlier age; this phenomenon is referred to as *anticipation*. In Huntington disease, for example, there is a correlation between age of onset and length of the triplet codon expansion (Chap. 362). Anticipation has also been documented in other diseases caused by dynamic mutations in trinucleotide repeats (Table 65-6). The repeat number may also vary in a tissue-specific manner. In myotonic dystrophy, the CTG repeat may be tenfold greater in

muscle tissue than in lymphocytes (Chap. 383).

POPULATION GENETICS AND ASSOCIATION STUDIES

Overview of Population Genetics In population genetics, the focus changes from alterations in an individual's genome to the distribution pattern of different genotypes of alleles in the population. In a case where there are only two alleles, A and a, the frequency of the genotypes will be $p^2 + 2pq + q^2 = 1$, with p^2 corresponding to the frequency of AA, $2pq$ to the frequency of Aa, and q^2 to aa. When the frequency of an allele is known, the frequency of the genotype can be calculated. Alternatively, one can determine an allele frequency, if the genotype frequency has been determined.

Allele frequencies vary among ethnic groups and geographical regions. For example, heterozygous mutations in the *CFTR* gene are relatively common in populations of European origin but are rare in the African population. Allele frequencies may vary because certain allelic variants confer a selective advantage. For example, heterozygotes for the sickle cell mutation, which is particularly common in West Africa, are more resistant to malarial infection because the erythrocytes of heterozygotes provide a less favorable environment for *Plasmodium* parasites. Though homozygosity for the sickle cell gene is associated with severe anemia and sickle crises (Chap. 106), heterozygotes have a higher probability of survival because of the reduced morbidity and mortality from malaria; this phenomenon has led to an increased frequency of the mutant allele. Recessive conditions are more prevalent in geographically isolated populations because of the more restricted gene pool.

Allelic Association and Linkage Disequilibrium There are two primary strategies for mapping genes that cause or increase susceptibility to human disease: (1) classic linkage can be performed based on a known genetic model (see above) or, when the model is unknown, by studying pairs of affected relatives; or (2) disease genes can be mapped using allelic association studies (Table 65-7). *Allelic association* refers to a situation in which the frequency of an allele is significantly increased or decreased in a particular disease. Linkage and association differ in several aspects. Genetic linkage is demonstrable in families or sibships. Association studies, on the other hand, compare a population of affected individuals with a control population. Association studies can be performed as case-control studies that include unrelated affected individuals and matched controls, or as family-based studies that compare the frequencies of alleles transmitted or not transmitted to affected children.

Allelic association studies are particularly useful for identifying susceptibility genes in complex diseases. When alleles at two loci occur more frequently in combination than would be predicted (based on known allele frequencies and recombination fractions), they are said to be in *linkage disequilibrium*. In Fig. 65-12, a mutation, Z, has occurred at a susceptibility locus where the normal allele is Y. The mutation is in close proximity to a genetic polymorphism with allele A or B. With time, the chromosomes carrying the A and Z alleles accumulate and represent 10% of the chromosomes in the population. The fact that the disease susceptibility gene, Z, is found preferentially, or exclusively, in association with the A allele illustrates linkage disequilibrium. Though not all chromosomes carrying the A allele carry the disease gene, the A allele is associated with an increased risk because of its possible association with the Z allele. This model

implies that it may be possible in the future to identify Z directly to provide a more accurate prediction of disease susceptibility. Evidence for linkage disequilibrium can be helpful in mapping disease genes because it suggests that the two loci, in this case A and Z, are tightly linked.

POLYGENIC DISEASE AND COMPLEX GENETIC TRAITS

Approach to Polygenic and Multifactorial Disease The expression of many common diseases such as cardiovascular disease, hypertension, diabetes, asthma, psychiatric disorders, and certain cancers is determined by genetic background, environmental factors, and lifestyle (Table 65-8). A trait is called *polygenic* if multiple genes are thought to contribute to the phenotype or *multifactorial* if multiple genes are assumed to interact with environmental factors. Genetic models for complex traits need to account for genetic heterogeneity and interactions with other genes and the environment. Complex genetic traits may be influenced by modifying genes that are not linked to the main gene involved in the pathogenesis of the trait. This type of gene-gene interaction, or *epistasis*, plays an important role in polygenic traits that require the simultaneous presence of variations in multiple genes in order to result in a pathologic phenotype.
Gene-environment interactions are relevant for many monogenic and polygenic disorders. In phenylketonuria, the phenotypic expression of the disease depends not only on the presence of the mutation in the phenylalanine hydroxylase gene but also on the exposure to the amino acid phenylalanine (Chap. 352). Another example is type 2 diabetes mellitus, in which genetic, nutritional, and lifestyle factors are intimately interrelated in disease pathogenesis (Chap. 333). The identification of genetic variations and environmental factors that either predispose or protect against disease is essential for predicting disease risk, designing preventive strategies, and developing novel therapeutic approaches (Chap. 68). The study of rare monogenic diseases may provide insights into genetic and molecular mechanisms that are subsequently of importance for the understanding of complex diseases. For example, the identification of the insulin promoter factor 1 in maturity-onset of diabetes type 4 was followed by the observation that it also plays a role in the pathogenesis of diabetes mellitus type 2 (Tables 65-1 and65-8).

Approach to the Patient

Identifying the Disease-Causing Gene *Genomic medicine* aims to enhance the quality of medical care through the use genotypic analysis (DNA testing) to identify genetic predisposition to disease, to select more specific pharmacotherapy, and to design individualized medical care based on genotype. Genotype can be deduced by analysis of protein (e.g., hemoglobin, apoprotein E), mRNA, or DNA. However, technological advances have made DNA analysis particularly useful because it can be readily applied to all but the largest genes (Fig. 65-13).

DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family. Mass screening programs require tests of high sensitivity and specificity to be cost-effective. Prerequisites for the success of genetic screening programs include the following: that the disorder is potentially serious; that it can be influenced at a presymptomatic stage by changes in behavior, diet, and/or pharmaceutical manipulations; and that the screening does not result in any

harm or discrimination. Screening in Jewish populations for the autosomal recessive neurodegenerative storage disease Tay-Sachs has reduced the number of affected individuals. In contrast, screening for sickle cell trait/disease in African Americans has led to unanticipated problems of discrimination by health insurers and employers. Mass screening programs harbor additional potential problems. For example, screening for the most common genetic alteration in cystic fibrosis, the DF508 mutation with a frequency of ~70% in northern Europe, is feasible and seems to be effective. One has to keep in mind, however, that there is pronounced allelic heterogeneity and that the disease can be caused by >600 other mutations. The search for these less common mutations would substantially increase costs but not the effectiveness of the screening program as a whole. Occupational screening programs aim to detect individuals with increased risk for certain professional activities (e.g.,$a_1$antitrypsin deficiency and smoke or dust exposure).

MUTATIONAL ANALYSES DNA sequence analysis is increasingly used as a diagnostic tool and significantly enhanced diagnostic accuracy. It is used for determining carrier status and for prenatal testing in monogenic disorders (Table 65-5). Certain cancer susceptibility genes, such as *BRCA1* and *BRCA2*, may identify individuals with an increased risk for the development of malignancies. The detection of mutations is an important diagnostic and prognostic tool in leukemias and lymphomas. The demonstration of the presence or absence of mutations is also relevant for the rapidly evolving field of pharmacogenetics, including the identification of differences in drug treatment response or metabolism as a function of genetic background.

A general algorithm for the approach to mutational analysis is outlined inFig. 65-13. The importance of a detailed clinical phenotype cannot be overemphasized. This is the step where one should also consider the possibility of genetic heterogeneity and phenocopies. If obvious candidate genes are suggested by the phenotype, they can be analyzed directly. After identification of a mutation, it is essential to demonstrate that it segregates with the phenotype. The functional characterization of novel mutations is labor-intensive and may require analyses in vitro or in transgenic models in order to document the relevance of the genetic alteration.

Numerous techniques are available for the detection of mutations (Table 65-9). In a very broad sense, one can distinguish between techniques that allow for screening the absence or presence of known mutations (screening mode) or techniques that definitively characterize mutations. Analyses of large alterations in the genome are possible using cytogenetics, fluorescent in situ hybridization (FISH), and Southern blotting (Chap. 66).

More discrete sequence alterations rely heavily on the use of thePCR, which allows rapid gene amplification and analysis. Moreover, PCR makes it possible to perform genetic testing and mutational analysis with small amounts of DNA extracted from leukocytes or even from single cells, buccal cells, or hair roots. Screening for point mutations can be performed by numerous methods (Table 65-9); most are based on the recognition of mismatches between nucleic acid duplexes, electrophoretic separation of single- or double-stranded DNA, or sequencing of DNA fragments amplified by PCR. DNA sequencing can be performed directly on PCR products or on fragments cloned into plasmid vectors amplified in bacterial host cells.

RT-PCRmay be useful to detect absent or reduced levels of mRNA expression due to a mutated allele. Protein truncation tests (PTT) can be used to detect the broad array of mutations that result in premature termination of a polypeptide during its synthesis. The isolated cDNA is transcribed and translated in vitro, and the proteins are analyzed by gel electrophoresis. Comparison of electrophoretic mobility with the wild-type protein allows detection of truncated mutants.

The majority of traditional diagnostic methods are gel-based. Novel technologies for the analysis of mutations, genetic mapping, and mRNA expression profiles are in rapid development. DNA chip technologies allow hybridization of DNA or RNA to hundreds of thousands of probes simultaneously. Microarrays are being used clinically for mutational analysis of several human disease genes, as well as for the identification of viral sequence variations. Together with the knowledge gained from theHGP, these technologies provide the foundation to expand from a focus on single genes to analyses at the scale of the genome.

ACKNOWLEDGEMENT

This chapter reflects the cumulative contributions of many past contributors to Harrison's Principles of Internal Medicine. Most recently, this includes Dr. Joseph L. Goldstein, Dr. Michael S. Brown, Dr. Andrea Ballabio, and Dr. Arthur L. Beaudet.

66. CHROMOSOME DISORDERS - *Terry Hassold*, *Stuart Schwartz*

In humans, the normal diploid number of chromosomes is 46, consisting of 22 pairs of autosomal chromosomes (numbered 1 to 22 in decreasing size) and one pair of sex chromosomes (XX in females and XY in males). The genome is estimated to contain between 80,000 and 100,000 genes, with the smallest autosome housing between 500 and 1000 genes. Not surprisingly, duplications or deletions of even small chromosome segments have profound consequences on normal gene expression.

Deviations in the number or structure of the 46 human chromosomes are astonishingly common, despite severe deleterious consequences. Chromosomal disorders occur in an estimated 10 to 25% of all pregnancies. They are the leading cause of fetal loss and, among pregnancies surviving to term, the leading known cause of birth defects and mental retardation.

In recent years, the practice of cytogenetics has shifted from conventional cytogenetic methodology to a union of cytogenetic and molecular techniques. Formerly the province of research laboratories, *fluorescence in situ hybridization* (FISH) and related molecular cytogenetic technologies have been incorporated into everyday practice in clinical laboratories. As a result, there is an increased appreciation of the importance of "subtle" constitutional cytogenetic abnormalities, such as microdeletions and imprinting disorders, as well as previously recognized translocations and disorders of chromosome number.

VISUALIZING CHROMOSOMES

CONVENTIONAL CYTOGENETIC ANALYSIS

In theory, chromosome preparations can be obtained from any actively dividing tissue by causing the cells to arrest in metaphase, the stage of the cell cycle at which chromosomes are maximally condensed. In practice, only a small number of tissues are used for routine chromosome analysis: amniocytes or chorionic villi for prenatal testing; and blood, bone marrow, or skin fibroblasts for postnatal studies. Samples of blood, bone marrow, and chorionic villi can be processed using short-term culture techniques that yield results in 1 to 3 days. Analysis of other tissue types typically involves long-term tissue culture, requiring 1 to 3 weeks of processing before cytogenetic analysis is possible.

Regardless of the culturing technique, cells are processed to recover chromosomes at metaphase or prometaphase and treated chemically or enzymatically to reveal chromosome "bands" (Fig. 66-1). Analysis of the number of chromosomes in the cell, and the distribution of bands on individual chromosomes, allows the identification of numerical or structural abnormalities. This strategy is useful for characterizing the normal chromosome complement and determining the incidence and types of major chromosome abnormalities.

Chromosomes are complex structures, consisting of the DNA double helix and chromosome-associated proteins. As for virtually all organisms, each human chromosome contains two specialized structures: a centromere and two telomeres. The

centromere, or primary constriction, divides the chromosome into short (p) and long (q) arms and is responsible for the segregation of chromosomes during cell division. The *telomeres*, or chromosome ends, "cap" the p and q arms and are important for allowing DNA replication at the ends of the chromosomes. Prior to DNA replication, each chromosome consists of a single chromatid copy of the DNA double helix. After DNA replication and continuing until the time of cell division (including metaphase, when chromosomes are typically visualized), each chromosome consists of two identical sister chromatids (Fig. 66-1).

MOLECULAR CYTOGENETICS

The introduction ofFISHmethodologies in the late 1980s revolutionized the field of cytogenetics. In principle, FISH is similar to other DNA-DNA hybridization methodologies. The labeled probe DNA and the target DNA (usually metaphase chromosomes) are denatured to become single-stranded and are hybridized together. The probe is labeled with a hapten, such as biotin or digoxigenin, to allow detection with a fluorophore (e.g., FITC or rhodamine). Alternatively, many probes are already labeled with fluorophores and thus can be detected directly. After the hybridization step, the specimen is counter-stained and the preparations are visualized with a fluorescence microscope.

Types of FISH Probes A variety of probes are available for use with FISH, including chromosome-specific paints (chromosome libraries), repetitive probes, and single-copy probes. Chromosome libraries were developed initially from flow-sorted individual chromosomes and more recently from monochromosomal human-rodent hybrids. These probes hybridize to sequences that span the entirety of the chromosome from which they are derived and, as a result, they can be used to "paint" individual chromosomes (Fig. 66-2).

Repetitive probes recognize amplified DNA sequences present in chromosomes. The most common are a-satellite DNA probes that are complementary to DNA sequences found at the centromeric regions of all human chromosomes. There are also a-satellite probes that hybridize to the centromeric regions of specific chromosomes (Fig. 66-2).

A vast number of *single-copy probes* are now available, both commercially and as a result of the human genome project. These probes can be as small as 1 kb, though normally they are packaged in cosmids (40 kb), bacterial artificial chromosomes (BACs) or P1 clones (100 to 200 kb), or yeast artificial chromosomes (YACs) (1 to 2 Mb). With the advent of the National Cancer Institute BAC initiative, these large DNA fragments will be placed at 1-Mb intervals on every chromosome, each of which can be used forFISHhybridization. Probes for a variety of microdeletion syndromes and for subtelomeric regions of individual chromosomes are commercially available (Fig. 66-2).

Applications of FISH The majority of FISH applications involve hybridization of one or two probes of interest as an adjunctive procedure to conventional chromosomal banding techniques. In this regard, FISH can be utilized to identify specific chromosomes, characterize de novo duplications or deletions, and identify and clarify subtle chromosomal rearrangements. Its greatest utilization, however, is in the detection of microdeletions (see below), including those associated with Prader-Willi syndrome

(PWS), Angelman syndrome (AS), William syndrome, velocardiofacial (VCF) and DiGeorge syndromes, Smith-Magenis syndrome, and Miller-Dieker syndrome (MDS) (see below). Though conventional cytogenetic studies can detect some of these microdeletions, initial detection and/or confirmation with FISH is essential. In fact, since appropriate FISH probes have become available, detection of the aforementioned syndromes has increased significantly.

In addition to metaphaseFISH, cells can be analyzed at a variety of stages. *Interphase analysis*, for example, can be used to make a rapid diagnosis in instances where metaphase chromosome preparations are not yet available (e.g., amniotic fluid interphase analysis). Interphase analysis also increases the number of cells available for examination, allows for investigation of nuclear organization, and provides results when cells do not progress to metaphase. One specialized type of interphase analysis involves the application of FISH to paraffin-embedded sections, thereby preserving the architecture of the tissue.

The use of interphaseFISH has increased recently, especially for analyses of amniocentesis samples. These studies are performed on uncultured amniotic fluid, typically using DNA probes specific for the chromosomes most commonly identified in trisomies (chromosomes 13, 18, 21, and the X and Y). These studies can be performed rapidly (24 to 72 h) and will ascertain about 60% of the abnormalities detected prenatally. Nevertheless, guidelines from the American College of Medical Genetics suggest that standard cytogenetic analysis be conducted on all specimens following FISH analysis.

Another area in which interphase analysis is routinely utilized is cancer cytogenetics (Chap. 81). Many site-specific translocations are associated with specific types of malignancies. For example, there are probes available for both the Abelson (Abl) oncogene and breakpoint cluster region (bcr) involved in chronic myelogenous leukemia (CML). These probes are labeled with rhodamine and FITC, respectively; the fusion of these genes in CML combines the fluorescent colors and appears as a yellow hybridization signal.

In addition to standard metaphase and interphaseFISHanalyses, a number of enhanced techniques have been developed for specific types of analysis, including multicolor FISH techniques, reverse painting, comparative genomic hybridization, and fiber FISH. *Spectral karyotyping* (SKY) and*multicolor FISH* (m-FISH) techniques use combinatorially labeled probes that create a unique color for individual chromosomes. In this manner, all of the chromosomes are studied simultaneously, and computer software is used to generate "pseudo-colors" for the individual chromosomes. This technology is useful in the identification of unknown chromosome material (such as markers of duplications) but is most commonly used with the complex rearrangements seen in cancer specimens.

Reverse painting is accomplished by either flow-sorting a chromosome of interest or scraping the chromosome off a slide. The DNA from this chromosome (or portion of a chromosome) is extracted, amplified, labeled, and used as aFISHprobe. This probe is then hybridized to a normal metaphase chromosome to identify the origin of the DNA of interest. It is also utilized to identify marker chromosomes or chromosome duplications

of unknown origin.

Comparative genomic hybridization (CGH) is a method that can be used when only DNA is available from a specimen of interest. The entire DNA specimen from the sample of interest is labeled in one color (e.g., green), and the normal control DNA specimen in another color (e.g., red). These are mixed in equal amounts and hybridized to normal metaphase chromosomes. The red-to-green ratio is analyzed by a computer program, which determines where the DNA of interest may have gains or loss of material. This technique is useful in the analysis of tumors, particularly in those cases where cytogenetic analysis is not possible.

Fiber FISH is a technique in which chromosomes are mechanically stretched, using one of a variety of different methods. FiberFISHprovides a higher resolution of analysis than conventional FISH and more precise information on the chromosomal localization of a specific probe.

CYTOGENETIC TESTING IN PRENATAL DIAGNOSIS (See also Chap. 68)

The vast majority of prenatal diagnostic studies are performed to rule out a chromosomal abnormality, but cells may also be propagated for biochemical studies or molecular analyses of DNA. Three procedures are used to obtain samples for prenatal diagnosis: amniocentesis, chorionic villus sampling (CVS), and fetal blood sampling. *Amniocentesis* is the most commonly used procedure and is routinely performed at 15 to 17 weeks of gestation. On some occasions, early amniocentesis at 12 to 14 weeks is done to expedite results, though less fluid is obtained at this time. Early amniocentesis carries a greater risk of spontaneous abortion or fetal injury but provides results at an earlier stage of pregnancy.

The vast majority of amniocentesis are performed in the context of advanced maternal age, the best-known correlate of trisomy (see below). Additional reasons for referral for amniocentesis include an abnormal "triple-marker assay" and/or detection of ultrasound abnormalities. In the triple-marker assay, levels of human chorionic gonadotropin, a fetoprotein, and unconjugated estriol in the maternal serum are quantified and used to adjust the maternal age-predicted risk of a trisomy 21 or trisomy 18 fetus. Specific ultrasound abnormalities, when detected at mid-trimester, can also be associated with chromosomal defects. When a nonspecific ultrasound abnormality is present, the estimated risk of a chromosomal defect is approximately 16%. Associations of chromosomal abnormalities and specific types of abnormal ultrasound findings are listed in Table 66-1.

Chorionic villus sampling is the second most common procedure for genetic prenatal diagnosis. Because this procedure is routinely performed at about 8 to 10 weeks of gestation, it allows for an earlier detection of abnormalities and a safer pregnancy termination, if desired.CVS is a relatively safe procedure (spontaneous abortions <0.5 to 1%). Because there is an increased association of limb defects when the procedure is performed later (³11 weeks of gestation), CVS is applicable during a very narrow window of time of gestation. CVS involves the use of a catheter inserted transvaginally; approximately 25 mg of villi are aspirated from the chorion frondosum (the fetal portion of the placenta). Care must be taken not to obtain villi from the maternal portion from

the placenta to avoid compromising the analysis. The majority of the sample (the mesenchymal cells from the CVS sample) is enzymatically digested and cultured in a fashion similar to amniotic fluid cells. However, cells in the outer layer of the villi -- the cytotrophoblasts -- are actively dividing and can be analyzed directly. Therefore, by adding colchicine directly to these cells, a result can be obtained within 24 to 48 h. Findings from these procedures should be confirmed by analyses of cultured mesenchymal cells, as they are more reliably derived from the fetus.

Percutaneous umbilical blood sampling (PUBS) is a method for obtaining fetal blood during the second and third trimesters of pregnancy. It allows for acquisition of a blood sample, which can be used for cytogenetic studies; results can be obtained within 48 h of sampling. PUBS is carried out under ultrasound guidance. It is usually performed when ultrasound abnormalities are detected late in the second trimester. PUBS is also used when cytogenetic results from amniocentesis need clarification, such as the detection of mosaicism.

CHROMOSOME ABNORMALITIES

CHROMOSOMES IN CELL DIVISION

To understand the etiology of chromosome abnormalities, it is important to review the movement of chromosomes during cell division. In somatic tissues, chromosomes are replicated during the S-phase of the cell cycle, so that each replicated chromosome consists of two identical sister chromatids (Fig. 66-1). When the cell enters mitosis, each of the 46 chromosomes align on the metaphase plate, with the centomeres cooriented toward opposite spindle poles (Fig. 66-3). At anaphase the sister chromatids separate, with each of the daughter cells receiving one sister chromatid from each of the 46 chromosomes.

Chromosome segregation is more complicated in germ cell division, since the number of chromosomes must be reduced from 46 to 23 in the mature sperm and eggs. This is accomplished by two rounds of division -- meiosis I and meiosis II (Fig. 66-3). In meiosis I, homologous chromosomes become paired and exchange genetic material, then align on the metaphase plate, and finally separate from one another. Thus, by the end of meiosis I, only 23 of the original 46 chromosomes are represented in each of the two daughter cells. Meiosis II quickly follows meiosis I and is essentially a "haploid mitosis," involving separation of the sister chromatids in each of the 23 chromosomes.

Although the fundamentals of meiosis are the same in males and females, there are important distinctions, particularly in the timing of the meiotic divisions. In males, meiosis begins with puberty and continues throughout the individual's lifetime. In females, meiosis begins prenatally, with oocytes proceeding through the first stages of meiosis I but arresting at mid-prophase. At the time of birth, the first meiotic division is suspended in oocytes. Only after ovulation many years later do oocytes complete meiosis I and proceed to the metaphase stage of meiosis II; if fertilized, the oocyte then completes the second meiotic division. Thus, in females, the first meiotic division takes at least 10 to 15 years, and possibly as many as 40 to 45 years, to complete. Maternal age-related increases in the incidence of trisomy are likely the consequence of this protracted process of cell division.

INCIDENCE AND TYPES OF CHROMOSOME ABNORMALITIES

Errors in meiosis, or in early cleavage divisions, occur with extraordinary frequency. At least 10 to 25% of all pregnancies, for example, involve chromosomally abnormal conceptions. A large proportion of these terminate in the earliest stages of pregnancy. Nevertheless, even among clinically recognized pregnancies, nearly 10% of fetuses are chromosomally unbalanced. The occurrence of different classes of chromosome abnormalities are summarized inTable 66-2 for the three types of clinically recognized pregnancies: spontaneous abortions, stillbirths, and livebirths. The commonest abnormalities are numerical, involving fetuses with additional (*trisomy*) or missing (*monosomy*) chromosomes or those with one (*triploidy*) or two (*tetraploidy*) additional sets of chromosomes. Structural chromosome abnormalities are much less common, although several of the most important clinical chromosomal disorders involve structural rearrangements (see below).

By far the most common abnormality is trisomy, which is identified in approximately 25% of spontaneous abortions and 0.3% of newborns. Trisomies for all chromosomes have now been identified in embryos or fetuses, but there is considerable variation in frequency for various chromosomes. For example, trisomy 16 is extraordinarily common, accounting for about one-third of all trisomies in spontaneous abortions, whereas trisomies 1, 5, 11, and 19 have been identified less often. Available evidence suggests two reasons for this variation: (1) some chromosomes (e.g., chromosome 16) are more likely to segregate abnormally or undergo nondisjunction during meiosis than are others; and (2) the potential for development varies widely among different trisomic conditions, with some being eliminated very early in gestation, others surviving to the time of clinical pregnancy recognition, and some (e.g., trisomies 13, 18, and 21 and sex chromosome trisomies) being compatible with survival to term.

CHROMOSOMAL SYNDROMES

While most chromosomally abnormal conceptions perish in utero (Table 66-2), several conditions are compatible with survival to term. The best-characterized of these are numerical abnormalities involving loss or gain of individual chromosomes and abnormalities resulting from unbalanced translocations.FISH and other molecular studies have led to the identification of two "new" types of chromosome abnormalities, commonly referred to as *microdeletion syndromes* and *imprinting syndromes*.

Numerical Abnormalities Virtually all types of numerical abnormalities are eliminated prenatally, so that only those involving small, gene-poor autosomes or the sex chromosomes are identified with any frequency among live-borns. Clinically, the most important of these is *trisomy 21*, the most frequent cause of Down syndrome. Depending on the maternal age structure of the population and the utilization of prenatal testing, the incidence of trisomy 21 ranges from 1/600 to 1/1000 live births, making it the most common chromosome abnormality in live-born individuals. Like most trisomies, the incidence of trisomy 21 is highly correlated with maternal age, increasing from about 1/1500 live births for women 20 years of age to 1/30 for women 45 years of age and older.

In addition to trisomy 21, only two other autosomal trisomies, 13 and 18, occur with any frequency in livebirths. Incidence rates for trisomies 13 and 18 in live births are 1/20,000 and 1/10,000 respectively. Unlike trisomy 21, which is associated with near-normal life expectancy, both trisomies 13 and 18 are associated with death in infancy, typically occurring during the first year of life.

Three sex chromosome trisomies -- the 47,XXX, 47,XXY (*Klinefelter syndrome*), and 47,XYY conditions -- are quite common, with each occurring in about 1/2000 newborns. Of all the trisomic conditions, these three have the fewest phenotypic complications. In fact, with the exception of infertility in Klinefelter syndrome (Chap. 335), it is likely that most individuals with such trisomic conditions would go undetected. The additional chromosome in the 47,XYY condition is small and contains only a few genes. Most Y-linked genes are involved in testicular development or spermatogenesis. Thus, dosage imbalance of Y-linked genes has relatively little effect on other developmental processes. The 47,XYY genotype is associated with increased height. Its role in antisocial behavior, postulated initially because of an increased prevalence among some penalized populations, is unclear.

For the 47,XXX and 47,XXY conditions, the situation is different -- the X chromosome contains over 1000 genes, many of them essential for normal development. How, then, are 47,XXX and 47,XXY individuals spared from the catastrophic consequences of dosage imbalance? The answer lies in the biology of X chromosome gene expression. In normal females, one of the X chromosomes is inactivated in somatic cells. The inactivation of the paternal or maternal X chromosome occurs randomly in each somatic cell and thereby serves as a mechanism of dosage compensation, ensuring that males and females have equal expression of most X-linked genes. The inactivation process occurs at the blastocyst stage of development; prior to this time both X chromosomes are active. In addition, the rules for inactivation are different for germ cells than for somatic cells: in female germ cells both X chromosomes remain active, whereas in male germ cells the X chromosome is inactivated. In addition, not all X-linked genes are inactivated. Some genes on the X chromosome "escape" the inactivating mechanism and are expressed from both X chromosomes. In disorders such as Klinefelter syndrome, some genes may be expressed from both X chromosomes, resulting in phenotypic abnormalities. Individuals with Klinefelter syndrome have small testes, hyalinized seminiferous tubules, and azoospermia or severe oligospermia (Chap. 335). Testosterone levels are variably reduced, and often there is gynecomastia and eunuchoidal body proportions. Antisocial behavior and mild mental deficiency are seen in some individuals. Females with the 47,XXX genotype are more likely to have mild mental deficiency and may be subfertile. Despite these features, sex chromosome trisomies impart relatively minor phenotypic complications in comparison to aneuploidies that involve autosomal chromosomes.

As a rule, monosomic conditions are incompatible with fetal development and, consequently, autosomal monosomies are only rarely identified in spontaneous abortions and are not found among live-born individuals. In fact, the only monosomy compatible with live birth is the 45,X condition, which causes *Turner syndrome*. The 45,X chromosome constitution occurs with surprisingly high frequency, being present in at least 1 to 2% of all pregnancies. More than 99% of all 45,X conceptions are spontaneously aborted. Thus, live-born individuals with a 45,X chromosome constitution

represent a rare group of survivors. The 45,X phenotype is mild, presumably because the second copy of many X chromosomal genes is normally inactivated. Nonetheless, Turner syndrome causes gonadal dysgenesis, resulting in infertility and failure to undergo secondary sexual development. Other prominent features are more variable and include short stature, webbing of the neck, and shield-shaped chest; lymphedema; increased carrying angle at the elbow; cardiovascular and renal abnormalities; and a propensity to hypertension, glucose intolerance, and autoimmune thyroid disease (Chap. 336). Several other structural abnormalities of the X chromosome such as partial deletions, isochromosome X, or ring chromosomes can cause Turner syndrome. Mosaicism, including 45,X/45,XX, 45X/45,XXX, 45,X/45,XY, and others, also occurs (see below) and contributes to the phenotypic spectrum seen in Turner syndrome.

Because numerical abnormalities originate in meiosis (Table 66-3), affected individuals have missing or extra chromosomes in all cells. In a small proportion of cases, though, a mitotic nondisjunctional event occurs at an early stage in an individual with an initially normal chromosome constitution. Alternatively, a "normalizing" mitotic nondisjunctional event may result in a normal chromosome complement in some cells of an embryo. In either case, the embryo is a *mosaic*, with some cells bearing a normal chromosome constitution and others an aneuploid number of chromosomes. The phenotypic consequences are difficult to predict because they depend on the timing of nondisjunction and the distribution of normal and abnormal cells in different tissues. Nevertheless, mosaicism may lead to clinical abnormalities indistinguishable from those of nonmosaic individuals; for example, nearly 5% of all cases of Down syndrome involve individuals with mosaic trisomy 21, and about 15% of individuals with Turner syndrome are mosaic for various sex chromosomal constitutions as described above.

The Origin and Etiology of Numerical Abnormalities Over the past decade, a number of studies have used DNA polymorphisms to investigate the origin of different types of chromosome abnormalities (Fig. 66-4). The most thoroughly investigated types have been numerical abnormalities (Table 66-3). Sex chromosome monosomy usually results from loss of the paternal sex chromosome. This is the case regardless of whether the conception is live-born or spontaneously aborted, indicating that the parental origin of the abnormality does not affect its likelihood of surviving to term.

Trisomies show remarkable variation in parental origin. For example, paternal nondisjunction is responsible for nearly 50% of 47,XXY but only 5 to 10% of cases of trisomies 13, 14, 15, 21, and 22; it is rarely, if ever, the source of the additional chromosome in trisomy 16. Similarly, there is considerable variability in the meiotic stage of origin. For example, among maternally derived trisomies, all cases of trisomy 16 may be due to meiosis I errors, whereas for trisomy 21, one-third of cases are associated with meiosis II errors, and for trisomy 18, the majority of cases are apparently due to meiosis II nondisjunction. In spite of this variation in parental and meiotic origin, nondisjunction at maternal meiosis I appears to be the most common source of trisomy.

Molecular studies have also begun to shed light on the molecular mechanisms underlying nondisjunction, the source of trisomy and monosomy. Most, if not all, trisomies are associated with alterations in genetic recombination. This is the process by which chromosomes exchange genetic material during the first of the two meiotic

divisions. In other organisms, the physical connections, or chiasmata, associated with recombination are known to hold chromosomes together at meiosis I. This mechanism is now known to be true for humans as well. Nondisjunction at meiosis I is linked to a reduced extent of crossing-over, with some cases involving outright failure of recombination between the homologous chromosomes, and others associated with distally placed exchanges. Unexpectedly -- since recombination occurs at meiosis I -- maternal meiosis II errors involving chromosome 21 may also be linked to altered recombination. In this instance, though, the effect involves increased -- not decreased -- recombination, especially in proximal 21q. Presumably, this indicates that errors scored as arising at meiosis II are, in fact, precipitated by events occurring at meiosis I.

Maternal Age and Trisomy The association between increasing maternal age and trisomy is arguably the most important etiologic factor in congenital chromosomal disorders. Among women under the age of 25, approximately 2% of all clinically recognized pregnancies are trisomic; by the age of 36, however, this figure increases to 10% and by the age of 42, to >33% (Fig. 66-5). This association between maternal age and trisomy is exerted without respect to race, geography, or socioeconomic factors and likely affects segregation of all chromosomes.

Despite the importance of increasing age, almost nothing is known about the mechanism by which aging leads to abnormal chromosomal segregation. As noted above, it is thought to originate in maternal meiosis I owing to the protracted time to completion (often³40 years) in females. As noted above, alterations in genetic recombination may explain age-related trisomy. In trisomy 21, for example, recombination patterns appear to be similarly altered in younger and older mothers of trisomic conceptions. With this in mind, it has been suggested that two distinct steps, or "hits," may be involved in maternal age-related nondisjunction. The first hit, which is age-independent, involves the establishment of a "vulnerable" recombination configuration in the fetal oocyte; the second hit, which is age-dependent, involves abnormal processing of the vulnerable bivalent structure at metaphase I. If this model is correct, it means that the nondisjunctional process is the same in younger and older women, but it occurs more frequently with aging, possibly because of age-dependent degradation of cell cycle proteins or meiotic proteins responsible for maintaining sister chromatid cohesion.

Structural Chromosome Abnormalities Structural rearrangements involve breakage and reunion of chromosomes. Although less common than numerical abnormalities, they present additional challenges from a genetic counseling standpoint. This is because structural abnormalities, unlike numerical abnormalities, can be present in "balanced" form in clinically normal individuals but transmitted in "unbalanced" form to progeny, thereby resulting in a hereditary form of chromosome abnormality.

Rearrangements may involve exchanges of material between different chromosomes (*translocations*) or loss, gain, or rearrangements of individual chromosomes (e.g., *deletions*, *duplications*, *inversions*, *rings* or *isochromosomes*). Of particular clinical importance are translocations, which involve two basic types: Robertsonian and reciprocal. *Robertsonian rearrangements* are a special class of translocation, in which the long arms of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) join together, generating a fusion chromosome that contains virtually all of the genetic

material of the original two chromosomes. If the Robertsonian translocation is present in unbalanced form, a monosomic or trisomic conception ensues. For example, approximately 3% of cases of Down syndrome are attributable to unbalanced Robertsonian translocations, most often involving chromosomes 14 and 21. In this instance, the affected individual has 46 chromosomes, including one structurally normal chromosome 14, two structurally normal chromosomes 21, and one fusion 14/21 chromosome. This effect leads to a normal diploid dosage for chromosome 14 and to a triplication of chromosome 21, thus resulting in Down syndrome. Similarly, a small proportion of individuals with trisomy 13 syndrome are clinically affected because of an unbalanced Robertsonian translocation.

Reciprocal translocations involve exchanges between any two chromosomes. In this circumstance, the phenotypic consequences associated with unbalanced translocations depend on the location of the breakpoints, which dictate the amount of material that has been "exchanged" between the two chromosomes. Because most reciprocal translocations involve unique sets of breakpoints, it is difficult to predict the phenotypic consequences in any one situation. In general, severity is determined by the amount of excess or missing chromosome material in individuals with unbalanced translocations.

In addition to rearrangements between chromosomes, there are several examples of intrachromosome structural abnormalities. The most common and deleterious of these involve loss of chromosome material due to deletions. The two best-characterized deletion syndromes, *Wolf-Hirschhorn syndrome* and *cri-du-chat syndrome*, result from loss of relatively small chromosomal segments on chromosomes 4p and 5p, respectively. Nonetheless, each is associated with multiple congenital anomalies, developmental delays, profound retardation, and reduced lifespan.

Microdeletion Syndromes The term *contiguous gene syndromes* refers to genetic disorders that mimic a combination of single gene disorders. They result from the deletion of a small number of tightly clustered genes. Because they are usually too small to be detected cytogenetically, they are termed *microdeletions*. The application of molecular techniques has led to the identification of at least 18 of these microdeletion syndromes (Table 66-4). Some of the more common ones include the Wilms' tumor-aniridia complex (WAGR),MDS, andVCFsyndrome. *WAGR* is characterized by mental retardation and involvement of multiple organs, including kidney (Wilm's tumor), eye (aniridia), and the genitourinary system. The cytogenetic abnormality involves a deletion of part of the short arm of chromosome 11 (11p13), which typically is detectable on well-banded chromosome preparations. In *MDS*, a disorder characterized by mental retardation, dysmorphic faces, and lissencephaly, the deletion involves chromosome 17 (17p13). UsingFISH, 17p deletions have been detected in >90% of MDS patients as well as in 20% of cases of isolated lissencephaly.

Deletions involving the long arm of chromosome 22 (22q11) are the most common microdeletions identified to date, present in approximately 1/3000 newborns.VCFsyndrome, the most commonly associated syndrome, consists of learning disabilities or mild mental retardation, palatal defects, a hypoplastic aloe nasi and long nose, and congenital heart defects (conotruncal defect). Some individuals with 22q11 deletion are more severely affected and present with *DiGeorge syndrome*, which involves abnormalities in the development of the third and fourth branchial arches

leading to thymic hypoplasia, parathyroid hypoplasia, and conotruncal heart defects. In approximately 30% of these cases, a deletion at 22q11 can be detected with high-resolution banding; by combing conventional cytogenetics,FISH, and molecular detection techniques (i.e., Southern blotting or polymerase chain reaction analyses), these rates improve to >90%. Additional studies have demonstrated a surprisingly high frequency of 22q11 deletions in individuals with nonsyndromic conotruncal defects. Approximately 10% of individuals with a 22q11 deletion inherited it from a parent with a similar deletion.

Smith-Magenis syndrome involves a microdeletion localized to the short arm of chromosome 17 (17p11.2). Affected individuals have mental retardation, dysmorphic facial features, delayed speech, peripheral neuropathy, and behavior abnormalities. Most of these deletions can be detected with cytogenetic analysis, althoughFISH is available to confirm these findings. In contrast, *William syndrome*, a chromosome 7 (7q11.23) microdeletion, cannot be diagnosed with standard or high-resolution analysis; it is only detectable utilizing FISH or other molecular methods. William syndrome involves a deletion of the elastin gene and is characterized by mental retardation, dysmorphic features, a gregarious personality, premature aging, and congenital heart disease (usually supravalvular aortic stenosis).

In addition to microdeletion syndromes, there is now at least one well-described microduplication syndrome, Charcot-Marie-Tooth type 1A (CMT1A). This is a nerve conduction disease previously though to be transmitted as a simple autosomal dominant disorder. Recent molecular studies have demonstrated that affected individuals are heterozygous for duplication of a small region of chromosome 17 (17p11.2-12). Although it is not yet clear why increased gene dosage would result in CMT1A, the inheritance pattern is explained by the fact that one-half of the offspring of affected individuals inherit the duplication-carrying chromosome.

Imprinting Disorders Two other microdeletion syndromes,PWS andAS, exhibit parent-of-origin, or "imprinting," effects. For many years, it has been known that cytogenetically detectable deletions of chromosome 15 occur in a proportion of patients with PWS, as well as in those with AS. This seemed curious, as the clinical manifestations of the two syndromes are very dissimilar. PWS is characterized by obesity, hypogonadism, and mild to moderate mental retardation, whereas AS is associated with microcephaly, ataxic gait, seizures, inappropriate laughter, and severe mental retardation. New insight into the pathogenesis of these disorders has been provided by the recognition that parental origin of the deletion determines which phenotype ensues: if the deletion is paternal, the result is PWS, whereas if the deletion is maternal, the result is AS (Fig. 66-2).

This scenario is complicated further by the recognition that not all individuals withPWS orAS carry the chromosome 15 deletion. For such individuals, it turns out that the parental origin of the chromosome 15 region is again the important determinant. In PWS, for example, nondeletion patients invariably have two maternal and no paternal chromosomes 15 [*maternal uniparental disomy* (UPD)], whereas for some nondeletion AS patients the reverse is true (*paternal UPD*). This indicates that at least some genes on chromosome 15 are differently expressed, depending on which parent contributed the chromosome. Additionally, this means that normal fetal development requires the

presence of one maternal and one paternal copy of chromosome 15.

Approximately 70% ofPWScases are due to paternal deletions of 15q11-q13, whereas 25% are due to maternal uniparental disomy, and about 5% are caused by mutations in a chromosome 15 imprinting center. Though 75% of theAS cases are due to maternal deletions, only 2% are due to paternal uniparental disomy. The rest of the cases are presumed to be caused by imprinting mutations (5%) or mutations in the UBE3A gene, which is one of the genes associated with AS. TheUPDcases are mostly caused by meiotic nondisjunction resulting in trisomy 15, subsequently followed by a normalizing mitotic nondisjunction event ("trisomy rescue") resulting in two normal chromosomes 15, both from the same parent. *UBE3A* is the only maternally imprinted gene known in the critical region of chromosome 15. However, several paternally imprinted genes, or expressed-sequence tags (ESTs), have been identified, including *ZNF127*, *IPW*, *SNRPN*, *SNURF*, *PAR1*, and *PAR5*.

Chromosomal regions that behave in the manner observed inPWS andAS are said to be *imprinted*. This phenomenon is involved in differential expression of certain genes on different chromosomes. Chromosome 11 must be one of these with an imprinted region, since it is known that a small proportion of individuals with the *Beckwith-Wiedemann overgrowth syndrome* have two paternal but no maternal copies of this chromosome.

ACQUIRED CHROMOSOME ABNORMALITIES IN CANCER

In addition to the constitutional cytogenetic chromosomal abnormalities that are present at birth, somatic chromosomal changes can be acquired later in life and are often associated with malignant conditions. As with constitutional abnormalities, somatic changes can include the net loss of chromosomal material (due to a deletion or loss of a chromosome), net gain of material (duplication or gain of a chromosome), and relocation of DNA sequences (translocation). These chromosomal changes are intertwined with the three major categories of cancer genes: (1) *tumor-suppressor genes* that inhibit cell proliferation may be deleted; (2) *oncogenes* that activate cell proliferation may be activated by duplication, amplification, or translocation; and (3) *DNA repair genes* may also be deleted from somatic cells, thereby predisposing to the accumulation of additional DNA damage. Cytogenetic changes have been particularly well studied in (1) leukemias, e.g., Philadelphia chromosome translocation inCML[t(9;22)(q34.1;q11.2)]); and (2) lymphomas, e.g., translocations of MYC in Burkitt's [t(8;14)(q24;q32)]. These and other translocations are useful for diagnosis, classification, and prognosis. Analyses of cytogenetic changes are also proving useful in certain solid tumors. For example, a complex karyotype with Wilms' tumor, diploidy in medulloblastoma, and Her-2/neu amplification in breast cancer are poor prognostic signs. The genetic basis of malignancy, including the role of germline and somatic chromosomal alterations, is discussed further inChap. 81.

67. DISEASES CAUSED BY GENETIC DEFECTS OF MITOCHONDRIA - *Donald R. Johns*

Mitochondrial defects play a role in several metabolic and neurodegenerative diseases as well as aging. Mitochondrial disorders have protean clinical manifestations, reflecting the fact that nearly all organ systems utilize oxidative metabolism. Clinical features often involve tissues with high energy requirements such as the central and peripheral nervous systems, the eye, muscle, kidney, and endocrine organs. The age and mode of onset and clinical course of mitochondrial diseases range widely as a result of the unusual mechanisms of mitochondrial DNA (mtDNA) replication, which is distinct from that of the nuclear genome. A maternal mode of inheritance is characteristic of many mitochondrial diseases because mtDNA is transmitted by the oocyte. Hundreds of different mtDNA mutations have been described since the first mutation was described in 1988.

STRUCTURE AND FUNCTION OF MITOCHONDRIAL DNA

Most cells contain several hundred mitochondria, though the number varies depending on the energy requirements and function of a tissue. Mitochondria are the only cellular organelles that contain their own extrachromosomal DNA. HumanmtDNA is a small (16,569 bp) double-stranded, circular molecule that encodes 13 protein subunits of 4 different oxidative phosphorylation biochemical complexes. mtDNA also encodes the 24 structural RNAs (2 ribosomal RNAs and 22 transfer RNAs) required for the intramitochondrial translation of these proteins. The noncoding D (displacement)-loop is a regulatory region that controls transcription and replication. mtDNA mutations are found in each type of mitochondrial gene (Fig. 67-1).

Mitochondria probably evolved from independent organisms that became endosymbiotically incorporated into the cell. As a result, mitochondria replicate, transcribe, and translate their DNA independently of nuclear DNA. However, cellular and mitochondrial function are interdependent. Nuclear DNA-encoded proteins are also involved in oxidative phosphorylation, and the myriad macromolecular compounds required for mitochondrial structure and function (e.g.,mtDNAreplication, transcription, and translation) are imported from the cytoplasm into the mitochondria.

Oxidative phosphorylation and the generation of adenosine triphosphate (ATP) for energy-requiring cellular processes are the central functions of mitochondria. Alterations in mitochondrial function lead to disease pathogenesis by three main mechanisms: (1) reduction of ATP supply when mutations impair oxidative phosphorylation; (2) generation of reactive oxygen species such as $H_2O_2$and OH× free radicals that can damage DNA, proteins, or lipids; and (3) execution of the apoptosis pathway when mitochondria release cell death-promoting factors including caspases, cytochrome c, and apoptosis-inducing factor.

Several unique features ofmtDNArender it vulnerable to mutations and contribute to its role in disease. For example, mtDNA has no introns (a random mutation will therefore usually strike a coding DNA sequence) or protective histones, and it has an imperfect DNA repair system and is exposed to oxygen free radicals generated by oxidative phosphorylation. mtDNA is estimated to mutate 10 times more rapidly than nuclear

DNA. Importantly, mtDNA is strictly *maternally inherited* and does not recombine, and mtDNA mutations sequentially accumulate along maternal lineages. These properties have made mtDNA sequence variation an invaluable tool for evolutionary biologists and forensic scientists.

Each mitochondrion contains 2 to 10mtDNAmolecules, and each cell contains multiple mitochondria (*polyplasmy*). Population genetic principles, as opposed to Mendelian genetics, govern mitochondrial genetics. When a new mtDNA mutation arises, cells initially harbor copies of both normal and mutant DNA sequences -- a condition known as *heteroplasmy* -- which allows an otherwise lethal mutation to persist and cause disease. The presence of either completely normal or completely mutant mtDNA is known as *homoplasmy*. During cell division, mitchondria are unevenly partitioned to the daughter cells through the process of *replicative segregation*; consequently, the proportion of mutant and normal mtDNA molecules can drift. Selection pressures apply at the molecular, cellular, and organismal levels. The critical proportion of mutant mtDNA required for deleterious phenotypic expression is known as the *threshold effect*. It varies among individuals, among organ systems, and within a given tissue, depending on the delicate balance of oxidative supply and demand. These features of mtDNA segregation, combined with the uneven transmission of mitochondria to daughter cells during cell division, form much of the basis for the phenotypic diversity seen in mitochondrial diseases.

MITOCHONDRIAL DNA MUTATIONS

mtDNAmutations that cause a severe, lethal impairment of oxidative phosphorylation -- such as gross structural defects or point mutations in structural RNAs -- are only viable if heteroplasmic. In contrast, the majority of the milder, missense mtDNA mutations in protein-coding genes are homoplasmic. mtDNA point mutations have been found in each type of mtDNA gene, but tRNA mutations predominate in severe, multisystemic mitochondrial encephalomyopathy phenotypes; protein-coding gene mutations predominate in Leber's hereditary optic neuropathy (LHON). A point mutation in the 12S ribosomal RNA gene is associated with both spontaneous and aminoglycoside-associated sensorineural deafness (Fig. 67-1).

A definitive cause-and-effect relationship between amtDNAmutation and a clinical phenotype can be difficult to establish for several reasons: (1) mtDNA is highly polymorphic, (2) different mutations can be associated with the same phenotype or the same mutation can be associated with different phenotypes, and (3) epigenetic factors can affect clinical manifestations.

CLASSIC MITOCHONDRIAL ENCEPHALOMYOPATHY PHENOTYPES

Many diseases were provisionally classified as mitochondrial disorders on the basis of abnormal mitochondrial morphology, biochemistry, or a pattern of maternal inheritance. Disease-associatedmtDNAmutations are now an important diagnostic criterion. Though each classic mitochondrial encephalomyopathy phenotype has distinctive clinical features (Table 67-1), each also shares many clinical and laboratory features (Tables 67-2 and67-3).

Mitochondrial Myopathy Mitochondrial myopathy is characterized by fixed proximal weakness with marked exercise intolerance. Fatigability and poor stamina are prominent clinical features, but a mitochondrial etiology is often considered in the context of other neurologic, somatic, or laboratory features. Frank rhabdomyolysis is rare. Electromyography documents a nonirritative myopathy, and serum creatine kinase is usually normal or slightly elevated. Skeletal muscle biopsy shows abnormal proliferating mitochondria and "ragged red fibers," a histologic hallmark of the severe biochemical defects in oxidative phosphorylation. LargemtDNAdeletions and a variety of mtDNA point mutations occur in mitochondrial myopathy.

Chronic Progressive External Ophthalmoplegia (CPEO) Ptosis, ophthalmoplegia, and limb myopathy characterize CPEO. Additional clinical features (Table 67-2) may also occur along with the laboratory abnormalities characteristic of mitochondrial disorders (Table 67-3). Patients with CPEO have abnormal skeletal muscle biopsies, with ragged red fibers and ultrastructural changes. Additional somatic and central nervous system findings in conjunction with CPEO are known as the "CPEO-plus" syndromes. Kearns-Sayre syndrome is a subset of CPEO-plus that begins before age 20 and is characterized by CPEO and atypical pigmentary retinopathy; ancillary features include elevated cerebrospinal fluid protein, ataxia, or heart block.

Most patients withCPEOhave large, single deletions inmtDNAthat can be reliably detected by molecular genetic methods. However, skeletal muscle is required as the source of DNA because almost all single mtDNA deletions occur sporadically. The presence of pigmentary retinopathy is strongly predictive of a deletion. The mechanism of DNA deletion is unknown, though recombination or slippage during replication is plausible. The junctions of most deletions contain directly repeated sequences, including a 13-nucleotide direct repeat "hot spot" that accounts for about 25% of all deletions. Approximately half of all deletions are bound by other direct repeats; one-quarter have no apparent direct repeat. A few patients have partially duplicated mtDNA molecules. A point mutation at nucleotide position 3243 has been found in many patients who lack a mtDNA deletion or duplication.

Autosomally Transmitted Multiple Mitochondrial DNA Deletions Several families with clinical variants ofCPEOhave been found to harbor multiplemtDNAdeletions in skeletal muscle. The autosomal inheritance of multiple mtDNA deletions implies a primary defect in a nuclear DNA gene that has secondary qualitative effects on mtDNA. Multiple mtDNA deletions can be transmitted in either an autosomal dominant or autosomal recessive mode or can occur as somatic mutations.

Thymidine phosphorylase was the first nuclear-encoded gene shown to influence the regulation and function of normalmtDNA in a trans-acting manner. Mutations in thymidine phosphorylase cause an autosomal recessive disease known as *myoneurogastrointestinal encephalomyopathy* (MNGIE). Several different nuclear loci have been linked to the autosomal dominant forms ofCPEO. Tissue-specific, autosomally transmitted depletion of mtDNA represents a quantitative mtDNA defect caused by an intergenomic communication error.

Mitochondrial Encephalomyopathy, Lactic Acidosis, and Strokelike Episodes (MELAS) This syndrome is characterized by strokelike events that cause subacute

brain dysfunction, cerebral structural changes, seizures, and several other common clinical and laboratory features (Tables 67-2,67-3). Maternal inheritance of the MELAS syndrome may be obscured because of mild clinical features in relatives. A point mutation at nucleotide 3243 in the $tRNA_{Leu(UUR)}$gene accounts for 80% of MELAS cases. However, the clinical features of the 3243 mtDNA mutation are pleiomorphic; it is also associated with nondeletionCPEO, myopathy, deafness, diabetes, and dystonia.

Myoclonic Epilepsy with Ragged Red Fibers (MERRF) Syndrome The MERRF syndrome consists of myoclonus, seizures, cerebellar ataxia, and mitochondrial myopathy. Pathogenetic mutations have been demonstrated at nucleotide positions 8344 and 8356 in the $tRNA_{Lys}$gene. Neurologic and laboratory features common to other mitochondrial encephalomyopathies are seen. Maternal relatives may be asymptomatic or may have partial clinical syndromes, including lipomas in a characteristic "horse-collar" distribution, and hypertension.

Neuropathy, Ataxia, and Retinitis Pigmentosa (NARP)/Maternally Inherited Leigh's Disease NARP is characterized by proximal weakness, sensory neuropathy, developmental delay, ataxia, seizures, dementia, and retinal pigmentary degeneration. This maternally inherited disorder is associated with two different heteroplasmic missense mutations at nucleotide position 8993 in the ATPase 6 gene. High proportions of the same mutations are also seen in maternally inherited Leigh's disease. Autosomal recessive Leigh's disease is associated with cytochrome c oxidase deficiency and is caused by a deficiency of the nuclear-encoded protein, SURF1, which is required for biogenesis of the cytochrome c oxidase complex (complex IV). ThemtDNApoint mutations associated with NARP,MELAS,MERRF, and other mitochondrial disorders are readily detected by molecular genetic analysis of mtDNA extracted from muscle or blood.

Leber's Hereditary Optic Neuropathy LHONtypically presents with painless, subacute, bilateral visual loss with central scotomas and dyschromatopsia. The mean age of onset is 23 years, and males are affected three to four times more commonly than females. LHON bears little clinical resemblance to the other mitochondrial disease phenotypes. It was first classified in this group on the basis of the maternal inheritance pattern. The pathophysiology of visual loss appears to involve both genetic and epigenetic (tobacco and alcohol) factors. ThemtDNAmutations exhibit a high degree of genetic heterogeneity. Primary LHON-associated mtDNA mutations predominantly affect complex I genes [at nucleotide positions 11778 (ND-4 gene), 3460 (ND-1 gene), and 14484 (ND-6 gene)] (Fig. 67-1). Several other mtDNA mutations may have secondary pathogenetic roles in LHON, including a mutation at nucleotide position 13708 (ND-5 gene) of Caucasian haplogroup J mtDNA.

Genotype-phenotype correlations are beginning to emerge for the primaryLHON-associatedmtDNAmutations. The prognosis for visual recovery, for example, varies nearly ten-fold depending on the mutation. mtDNA mutations that cause LHON plus dystonia have also been described.

ORGAN SYSTEM MANIFESTATIONS OF MITOCHONDRIAL DISEASE

Because virtually all tissues of the body depend, to some extent, on oxidative

metabolism, patients with mitochondrial disease can present to many specialists in medicine. The somatic manifestations listed in Table 67-2, first noted in association with the classic mitochondrial diseases, may be the dominant or initial clinical symptom or may be important comorbid features.

The ophthalmologic manifestations ofmtDNAmutations are prominent, with involvement of virtually the entire visual axis from the lids, cornea, and extraocular muscles to the occipital cortex. The cardinal eye findings include ophthalmoplegia, optic neuropathy, and pigmentary retinopathy. Cardiovascular manifestations include dilated and hypertrophic cardiomyopathy, conduction disease and heart block, Wolff-Parkinson-White syndrome, and hypertension. The prevalence of diabetes mellitus is higher than expected in patients with mitochondrial encephalomyopathies, and it occurs in association with a variety of mtDNA mutations. Diabetes mellitus has been linked with the 3243 mtDNA point mutation, usually, but not exclusively, in association with sensorineural hearing loss.

ROLE OF MITOCHONDRIAL DNA MUTATIONS IN PREVALENT DISEASES

The role ofmtDNAmutations in common, socioeconomically significant diseases is under active investigation. The genetic basis of many prevalent diseases is complex and does not follow simple, single-gene Mendelian inheritance (Chap. 65). Mitochondrial diseases, such asLHON and aminoglycoside-induced deafness, illustrate the potential for complex pathophysiologic interactions between genetic and epigenetic factors. As a result of these interactions, mtDNA mutations may be involved in subsets of common diseases, such as diabetes mellitus, in which the maternal inheritance pattern is not obvious.

The tissue-specific accumulation of somatic (noninherited)mtDNAmutations is likely relevant to some late-onset degenerative disorders, such as Alzheimer's disease and Parkinson's disease. It has been shown, for example, that as people age, mtDNA mutations accumulate in tissues, including some postmitotic tissues such as the basal ganglia and cerebral cortex. The high mutations rate and poor repair capacity of mtDNA contribute to the buildup of mtDNA mutations in postmitotic tissues or those with a slower turnover rate. Oxidative damage, as occurs with repeated episodes of ischemia and reperfusion, markedly increases the accumulation of mtDNA mutations. Environmental factors may also affect mtDNA. The anti-retroviral drug azidothymidine depletes muscle mtDNA and causes an acquired mitochondrial myopathy. Cumulative, age-dependent mitochondrial dysfunction, mediated to a significant degree by oxidative damage to mtDNA and other mitochondrial macromolecules, may be a major contributor to aging.

The unequivocal establishment of the diagnosis of a mitochondrial disease by molecular genetic methods is a prerequisite for proper genetic counseling and ultimately treatment.

68. SCREENING, COUNSELING, AND PREVENTION OF GENETIC DISORDERS - *Susan Miesfeldt*, *J. Larry Jameson*

IMPLICATIONS OF MOLECULAR GENETICS FOR INTERNAL MEDICINE

Approximately 1 in 50 children is born with a serious congenital abnormality or mental handicap. It is known that each of us harbors mutations in several genes that can potentially lead to serious diseases. The field of medical genetics has traditionally focused on chromosomal abnormalities (Chap. 66) and Mendelian disorders (Chap. 65). However, there is genetic susceptibility to many common adult-onset diseases including atherosclerosis, hypertension, autoimmune diseases, diabetes mellitus, Alzheimer disease, psychiatric disorders, and many forms of cancer. Genetic contributions to these common disorders involve more than the ultimate expression of a disease; these genes can also influence the severity of infirmity, response to treatment, and progression of disease.

The primary care clinician is now faced with the role of recognizing and counseling patients at risk for a large number of genetically influenced illnesses. This role reflects the advances in genetic medicine that are changing the way diseases are classified, enhancing our understanding of pathophysiology, providing practical information concerning drug metabolism and therapeutic responses, and promising to allow individualized screening and health care management programs. In view of these changes, the physician must integrate personal medical history, family history, and diagnostic molecular testing into the overall care of individual patients and their families. In addition, the internist has an important role in educating patients about the indications, benefits, risks, and limitations of genetic testing in the management of diverse diseases. This is a formidable task as scientific advances in genetic medicine, and media attention to these advances, have outpaced the translation into standards of clinical care.

PRENATAL AND NEWBORN GENETIC SCREENING AND TESTING

During pregnancy and in the newborn period, genetic screening and testing are both used to detect genetic disorders (Table 68-1). *Genetic screening* refers to the search for a genetic disorder in the entire population or in a high-risk population. Screening techniques must be cost-effective, have a high positive predictive value, and should yield information that leads to disease prevention or a useful therapeutic intervention. Examples of screening tests include maternal serum markers used to detect increased risk of Down syndrome, postnatal tests for phenylketonuria, and cholesterol levels in children used to identify individuals at risk for familial hyperlipidemias. Thus, genetic screening tests do not necessarily imply DNA- or chrozmosome-based tests. Instead, many such tests use a surrogate biochemical marker or phenotypic feature of the underlying genetic disorder. Determination of which genetic disorders should be screened routinely depends on disease frequency, the severity of the disorder, cost of screening, and whether treatment interventions can alter the course of the disease.

Genetic testing, on the other hand, is used in an individual suspected to have a disease based on physical features, family history, or biochemical findings. Genetic testing can include the following: (1) diagnostic testing as for hemochromatosis, (2) predictive

testing as for breast cancer predisposition, (3) carrier testing as for muscular dystrophy, and (4) prenatal testing as forb-thalassemia when both parents are carriers.

Depending on the disorder(s) under consideration, several different techniques are currently used for genetic screening during pregnancy. For instance, first-trimester screening for Down syndrome is performed using measurements of maternal serum pregnancy-associated plasma protein A and the free b subunit of human chorionic gonadotropin in combination with ultrasonographic measurement of nuchal translucency (at 10 to 14 weeks of gestation). Second-trimester maternal serum screening includes measurements of human chorionic gonadotropin, unconjugated estriol, a-fetoprotein, and inhibin that, in combination, increase the sensitivity of Down syndrome detection (Chap. 66). Increaseda-fetoprotein levels are also associated with open neural tube defects.

Amniocentesis or *chorionic villus sampling* (CVS) is used to isolate fetal cells for chromosomal analysis or to test for specific genetic abnormalities. Amniocentesis is typically performed during the early second trimester (14 to 16 weeks' gestational age). CVS can be performed earlier (8 to 10 weeks' gestational age) and involves transcervical or transabdominal biopsy of fetal trophoblastic tissue. CVS is associated with a somewhat greater risk of spontaneous abortion (<0.5 to 1%) than amniocentesis (<0.5%) but allows for elective abortion earlier during pregnancy. Ultrasonography is used to analyze the fetus directly at different stages of development. Preimplantation molecular diagnostic testing is now possible by isolating single cells from the 8- to 10-cell embryo. The polymerase chain reaction (PCR) is then used to test for selected single-gene disorders such as Tay-Sachs disease, cystic fibrosis, or sickle cell anemia. This testing strategy requires in vitro fertilization but has the advantage that affected embryos are not implanted.

It should be remembered that prenatal genetic testing focuses on chromosomal abnormalities (Chap. 66), along with specific genetic disorders for which there is increased risk of parental transmission. There is no guarantee that a child will be free of birth defects or other genetic disorders not included among the diagnostic tests.

The genetic counseling process should begin before prenatal testing and should include: (1) a description of the test, (2) the types of disorders that will be screened, (3) the limitations of the screening,z (4) an exploration of what the parents will do with the information, and (5) an indication of when the results will be available. If a genetic disorder is identified, the full repertoire of genetic counseling skills is required (see below). The nature of the genetic disease needs to be reviewed with the parents, often on separate occasions. The counselor should also discuss the kinds of physical and emotional challenges that a genetic disease might pose for the affected individual and the family. Written information should be provided, if available. Ultimately, the parents must reach a decision to continue or terminate the pregnancy. If pregnancy is terminated, counseling should continue after the procedure. If pregnancy is continued, counseling should continue to address the medical needs of the affected fetus or child, as well as to help the family meet any challenges presented by the genetic disorder.

At the time of birth, all newborns undergo a complete physical examination to detect gross developmental abnormalities. Within 24 to 72 h of birth, blood samples from

newborns are sent to a state-designated laboratory to screen for selected diseases, such as congenital hypothyroidism and a variety of inherited metabolic disorders (Table 68-1). This program represents a clear example of the benefits of selected genetic screening. The early diagnosis of phenylketonuria, for example, permits parents to introduce a phenylalanine-free diet before the development of severe neurologic sequelae (Chap. 352).

COMMON ADULT-ONSET GENETIC DISORDERS

MULTIFACTORIAL INHERITANCE

The risk for many adult-onset disorders reflects the additive effects of genetic factors at multiple loci that may function independently -- or in combination -- with other genes or environmental factors. Our understanding of the genetic basis of these disorders is incomplete, despite the clear recognition of genetic susceptibility. In type 2 diabetes mellitus, for example, the concordance rate in monozygotic twins ranges between 50 to 90%. Diabetes or impaired glucose tolerance occurs in 40% of siblings and in 30% of the offspring of an affected individual. Despite the fact that diabetes affects 5% of the population and exhibits a high degree of heritability, there are only a few examples of genetic mutations that might account for the familial nature of the disease (most of which are rare). They include certain mitochondrial DNA disorders (Chap. 67), mutations in a cascade of genes that control pancreatic islet cell development and function (*HNF4*a, *HNF1*a, *IPF1*), insulin receptor mutations, and others (Chap. 333). Obesity and other factors that contribute to insulin resistance also represent important risk factors for type 2 diabetes. Current models for the genetic basis of type 2 diabetes propose the involvement of more than a dozen genes: some genes influence pancreatic islet development or function; others likely modulate glucose-sensing; and an important group determine insulin sensitivity, either directly by affecting insulin signaling or indirectly by regulating body weight or composition. Superimposed on this genetic background are environmental influences such as diet, exercise, pregnancy, and medications.

Identifying these susceptibility genes is a formidable task. Nonetheless, a reasonable goal for this type of disease is to identify genes that increase (or decrease) disease risk by a factor of two or more. For common diseases such as diabetes or heart disease, this level of risk has important implications for health. Much the same way that cholesterol is currently used as a biochemical marker of cardiovascular risk, we can anticipate the development of genetic panels with similar predictive power. Genetic tests for a large number of genetic disorders are now available; a web site (http://www.genetests.org) lists various laboratories that perform specific tests. The advent of DNA-sequencing chips represents an important technical advance that promises to make large-scale testing more feasible (Chap. 65). The decision whether or not to perform a genetic test for a particular inherited adult-onset disorder, such as hemochromatosis, multiple endocrine neoplasia (MEN) type 1, prolonged QT syndrome, or Huntington disease, is complex; it depends on the clinical features of the disorder, the desires of the patient and family, and whether the results of genetic testing will alter medical decision-making or treatment (see below).

THE FAMILY HISTORY

Pending additional advances in genetic testing, the key to determining the inherited risk for common adult-onset diseases still rests in the collection and interpretation of a detailed personal and family medical history in conjunction with a directed physical examination. For example, a history of multiple family members with early-onset coronary artery diseases, glucose intolerance, and hypertension should suggest increased risk for genetic, and perhaps environmental, predisposition to insulin resistance (Chap. 333). Individual patients with this family history should be monitored for the possible development of hypertension, diabetes, and hyperlipidemia. They should be counseled about the importance of avoiding additional risk factors such as obesity and cigarette smoking.

Family history, recorded in the form of a pedigree, greatly assists the assessment of risk in the individual patient. At a minimum, pedigrees should convey health-related data on all first-degree relatives and selected second-degree relatives, including grandparents. When pedigrees appear to suggest an inherited disease, they should be extended to include additional family members. The determination of risk for an asymptomatic individual will vary depending on the size of the pedigree, the number of unaffected relatives, and the types of diagnoses within the family. For example, a woman with two first-degree relatives with breast cancer is more at risk if she has a total of three female first-degree relatives than if she has a total of eight female first-degree relatives. Additional variables that factor into the assessment of risk -- and should be documented in the pedigree -- include the age at diagnosis of each affected family member, present age of all family members, and the presence or absence of nonhereditary risk factors among those affected with diseases.

When assessing the personal and family history, the physician should be alert to a younger age of disease onset than is usually seen in the general population. A 30-year-old with acute myocardial infarction should be considered at risk for a hereditary trait, even if there is no family history of premature coronary artery disease (Chap. 241). The absence of the nonhereditary risk factors typically associated with a disease also raises the prospect of genetic risk factors. A personal or family history of deep vein thrombosis, in the absence of known nongenetic risk factors, might suggest a hereditary thrombotic disorder (Chap. 117). The physical examination may also provide important clues concerning the risk for a specific inherited disorder. A patient with xanthomas at a young age should prompt consideration of familial hypercholesterolemia. Some adult-onset disease-causing mutations are more prevalent in certain ethnic groups. For instance,>2% of the Ashkenazi population carry one of three specific mutations in the *BRCA1* or *BRCA2* genes. The prevalence of the factor V Leiden allele ranges from 3 to 7% in Caucasians but is much less common in Africans or Asians.

Recall of family history is often inaccurate. This is especially so when the history is remote and as families become more dispersed. It can be helpful to ask patients to fill out family history forms before or after their visits, as this provides them with an opportunity to contact relatives. Attempts should be made to confirm the illnesses reported in the family history before making management decisions. This process is often labor-intensive and ideally involves interviews of additional family members or reviewing medical records, autopsy reports, and death certificates.

Nongenetic factors associated with disease risk should also be reviewed in full, including occupation, diet, living conditions, and social habits. For example, patients at hereditary risk for heart disease should be questioned about tobacco use, diet, exercise, and lipid levels. Patients should also be asked about their health screening and prevention behaviors. These nonhereditary factors contribute to the assessment of overall risk and represent an important focus for disease prevention.

Although many inherited disorders will be suggested by the clustering of relatives with the same or related conditions, it is important to note that *disease penetrance* is incomplete for most multifactorial genetic disorders. As a result, the pedigree obtained in such families may not exhibit a clear Mendelian pattern of inheritance, as not all family members carrying the disease-associated alleles will manifest disease. Furthermore, genes associated with some of these disorders often exhibit *variable expression* of disease. For example, the breast cancer-associated gene, *BRCA1*, can predispose to several different malignancies in the same family, including cancers of the breast, ovary, and prostate (Chap. 81). For common diseases such as breast cancer, some family members without the disease-causing mutation may also develop breast cancer, representing another confounding variable in the pedigree analysis.

Some of the aforementioned features of the family history are illustrated inFig. 68-1. The proband, a 36-year-old woman, has a strong history of breast and ovarian cancer on the paternal side of her family. The early age of onset, as well as the co-occurrence of breast and ovarian cancer in this family, suggests the possibility of an inherited mutation in *BRCA1* or *BRCA2*. It is unclear though -- without genetic testing -- whether her father inherited such a mutation and transmitted it to her. After appropriate genetic counseling of the proband and her family, one approach to DNA analysis in this family is to test the potentially affected 42-year-old living cousin (IV-4) for the presence of a *BRCA1* or *BRCA2* mutation. If a mutation is found, then it is possible to test for this particular alteration in the proband and other family members, if they so desire. In the example shown, if the proband's father has inherited the *BRCA1* mutation, there is a 50:50 probability that the mutation has been transmitted to her. Genetic testing can be used to establish the absence or presence of this particular risk factor.

GENETIC TESTING FOR ADULT-ONSET DISORDERS

A critical first step before initiating genetic testing is to assure that the correct clinical diagnosis has been made, whether based on family history, characteristic physical findings, or biochemical testing. Careful clinical assessment will prevent unnecessary testing and will direct testing towards the most probable candidate genes. Many disorders exhibit the feature of *locus heterogeneity*, which refers to the fact that mutations in different genes can cause phenotypically similar disorders. For example, osteogenesis imperfecta (Chap. 351), muscular dystrophy (Chap. 383), homocystinuria (Chap. 352), and hereditary predisposition to colon cancer (Chap. 90) or breast cancer (Chap. 89) can each be caused by mutations in distinct genes. The pattern of disease transmission, clinical course, and treatment may differ significantly, depending on which gene is affected. In these cases, the choice of which genes to test is often determined by unique clinical features, the relative prevalence of mutations in various genes, or test availability.

Like all laboratory tests, there are limitations to the accuracy and interpretation of genetic tests. In addition to technical errors, genetic tests are often designed to detect only the most common mutations. In this case, a negative result must be qualified by the possibility that the individual may have a mutation that is not included in the test.

In addition to molecular testing for established disease, presymptomatic testing for susceptibility to chronic disease is being increasingly integrated into the practice of medicine. In most cases, however, the discovery of disease-associated genes has greatly outpaced studies that assess clinical outcomes and the impact of interventions. Until such outcomes-based studies are available, predictive molecular testing must be approached with caution and should be offered only to patients who have been adequately counseled and have provided informed consent (Fig. 68-2). In the majority of cases, presymptomatic testing should be offered only to individuals with a suggestive personal or family medical history or in the context of a clinical trial.

Molecular analysis is generally more informative if testing is initiated in a symptomatic family member, since the identification of a mutation can direct the testing of other at-risk family members (whether they are symptomatic or not). In the absence of additional familial or environmental risk factors, individuals who test negative for the mutation found in the affected family member can be informed that they are at general population risk for that particular disease. Furthermore, they can be reassured that they are not at risk for passing on the mutation to their children. On the other hand, asymptomatic family members who test positive for the known mutation must be informed that they are at increased risk for disease development and for transmitting the mutation to their children. Nevertheless, for most multifactorial genetic disorders, the test results cannot predict with confidence whether, or when, the disease will develop. For example, not everyone with the apolipoprotein E allele (e4) will develop Alzheimer disease, and many individuals without this susceptibility gene can still develop the disorder (Chap. 362).

A negative test result is interpreted differently when no genetic mutation is found in a symptomatic family member. In this difficult circumstance, the test performed on a given gene may not detect all mutations in that gene (false negative) or the individual may have a mutation in a different disease-associated gene that was not tested.

Clinicians providing pretest counseling and education should assess the patient's emotional ability to cope with test results. Individuals who demonstrate signs and symptoms of psychiatric illness should have their emotional needs addressed before proceeding with molecular testing. Generally, genetic testing should not be offered at a time of personal crisis or acute illness within the family. Patients will derive more benefit from test results if they are emotionally able to comprehend and absorb the information. It is important to assess patients' preconceived notions of their personal likelihood of disease in preparing pretest educational strategies. Often, patients harbor unwarranted fear or denial of their likelihood of genetic risk.

Genetic testing has the potential of affecting the way individual family members relate to one another, both negatively and positively. As a result, patients addressing the option of molecular testing must consider how test results might impact their relationships with relatives, spouses, and friends. In families with a known genetic mutation, those who

test positive must address the impact of the disease on their present and future lifestyles; those who test negative may manifest survivor guilt. Family members are likely to differ in their emotional and social responses to the same information. Counseling should also address the potential consequences of test results on relationships with a spouse or child. Parents who are found to have a disease-associated mutation often express considerable anxiety and despair as they address the issue of risk to their children.

When a condition does not manifest until adulthood, clinicians will be faced with the question of whether at-risk children should be offered molecular testing and, if so, at what age. Several professional organizations have cautioned that genetic testing for adult-onset disorders should not be offered to children. Many of these conditions are not preventable and, consequently, such information can pose significant psychosocial risk. In addition, there is concern that testing during childhood violates a child's right to make an informed decision regarding testing upon reaching adulthood. On the other hand, testing should be offered in childhood for disorders that may be manifest early in life, especially when management options are available. For example, children at risk for familial adenomatous polyposis (FAP) may develop polyps as early as their teens, and progression to an invasive cancer can occur by their twenties. Likewise, children at risk forMEN type 2, which is caused by mutations in the *RET* proto-oncogene, may develop medullary thyroid cancer as early as 6 years of age, and the issue of prophylactic thyroidectomy should be addressed with the parents of children with documented mutations (Chap. 339).

INFORMED CONSENT

When the issue of testing is addressed, patients should be strongly encouraged to involve other relatives in the decision-making process, as molecular diagnostics will likely have an impact on the entire family. Informed consent for molecular testing begins with detailed education and counseling. The patient must fully understand the risks, benefits, and limitations of undergoing the analysis. Informed consent should be in the form of a written document, drafted clearly and concisely in a language and format that is comprehensible to the patient, who should be made aware of the disposition of test results. Informed consent should also include a discussion of the mechanics of testing. Most molecular testing for hereditary disease involves DNA-based analysis of peripheral blood. In the majority of circumstances, test results should be given only to the individual, in person, and with a support person in the room.

Because molecular testing of an asymptomatic individual often allows prediction of future risk, the patient should understand any potential long-term medical, psychological, and social implications of this decision. In the United States, legislation affecting this area is still evolving, and it is important to explore with the patient the potential impact that test results may have on employment, future health, and life insurance coverage.

Patients should understand that alternatives to molecular analysis remain available if they decide not to proceed with this option. They should also be notified that testing is available in the future if they are not prepared to undergo analysis immediately. The option of DNA banking should be presented so that samples are readily available for

future use by family members, if needed.

FOLLOW-UP CARE AFTER TESTING

Depending on the nature of the genetic disorder, posttest interventions may include (1) cautious surveillance and appropriate health care screening, (2) specific medical interventions, (3) chemoprevention, (4) risk avoidance, and (5) referral to support services. For example, patients with known pathologic mutations in *BRCA1* or *BRCA2* are offered intensive screening as well as the option of prophylactic mastectomy and/or oophorectomy. In addition, such women may be eligible for preventive treatment with agents such as tamoxifen, raloxifene, or retinoids. In contrast, those at known risk for Huntington disease are offered continued follow-up and supportive services, including physical and occupational therapy, and social services and support groups as indicated. Specific interventions will change as translational research enhances our understanding of these genetic diseases and as more is learned about the functions of the genes involved.

Individuals who test negative for a mutation in a disease-associated gene identified in an affected family member must be reminded that they may still be at risk for the disease. This is of particular importance for common diseases such as diabetes mellitus, cancer, and coronary artery disease. For example, a woman who finds that she does not carry the disease-associated mutation in *BRCA2* previously discovered in her family must be reminded that she still requires the same breast cancer screening used in the general population.

GENETIC COUNSELING AND EDUCATION

Genetic counseling should be distinguished from genetic testing and screening, even though genetic counselors are often involved in issues related to testing. Genetic counseling refers to *a communication process that deals with human problems associated with the occurrence or risk of a genetic disorder in a family*. Genetic risk assessment can be complex and often involves elements of uncertainty. Counseling therefore includes genetic education as well as psychosocial counseling. Genetic counselors may be called upon by other health care professionals (or by individual patients and families) to address a broad range of issues directly and indirectly involved with genetic disease (Table 68-2). The genetic counselor will do the following:

· Gather and document a detailed family history

· Educate the patient about general genetic principles related to disease risk, both for themselves and others in the family

· Assess and enhance the patient's ability to cope with the genetic information offered

· Discuss how nongenetic factors may relate to the ultimate expression of disease

· Address medical management issues

· Assist in determining the role of genetic testing for the individual and family

· Ensure that the patient is aware of the risks, benefits, and limitations of the various genetic testing options

· Refer the patient and other at-risk family members for additional medical and support services, if necessary.

The complexity of genetic counseling and the broad scope of genetic diseases are leading to the development of specialized, multidisciplinary clinics designed to provide broad-based support and medical care for those at risk and their family members. Such multidisciplinary teams are often composed of medical geneticists, specialist physicians, genetic counselors, nurses, psychologists, social workers, and biomedical ethicists who work together to consider difficult diagnostic, treatment, and testing decisions. Such a format also provides primary care physicians with invaluable support and assistance as they follow and treat at-risk patients.

The approach to genetic counseling has important ethical, social, and financial implications. Philosophies related to genetic counseling vary widely by country and center. In North American centers, for example, counseling is generally offered in a nondirective manner, wherein patients learn to understand how their values factor into a particular medical decision. Nondirective counseling is particularly appropriate when there are no data demonstrating a clear benefit associated with a particular intervention or when an intervention is considered experimental. For example, nondirective genetic counseling is employed when a person is deciding whether or not to undergo genetic testing for Huntington disease (Chap. 362). At this time, there is no clear benefit (in terms of medical outcome) to an at-risk individual undergoing genetic testing for this disease, as its course cannot be altered by therapeutic interventions. However, testing can have an important impact on such a person's perception of the future and his or her interpersonal relationships and plans for reproduction. Therefore, the decision to pursue testing rests on the individual's belief system and values. On the other hand, a more directive approach is appropriate when a condition can be treated. In a family withFAP(associated with mutations in the *APC* gene), colon cancer screening and prophylactic colectomy should be recommended for known *APC* mutation carriers. The counselor and clinician following this family must ensure that the at-risk individuals have access to the resources necessary to adhere to these recommendations.

Genetic education is central to an individual's ability to make an informed decision regarding testing options and treatment. Although genetic counselors represent one source of genetic education, other health care providers also need to contribute to patient education. Patients at risk for genetic disease should understand fundamental medical genetic principles and terminology relevant to their situation. This includes the concept of genes, how they are transmitted, and how they confer hereditary disease risk. An adequate knowledge of patterns of inheritance will allow patients to understand the probability of disease risk for themselves and other family members. It is also important to impart the concepts of disease penetrance and expression. For complex genetic disorders, asymptomatic patients should be advised that a positive test result does not always translate into future disease development. In addition, the role of nongenetic factors, such as environmental exposures, must be discussed in the context of multifactorial disease risk and disease prevention. Finally, patients should understand

the natural history of the disease as well as the potential options for intervention, including screening, prevention, and -- in certain circumstances -- pharmacologic treatment or prophylactic surgery.

THERAPEUTIC INTERVENTIONS BASED ON GENETIC SUSCEPTIBILITY TO DISEASE

Specific treatments are now available for an increasing number of genetic disorders, whether identified through population-based screening or directed testing (Table 68-3). A number of metabolic disorders fall into this group. For example, the complications of phenylketonuria can be mitigated by recognizing the disease early and avoiding foods that contain phenylalanine (Chap. 352). Similar principles apply to maple syrup urine disease (Chap. 352) and galactosemia (Chap. 350). Children with 21-hydroxylase deficiency present with adrenal insufficiency, usually within the first few weeks of life (Chap. 331). Because of the block in cortisol synthesis, the adrenal steroid precursors are shunted into the androgen pathway, causing ambiguous genitalia in females and premature virilization in males. In this disorder, treatment with glucocorticoid and mineralocorticoid not only corrects the hormone deficits but is also required to suppress ACTH overproduction, which otherwise worsens virilization.

Although the strategies for therapeutic interventions are best developed for childhood genetic diseases, these principles are gradually making their way into the diagnosis and management of adult-onset disorders. Hereditary hemochromatosis illustrates many of the issues raised by the potential availability of genetic screening in the adult population. For instance, it is relatively common (approximately 1 in 200 individuals of northern European descent are homozygous), and its complications are potentially preventable through phlebotomy (Chap. 345). The recent identification of the *HFE* gene, mutations of which are associated with this syndrome, has sparked interest in the use of DNA-based testing for presymptomatic diagnosis of the disorder. However, up to one-third of individuals who are homozygous for the *HFE* mutation do not have evidence of iron overload. Consequently, in the absence of a positive family history, current recommendations are phenotypic screening for evidence of iron overload followed by genetic testing. Whether genetic screening for hemochromatosis will someday be coupled to assessment of phenotypic expression awaits further studies. In contrast to the issue of population screening, it is important to test and counsel other family members when the diagnosis of hemochromatosis has been made in a proband. Testing allows the physician to exclude family members who are not at risk. It also permits presymptomatic detection of iron overload and the institution of treatment (phlebotomy) before the development of organ damange.

Preventive measures and therapeutic interventions are not restricted to metabolic disorders. Identification of familial forms of long QT syndrome, associated with ventricular arrythmias, allows early electrocardiographic testing and the use of prophylactic antiarrythmic therapy (Chap. 230). Individuals with familial hypertrophic cardiomyopathy can be screened by ultrasound, treated with beta blockers or other drugs, and counseled about the importance of avoiding strenuous exercise and dehydration (Chap. 238). Likewise, individuals with Marfan syndrome can be treated with beta blockers and monitored for the development of aortic aneurysms (Chap. 247). Individuals with $\alpha_1$antitrypsin deficiency can be strongly counseled to avoid cigarette

smoking and exposure to environmental pulmonary and hepatotoxins. Various host genes influence the pathogenesis of certain infectious diseases in humans, including HIV (Chap. 309). The factor V Leiden allele increases risk of thrombosis (Chap. 62). Approximately 3% of the worldwide population is heterozygous for this mutation. Moreover, it is found in up to 25% of patients with recurrent deep venous thrombosis or pulmonary embolism. Women who are heterozygous or homozygous for this allele should therefore avoid the use of oral contraceptives and receive heparin prophylaxis after surgery or trauma.

The field of pharmacogenetics seeks to identify genes that alter drug metabolism or confer susceptibility to toxic drug reactions (Chap. 71). Examples include succinylcholine sensitivity, malignant hyperthermia, the porphyrias, and glucose-6-phosphase dehydrogenase (G6PD) deficiency.

As noted above, the identification of genes that increase the risk of specific types of neoplasia is rapidly changing the management of many cancers. Identifying family members with mutations that predispose toFAP or hereditary nonpolyposis colon cancer (HNPCC) can lead to recommendations of early screening by colonoscopy or prophylactic surgery (Chap. 90). Similar principles apply to familial forms of melanoma, basal cell carcinoma, and breast cancer. It should be recognized, however, that most cancers harbor several distinct genetic abnormalities by the time they acquire invasive or metastatic potential (Chaps. 81 and82). Consequently, the major impact of genetic testing in these cases is to allow more intensive clinical screening, as it remains very challenging to predict disease penetrance or the clinical course of these diseases.

Although genetic diagnosis of these and other disorders is only beginning to be used in the clinical setting, susceptibility testing holds the promise of allowing earlier and more targeted interventions that can reduce the morbidity and mortality associated with these disorders. We can expect the availability of genetic tests to expand rapidly. A critical challenge for physicians and other health care providers is to keep pace with these advances in genetic medicine and to implement testing judiciously. Meeting this goal will enhance patient care through adequate counseling, directed testing, and appropriate interventions, with the ultimate objective being the reduction of morbidity and mortality from genetic diseases.

69. GENE THERAPY - *Mark A. Kay*, *David W. Russell*

Gene therapy is generally defined as *the delivery of nucleic acids to alter or prevent a pathologic process*. Although initially considered primarily in the context of inherited monogenic disorders, gene therapy is now recognized as a potential treatment strategy for a wide range of acquired disorders, such as cancer, neurodegenerative diseases, and infections. Gene therapy has been used in several hundred protocols. Despite early hopes that gene therapy might be quickly incorporated into medical practice, it has yielded limited success to date and remains an investigational treatment. The technical challenges associated with gene therapy are formidable, but with steady progress in vector development, definitive therapeutic milestones may soon be realized for selected disorders.

GENERAL APPROACHES TO GENE THERAPY

FORMS OF GENE THERAPY

Gene therapy can be used, in principle, to modify all cells in the body, including the germ line. *Germ-line gene therapy* would allow transmission of the modified genetic information to the next generation and is not currently accepted as an appropriate therapeutic approach. For ethical reasons, opposition to germ-line gene therapy is likely to continue in the foreseeable future. *Somatic gene therapy* refers to modification of the somatic, differentiated cells of the body. It is used in an effort to correct inherited diseases such as cystic fibrosis and acquired disorders such as rheumatoid arthritis or malignancies.

Whole-organ transplantation (e.g., bone marrow, liver, and kidney) has been used for years as a strategy to replace the function of defective genes. The idea of using nonautologous cell transplantation has been revisited in the past few years, and with the advent of human embryonic stem cells, similar transplantation strategies are being considered for a variety of disorders once considered prime targets for gene therapy. Thus, the interface between gene therapy and *cell transplantation* is complementary.

The production of *genetically engineered proteins* is another area closely aligned with gene therapy. The cloning of human genes allows proteins to be produced in unlimited quantities and free of the potential contaminants associated with their purification from natural sources such as plasma. Moreover, recombinant DNA technology allows these proteins to be modified in ways that can enhance their therapeutic benefit. Examples of recombinant proteins are listed in Table 69-1. These include: (1) hormones such as insulin, growth hormone, and gonadotropins; (2) factors used to enhance blood cell production including erythropoietin, granulocyte colony stimulating factor (CSF), granulocyte-macrophage CSF, and thrombopoietin; (3) interferons (IFNs) and interleukins (ILs) used to treat a variety of autoimmune, infectious, and neoplastic diseases; (4) clotting factors VIII and IX; (5) thrombolytic agents such as tissue plasminogen activator or the antithrombotic agent hirudin; (6) recombinant antigens used for hepatitis B vaccines; and (7) humanized monoclonal antibodies used for immunosuppression or to treat specific types of malignancy. Although these recombinant proteins are an indirect form of gene therapy, they represent an important outgrowth of genetic medicine.

Long-Term versus Transient Gene Delivery Strategies for Gene Therapy The goals of gene therapy vary depending on the nature of the disease being treated. For an inherited, monogenic disorder such as hemophilia, the goal is lifelong replacement of the missing gene product. Expression of the missing secreted clotting factor, even at modest levels, might ameliorate the disease or reduce the need for exogenous treatment. For other inherited disorders, such as sickle cell anemia, strategies for gene replacement are more demanding. In this case, there is a requirement for cell-specific and exquisitely regulated expression of the transferred gene, and one is still faced with endogenous expression of the mutant form ofb-globin. Long-term gene delivery strategies typically involve direct modification of host chromosomal sequences, which allows normal inheritance and stability of the delivered gene.

A growing use of gene therapy involves transient gene expression to treat a variety of diseases (Table 69-2). Gene therapy is now being considered or used for (1) killing cancer cells; (2) providing chemoprotection to normal cells; (3) preventing coronary restenosis or enhancing vascularization; (4) providing DNA-based immunization (e.g., viral DNA), in which the injection of DNA results in antigen expression and generation of an immune response; and (5) impairing viral replication. In cancer therapy, for example, the requirements for long-term gene expression and the level of gene expression are not as stringent as for gene replacement. Rather, the challenge of many cancer-based gene therapies is to achieve highly efficient gene transfer into cancer cells without expression in surrounding normal cells.

EX VIVO VERSUS IN VIVO ADMINISTRATION OF GENE THERAPY

Gene therapy has been administered ex vivo for conditions in which cells can be readily harvested, manipulated in tissue culture, and then reintroduced into the patient. The ex vivo approach is potentially applicable to a variety of hematologic or immune deficiency disorders. For example, in adenosine deaminase (ADA) deficiency, the missing ADA gene has been integrated into the patient's T lymphocytes, which are then reintroduced after genetic manipulation. In familial hypercholesterolemia, an analogus approach has been used for ex vivo treatment of hepatocytes. After surgical resection of liver tissue, the low-density lipoprotein (LDL) receptor gene is inserted into hepatocytes in cell culture, and the modified cells are infused back through the portal vein. Another form of ex vivo gene therapy involves the treatment of saphenous veins with oligonucleotides designed to block vascular smooth-muscle cell proliferation before using the tissue for coronary artery bypass graft.

In vivo approaches to gene therapy vary depending on the nature of the disease. In cystic fibrosis, an aerosol has been used to administer viral vectors to the lung. Factor IX expression has been achieved by introduction of the gene into muscle. Tumors have been injected directly with viral vectors expressing cytotoxic genes or immunotherapies. A major advantage of in vivo approaches is the potential to target cells that cannot easily be removed from the patient.

GENE TRANSFER VECTORS

A vector, or vehicle, is required to transfer a gene to an appropriate cell. When the goal

is to add a gene (often called a *transgene*) to supply a function not present in the recipient cell, the vector typically contains DNA sequences encoding a therapeutic protein under the control of transcriptional regulatory elements necessary for gene expression (Fig. 69-1). The gene is expressed from an ectopic location as opposed to its normal chromosomal position. An alternative strategy is to correct mutant genes at their normal chromosomal location through *gene targeting*. Although this represents an ideal approach for many genetic diseases, it is far more technically demanding, and therapeutic gene-targeting efficiencies are difficult to achieve currently.

Two major classes of vectors are used for transferring nucleic acids into cells for the purposes of gene therapy: viral and nonviral vectors. *Viral vectors* have been genetically engineered so that the viruses transfer exogenous (therapeutic) nucleic acids into cells through a process called transduction. *Nonviral vectors* consist of nucleic acids that are typically complexed with other chemicals to facilitate gene transfer. Although nonviral vectors offer improved safety by avoiding viral components, their gene transfer efficiencies are generally much lower than those of viral vectors. The major vector systems currently used in clinical trials or under development are summarized in Table 69-3.

Vectors that integrate into host chromosomes are considered ideal for lifelong gene expression, whereas episomal (unintegrated) vectors are preferred for transient gene delivery. The host range of a particular vector, in combination with the mode of delivery, will determine which cell types can be genetically modified. Also, it may be possible to alter the natural tropism of viral capsids or envelopes, as well as of nonviral vector complexes, to limit transduction to particular cell types. Transcriptional control elements, such as promoters and enhancers, can be used to regulate expression of the transgene. In some cases, the inclusion of special regulatory elements may allow gene expression to be controlled by the administration of pharmacologic agents that specifically switch the regulatory elements on or off. Many types of vectors, each exhibiting a unique set of properties, will ultimately be needed for safe and effective gene therapy of different diseases.

RETROVIRAL VECTORS

Retroviral vectors based on murine leukemia viruses (MLVs) were the first vectors used in clinical gene transfer protocols and illustrate many of the principles of viral-mediated gene therapy. Typically, the vector genome consists of a transgene cassette placed between the two *cis*-acting long terminal repeats (LTRs) of the viral genome. Viral coding regions are removed from the vector genome to allow the insertion of the therapeutic gene and to prevent viral replication and toxicity to the host. The packaging capacity of MLV vectors is approximately 8 kb (including the LTRs), enough to accommodate most therapeutic cDNAs. The viral gene products needed for vector production and packaging are supplied by helper virus expression constructs.

The envelope protein of the virus interacts with specific cellular receptors to allow cellular entry of the core proteins and vector genome. After transduction, the vector gene integrates at random locations in host chromosomes and replicates with the host chromosome during cell proliferation, offering the potential for lifelong transgene expression. *Chromosomal integration* may also cause insertional mutagenesis, but no

clinically relevant consequences of such events have been observed to date with replication-incompetent retroviral vectors.

AlthoughMLVvectors are widely used, primarily because of their ability to integrate and simple production requirements, they still have significant disadvantages. Complement-mediated vector particle inactivation has largely limited their use to ex vivo applications. MLV vectors also require cell division for transduction because the vector genome can only enter the cell nucleus during mitosis, when the nuclear membrane breaks down. Since the majority of cells present in the human body are nondividing, this severely limits the potential uses of MLV-based vectors.

Promising new retroviral vectors are based on complex retroviruses (rather than the relatively simple oncoviruses such asMLV). Both lentiviral vectors and spumaviral vectors have broad host ranges, improved transduction of nondividing cells, and may function well in vivo. Although lentiviral vector production systems can be designed to eliminate the potential for replication-competent retrovirus contamination, and these vectors appear safe from a virologic standpoint, the stigma associated with vectors based on human pathogens such as HIV may limit their acceptance.

ADENOVIRAL VECTORS

Adenoviral-mediated gene expression is not lifelong, making it well suited for applications that require transient gene expression. In contrast to retroviruses, which integrate into the host genome, the adenoviral vector genome remains *episomal*, or extrachromosomal. Adenoviral vectors typically are derived from serotypes 2 or 5 and contain double-stranded DNA genomes. Wild-type adenovirus encodes over 50 peptides on overlapping gene fragments from both DNA strands. Nonessential viral genes have been removed to make room for up to 8 kb of exogenous DNA. The vector containing the therapeutic transgene is amplified in a cell line that supplies viral proteins needed for replication and packaging. Recombinant adenoviruses can be generated at high titers in the range of 10^{13} to 10^{14}particles per milliliter, a feature that is important for efficient in vivo gene therapy.

In clinical practice, adenoviral vectors are limited by relatively short durations of expression (usually several weeks) and by the synthesis of remaining cytotoxic or antigenic viral proteins that can cause an acute inflammatory response and/or a robust cellular immune response. These features of the virus appear to have contributed to hepatic failure and death in an individual receiving adenoviral-based gene therapy for ornithine transcarbamylase deficiency. On the other hand, the inflammatory properties of adenoviruses may enhance their efficacy in cancer trials, as discussed below. Several methods that eliminate the remaining viral genes have been devised recently, and these "gutted" vectors appear to exhibit much reduced toxicity and inflammatory properties in comparison to previous generations of adenoviral vectors.

ADENO-ASSOCIATED VIRUS VECTORS

Adeno-associated viruses (AAV) are parvoviruses that normally require a helper virus, such as adenovirus, to mediate a productive infection. A major limitation of the AAV vector is its relatively small packaging capacity, which restricts the size of exogenous

DNA to about 4.5 kb. AAV vectors have been shown to transduce cells both through episomal transgene expression and by chromosomal integration. They can also be used to modify homologous chromosomal sequences through gene targeting, which is an important strategy for the correction of genetic mutations.

Since theAAVvector genome lacks viral coding sequences, the vector itself causes little immune or inflammatory response (except for the generation of neutralizing antibodies that may limit readministration). The vector particle can be delivered to many different organs [e.g., the central nervous system (CNS), liver, lung, and muscle] by in vivo administration, and AAV vectors have been found to transduce nondividing cells efficiently. Clinical trials using AAV for the treatment of cystic fibrosis and hemophilia are underway.

OTHER VIRAL VECTORS

Many other viruses are under development as vector systems, such as herpesviruses, double-stranded RNA viruses, autonomous parvoviruses, and papovaviruses. Hybrid viral vectors that use components from more than one virus are also under development, offering the potential to combine the most desirable properties of different vectors. Ultimately, vectors will be developed that utilize both viral components and synthetic functions, allowing vectors to be custom designed.

NONVIRAL VECTORS

Nonviral vectors usually consist of DNA complexes with lipids, carbohydrates, proteins, and/or other synthetic chemicals to facilitate delivery or increase vector stability. Gene delivery with naked DNA is also possible but is relatively inefficient. Nonviral vectors are desirable because they eliminate the risk of viral contamination and can be produced under more controlled conditions. Their major disadvantage is low gene transfer rates, at least in relation to most viral vector systems. Because the vectors do not integrate and the majority of DNA molecules that enter the cell are rapidly degraded, only transient gene expression is possible. Examples of applications that may be well suited to gene delivery with nonviral vectors include vaccination with specific antigen genes, ex vivo treatment of vessels used for coronary artery bypass graft, and perhaps transient immune modulation for the treatment of cancer.

Nonviral vectors composed of RNA or modified nucleotides may also prove useful, if problems associated with effective delivery can be addressed. For example, antisense oligonucleotides can be used to inhibit gene expression by pairing with complementary mRNA molecules. Antisense oligonucleotides might be used, for example, to block the expression of cell cycle proteins or cytokines. Oligonucleotides with binding sites for specific DNA- or RNA-binding proteins may be designed to function as decoys that inhibit protein function. Chimeric RNA/DNA oligonucleotides have been used to introduce specific genetic modifications through gene targeting. In animal studies, this novel approach has been shown to work efficiently in the liver, and it may be used soon for clinical trials of uridine diphosphate-glucuronosyltransferase deficiency.

GENE THERAPY FOR SELECTED DISEASE CATEGORIES

LIVER AND GASTROINTESTINAL TRACT

The liver has been studied intensively as a target organ for gene therapy, in part because of the many genetic diseases amenable to gene replacement in hepatocytes. In addition, because of the regenerative capacity of the hepatocyte, integration of a vector offers the possibility of lifelong gene expression. The first hepatic gene therapy attempted in humans involved the ex vivo transplant of autologous hepatocytes transduced in culture by retroviral vectors encoding theLDLreceptor as a treatment for familial hypercholesterolemia. Due to the low levels (nontherapeutic) of gene expression observed and the labor-intensive nature of the ex vivo transduction process, current strategies are geared towards in vivo gene transfer.MLV-based retroviral vectors require cell division for transduction of host cells. The use of growth factors (rather than partial hepatectomy) to stimulate hepatocellular replication can enhance the efficacy of MLV vectors. Alternative retroviral vectors based on lentiviruses may overcome these obstacles.

Adenovirus vectors are very effective at gene transfer into the liver, thus allowing for the transduction of a majority of hepatocytes. However, the early generations of these vectors exhibited dose-dependent toxicity, inflammation, and immunogenicity that limited the persistence of transgene expression. Adenoviral vectors devoid of all viral genes have been shown to transduce hepatocytes efficiently with reduced toxicity or immunogenicity. In rodents, transgene expression appears to be lifelong, but in nonhuman primates, expression declines by 90% over a 2-year period.

AAVvectors stably integrate their proviral DNA into hepatocytes in vivo with no apparent toxicity. This vector has been used in preclinical liver gene therapy studies to cure mice with hemophilia B and to partially correct the defect in dogs with hemophilia B. Hepatocyte gene transfer by AAV vectors is likely to be useful for treating a variety of metabolic diseases, such as urea cycle disorders, aminoacidopathies, disorders of carbohydrate metabolism, and lysosomal storage diseases. This strategy is particularly applicable when expression of the transgene in a relatively small percentage of hepatocytes is of therapeutic benefit.

The intestinal tract offers a large cell mass for gene therapy and is accessible by oral administration of vectors. Although a number of vectors have been tested in the gastrointestinal tract, major limitations still exist, such as the rapid turnover of the intestinal epithelial cells, the inability to target the stem or early progenitor cells, and the effects of digestive secretions on vector delivery. If these obstacles can be overcome, many diseases may be amenable to treatment by intestinal gene transfer.

THE HEMATOPOIETIC SYSTEM

Clinical trials targeting hematopoietic cells have almost exclusively taken an ex vivo approach, with gene transfer occurring outside the body, followed by reinfusion of transduced cells. The most common cellular targets are lymphocytes and hematopoietic stem cells. Because stem cells can reconstitute the entire hematopoietic system, ex vivo genetic manipulation and autologous transplantation of bone marrow or peripheral blood stem cells represents a powerful therapeutic paradigm. Long-term gene transfer to hematopoietic stem cells requires the use of integrating viral vectors to ensure that the

transgene replicates with the chromosomes during the extensive cellular proliferation that occurs during hematopoiesis. Thus, most stem cell gene therapy trials have used retroviral vectors. In part, because stem cells are not actively dividing, transduction rates have been too low to be therapeutic. Despite this, recent success in treating X-linked severe combined immunodeficiency with MLV vectors encoding the cytokine receptor gamma common chain demonstrates the feasibility of this approach. The use of different envelope proteins and vectors based on lentiviruses or spumaviruses may yield greater success in stem cell transduction.

Gene transfer to hematopoietic stem cells could be used to treat diseases of erythroid, myeloid, and lymphoid cells as well as platelet disorders (since the stem cell ultimately differentiates into all these cell types). An important aspect of this approach is the level of myeloablation required to allow engraftment of ex vivo-modified stem cells. An optimal therapy would minimize myeloablation and its associated toxicity, perhaps by delivering a gene that confers a selective advantage to transduced stem cells along with the therapeutic transgene. Many of the clinical trials to date have involved genes that confer increased resistance to chemotherapeutic agents used in treating cancer. An alternative strategy is to apply gene therapy to disorders in which expression is not required in all cells to prevent clinical disease. In chronic granulomatous disease, in which there is failure of granulocytes and monocytes to generate the hydrogen peroxide needed for bacterial killing, it may be feasible to achieve a threshold level of normal cells to respond to infections. Another major area of stem cell gene therapy research is the treatment of hemoglobinopathies with vectors expressing globin genes. Although clinical trials have not begun, these efforts have helped define the problems that must be solved for successful stem cell gene therapy, especially with regard to regulating transgene expression levels. Globin gene replacement is a daunting task, since the gene must be expressed at high levels in a select subset of erythroid cells, thus requiring the inclusion of a variety of transcriptional control elements in the vector (many of which have resulted in vector instability and low viral titers).

Lymphocyte gene transfer has the potential to treat genetic immunodeficiencies and to modulate immune functions.ADAdeficiency was one of the first diseases to be treated with gene therapy and employed ex vivo transduction of lymphocytes. Although this early clinical trial represented an important milestone in gene therapy, the assessment of a therapeutic effect has been complicated by concomitant treatment with the ADA protein. Replacement of the ADA gene also confers a selective advantage to ADA-deficient lymphocytes, a property that would not be generally applicable to lymphocyte gene transfer. Still, as lymphocyte transduction protocols improve, many treatments may be developed with this cellular target, especially for acquired diseases. Genetic manipulations with antibody or cytokine genes offer a multitude of possible treatments for infectious and autoimmune diseases, as well as for cancer.

PULMONARY SYSTEM

Gene therapy of the lung has concentrated primarily on treatments for cystic fibrosis. The gene for cystic fibrosis, *CFTR*, was cloned in 1989; by 1993 the first trials using adenovirus vectors were attempted in the nasal epithelium and airway. Though no clinical efficacy was demonstrated, these studies underscored the need to develop defined clinical endpoints for future trials. In addition to the adenovirus trials, clinical

trials with nonviral liposome andAAVvectors also failed to demonstrate therapeutic effects. Difficulties encountered in pulmonary gene therapy include poor vector delivery due to respiratory secretions, lack of accessible vector receptors on the exposed cellular surface, transient transgene expression due to turnover of the respiratory epithelium, and vector-induced inflammation and pneumonitis. It also remains unclear which type of lung cells should be targeted with the *CFTR* gene to result in clinical benefit. As efficient and safe vectors for lung gene transfer are developed, treatments for acquired disorders such as chronic obstructive pulmonary disease may also be possible.

NERVOUS SYSTEM AND RETINA

Gene transfer to the nervous system will be important for the treatment of many inherited and acquired neurologic diseases. Depending on the disorder, both glial cells and neurons may be appropriate cellular targets. Several vectors have been shown to transduce cells (including neurons) in animals after in vivo injection into the brain. Gene transfer is typically localized near the site of injection, a feature that is desirable for disorders such as Parkinson's disease, where transduction in the striatum could allow selective expression of genes involved in dopamine synthesis. Vector delivery throughout the nervous system will be more difficult to achieve, making gene therapy of global neurologic disorders problematic. The possibility of delivering neurotrophic factors to theCNS is a potential strategy for the treatment of neurodegenerative diseases, such as amyotrophic lateral sclerosis, and for facilitating recovery after spinal cord injury. Genetically modified stem cells have also been suggested as a strategy for the treatment of neurodegenerative disorders, but studies of these cells are at very early stages.

Retinitis pigmentosa (RP), a common cause of blindness from retinal degeneration, represents one class of disorders that stands to benefit from gene therapy. Though many different gene defects may cause RP, treatment of a form caused by mutation in the rod photoreceptor cGMP phosphodiesterase b-subunit gene has been studied in animal models by intraocular gene addition with adenovirus, lentivirus, andAAVvectors. In a different type of RP, progression of an autosomal dominant form of the disease was significantly slowed in a transgenic rat model using AAV vectors that express *ribozymes* (RNA enzymes) against the mutant mRNA. Ribozymes are catalytically active RNA molecules that specifically anneal to, and cleave, other RNA sequences, resulting in their selective degradation. This strategy may be useful for the treatment of other genetic diseases caused by dominant mutations. Viral vectors that express cytotoxic genes have been used to treatCNStumors (see below).

MUSCULOSKELETAL SYSTEM

Efficient gene transfer to myotubes through intramuscular injection has been demonstrated with adenoviral vectors,AAVvectors, and lentiviral vectors. In the case of AAV vectors, long-term transgene expression in muscles has been observed in several animal species. The treatment of the muscular dystrophies will require efficient delivery to multiple muscle groups throughout the body, and vector delivery to all the necessary locations remains a formidable task. In the case of Duchenne muscular dystrophy, the large size of the dystrophin cDNA also poses technical challenges in vector design. In contrast to primary diseases of muscle, success is more likely in muscle gene therapy

trials aimed at the synthesis of secreted proteins, such as clotting factors. The large tissue mass and accessibility of muscle make it particularly attractive for these applications.

CARDIOVASCULAR SYSTEM

The cardiovascular system (including the peripheral vasculature) has become an important target for gene therapy. Vascular wall gene delivery is being studied as a way to inhibit smooth-muscle cell proliferation and prevent restenosis. The transgenes used in this application are designed to interfere with the cell cycle or induce apoptosis in smooth-muscle cells. This approach is especially attractive if the vector can be delivered during angioplasty.

Other gene therapy strategies are used to promote the vascularization of tissues. There is some evidence for a therapeutic response in patients with critical limb ischemia due to poor peripheral vascularization who received intramuscular injection of naked DNA vectors encoding the vascular endothelial growth factor (VEGF) gene. Small amounts of the protein are secreted from the muscle, resulting in collateral vessel development that can reverse the ischemia. Patients who were expected to require limb amputation were spared this procedure after gene therapy. Similar clinical trials with the VEGF gene using nonviral and viral vectors are being studied in the context of myocardial ischemia.

CANCER

Most of the gene therapy clinical trials to date have been aimed at the treatment of cancer. One approach uses gene therapy with cytokine or neoantigen genes to increase tumor immunogenicity. The vector is usually injected directly into the tumor, and there is some evidence that once the immune system is stimulated, nontransduced tumor cells may also be eliminated by the immune system. In melanoma, for example, cells have been genetically altered to express mismatched histocompatibility antigens or cytokines such as tumor necrosis factor,IFN-g, or IL-2 in an effort to stimulate an immune response. Another approach involves the delivery of genes to tumor cells that convert a prodrug into a cytotoxic compound. Although several strategies are being developed, the most common involves the transfer of the herpes thymidine kinase (TK) gene. The TK enzyme converts gancyclovir into a thymidine analogue that interferes with DNA synthesis and causes cell death. The toxic effects also occur in adjacent nontransduced cells due to the uptake of the toxic analogue; this process is referred to as the *bystander effect*. Vectors designed to replace defective tumor-suppressor proteins with normal versions are being considered for cancer gene therapy, but it is difficult to envision success with this approach unless virtually all the tumor cells are genetically modified. Genes that control tumor growth when expressed in nontumor cells may also be effective in cancer gene therapy. The delivery of gene products that interfere with tumor angiogenesis best exemplifies this approach. Finally, lytic viral vectors that selectively replicate and kill malignant cells are being developed. One example is an adenovirus designed to replicate in cells deficient in p53, a tumor-suppressor protein that is mutated in many different cancers.

These and other related strategies have shown efficacy in animal models when tumor cells are transplanted into various anatomic locations. These models do not always

emulate the natural processes that result in bonafide cancers, in part due to the tumor cells not being truly autologous in origin. Although there have been encouraging results in some of the clinical trials performed to date, efficacy has not been demonstrated definitively. In many cases the patient populations studied had advanced malignancies, and more informative results might be obtained at earlier disease stages. Still, cancer gene therapy has a promising future, and ongoing research involving tumor-specific antigens, angiogenesis, cell cycle control, and apoptosis are all likely to lead to new gene therapy approaches. Improvements in vector targeting of tumor cells and in the development of tumor-specific gene expression will also enhance future therapeutic approaches.

COAGULOPATHIES

Inherited coagulopathies, especially hemophilia A and B, are promising areas of gene therapy research because even a low level of coagulation factor reconstitution can potentially benefit a patient with a severe phenotype. Although the liver is the major site of synthesis for factors VIII and IX, several other tissues may support factor synthesis and secretion into the bloodstream.AAVvectors, in particular, have shown prolonged therapeutic effects in animal models of hemophilia B when delivered to muscle or liver. Hemophilia A has been more difficult to treat, due to the larger cDNA (which approaches the packaging capacity of AAV vectors) and the requirement that expressing cells deliver the protein directly into the intravascular space. Other coagulopathies, such as factor X deficiency, are also good candidates for gene therapy. Various approaches to the treatment of hemophilia are currently in the early stages of clinical trials.

INFECTIOUS DISEASES

Most infectious pathogens studied as targets for gene therapy are viral (particularly HIV), in part because they replicate inside human cells. One approach involves introducing inhibitory versions of essential viral proteins that disrupt the viral life cycle even in the presence of their normal counterparts (e.g., by disrupting the packaging of virions). Another strategy involves the expression of proteins, peptides, or even RNA transcripts that function as decoys by binding to other proteins required for viral replication and preventing them from acting on their normal viral target sites. The cellular proteins required for a pathogen's life cycle, such as receptor molecules used for viral entry, or specific proteins used for adherence of the pathogen, can also be manipulated through gene therapy; this tactic could also be applied to nonviral pathogens. Ribozymes can be engineered to cleave specific viral transcripts, thereby blocking expression of viral gene products or destroying viral genomes (in the case of RNA viruses). Because ribozymes can, in principle, be engineered to attack any RNA transcript, they are being considered as treatments for many different viral diseases. Clinical trials have begun using ribozymes to block HIV infection. Antisense oligonucleotides can also be used to interfere with viral or cellular nucleic acid sequences. Other gene therapy approaches that may be applied to infectious diseases include vaccination with specific antigens and manipulation of the immune system to enhance the clearance of pathogens.

SUMMARY

The gene can be thought of as a new pharmaceutical agent in the armamentarium used to treat disease. The availability of cloned genes has already yielded a large array of recombinant proteins for clinical use. The limited success of gene therapy to date is due primarily to difficulties inherent in the efficient and safe delivery of genes to their appropriate target cells. The field is still in its infancy, and many of the technical problems are likely to be solved by advances in vector design.

PART FOUR -CLINICAL PHARMACOLOGY

70. PRINCIPLES OF DRUG THERAPY - *John A. Oates*, *Dan M. Roden*, *Grant R. Wilkinson*

Safe and effective drug therapy requires that drugs be delivered to their molecular targets in tissues at concentrations within the range that yields efficacy without toxicity. Variability in drug effects between individual patients can thus be attributed, in part, to differences in the processes that determine these concentrations, i.e., drug disposition involving absorption, distribution, and elimination. *Pharmacokinetics* provides a quantitative description of these processes, i.e., what the body does to the drug. In addition, variability in response may also reflect differences in the drug-target interaction that affect the concentration-related effects of the drug on the body, termed *pharmacodynamics*. This chapter reviews the principles of pharmacokinetics and pharmacodynamics and their application to optimizing therapeutic regimens.

CLINICAL PHARMACOKINETICS

PLASMA LEVELS AFTER A SINGLE DOSE

The levels of lidocaine in plasma following intravenous administration decline in two phases, as illustrated in Fig. 70-1; such a biphasic decline is typical for many drugs. Immediately after rapid injection, essentially all of the drug is in the plasma or central compartment, and the high initial plasma level reflects the confinement of the drug to this small volume. The drug is then transferred into an extravascular or peripheral compartment during a period called the *distribution phase*. For lidocaine, the distribution phase is virtually complete within 30 min. A phase of slower decline, the *equilibrium phase*, then occurs. During this phase, the drug levels in the plasma and in tissues change in parallel. Although this disposition profile is common to many drugs given intravenously, the characteristic parameters vary among drugs.

Distribution Phase The pharmacologic effects during the distribution phase depend on whether the concentration of drug at the receptor site is similar to that in the plasma. If that is the case, the pharmacologic effects may be intense during this period because of the high initial levels in the plasma. For example, after a small bolus dose (50 mg) of lidocaine, antiarrhythmic effects may be evident during the early distribution phase but will disappear as levels fall below those that are minimally effective, even before equilibrium between plasma and tissue is reached. Thus, a larger single dose or multiple small doses must be administered to achieve an effect that is sustained into the equilibrium phase. Toxicity resulting from high levels of some drugs during the distribution phase precludes administration of a single intravenous loading dose that will yield therapeutic levels during the equilibrium phase. For example, the administration of the entire loading dose of phenytoin as a single intravenous bolus can cause cardiovascular collapse due to the high levels during the distribution phase. If a loading dose of phenytoin is administered intravenously, it must be given slowly, e.g., at infusion rates of 25 to 50 mg/min. For similar reasons, the intravenous loading dose of many potent drugs that equilibrate rapidly with their receptors is either divided into fractional doses given at intervals or administered by infusion over a similar period.

A dose given orally results in lower plasma levels during the initial period than an intravenous bolus dose that delivers the same amount of drug to the systemic circulation. Because the drug is not absorbed instantly after oral administration and is delivered into the systemic circulation more slowly, much of it has been distributed by the time absorption is complete. Thus, procainamide, which is almost totally absorbed after oral administration, can be given orally as a single 750-mg loading dose with little risk of hypotension; in contrast, loading of this drug by the intravenous route is more safely accomplished by giving the dose in fractions of about 100 mg at 5-min intervals or by slow infusion to avoid hypotension during the distribution phase.

Some drugs are so predictably lethal when infused too rapidly that special precautions should be taken to prevent even the inadvertent occurrence. For example, solutions of potassium for intravenous administration in excess of 20 meq/L should be avoided in all but the most exceptional and carefully monitored circumstances. This minimizes the possibility of cardiac arrests, which can occur as a result of accidental increases in infusion rates of more concentrated solutions.

As these examples illustrate, excessively rapid administration of many drugs can lead to catastrophic consequences that result from high concentrations in the blood during the distribution phase.

In contrast, for some centrally active drugs, the higher concentration of drug during the distribution phase after intravenous administration is used to advantage. The use of midazolam for "IV sedation," for example, depends upon its rapid uptake by the brain during the distribution phase to produce sedation quickly, with subsequent egress from the brain during the redistribution of the drug as equilibrium is achieved.

Some drugs are distributed slowly to their sites of action during the distribution phase, i.e., concentration at the relevant receptor does not parallel that in plasma early after drug administration. For example, the level of digoxin at the receptor site (and the drug's pharmacologic effect) do not reflect plasma levels during the distribution phase. Digoxin is transported (or bound) to its cardiac receptors slowly by a process that proceeds throughout distribution. Thus, over the distribution phase of several hours, plasma levels fall while the level at the site of action and the pharmacologic effect increase. Only at the end of the distribution phase, when the drug has reached equilibrium with the receptor, does the concentration of digoxin in plasma reflect pharmacologic effect. For this reason, there should be a 6- to 8-h wait after administration before plasma levels of digoxin are measured as a guide to therapy.

Equilibrium Phase After the concentration of drug in plasma has reached a dynamic equilibrium with that in the tissues, the levels in plasma and tissues fall in parallel as the drug is eliminated from the body. Thus, the equilibrium phase is also called the *elimination phase*. During this phase, drug concentrations measured in plasma can provide a useful index of drug levels in tissues.

Most drugs are eliminated as a first-order process. This means that the time required for the plasma level of the drug to fall to one-half the original value (the half-life, $t_{1/2}$) is the same regardless of the point on the plasma level curve at which measurement begins. Another characteristic of the first-order process is that a plot of the logarithm of the

plasma concentration versus time is linear. From such a plot (Fig. 70-1), it can be seen that the half-life of lidocaine is 108 min. If the half-life is known, the amount of a dose remaining in the body at any time following administration of a single dose can be calculated. Table 70-1 shows how this amount changes over five successive half-lives.

From a clinical standpoint, elimination is essentially complete when it has reached about 90%. Therefore, for practical purposes, *a first-order elimination process reaches completion after three to four half-lives*.

DRUG ACCUMULATION -- LOADING AND MAINTENANCE DOSES

If a drug is given repeatedly at intervals shorter than the time required to eliminate a dose, both the amount of drug in the body and its pharmacologic effect increase with successive doses until they reach a plateau.Figure 70-2 shows the accumulation of digoxin administered in repeated maintenance doses (without a loading dose). Since the half-life of digoxin is about 1.6 days in a patient with normal renal function, 65% of a digoxin dose remains in the body at the end of 1 day. Thus, the second dose will raise the amount of digoxin in the body (and the average plasma level) to 165% of the level produced by the first dose. Each subsequent dose causes a further increase until a *steady state* is achieved. At that point, the drug dosing rate (bioavailable dose/dosage interval) is equal to the rate of elimination, with the fluctuation between peak and trough plasma levels remaining constant. If the rate of drug delivery is then altered, a new steady state will be attained. Continuous infusion of a drug at constant rate also results in progressive accumulation to a predictable steady state (Fig. 70-2). In this case, the steady-state plasma level (C_{ss}) is equivalent to the average between the peak and trough levels ($C_{avg,ss}$) produced by intermittent administration of the same amount of drug over the same period. For *all* drugs with first-order kinetics, the time required to achieve steady-state levels can be predicted from the half-life, because accumulation is a first-order process with a half-life identical to that for elimination. Thus, accumulation reaches 90% of steady-state levels at the end of three to four half-lives. This is true for either intermittent or continuous dosing (Fig. 70-2).

When a therapeutic effect is required urgently, simply administering the maintenance dose of a drug with a long half-life results in an unacceptable delay in reaching steady-state levels of the drug and its intended effect. The time required to achieve the desired pharmacologic effect may be shortened by the administration of a *loading dose* -- the amount of drug that will bring the plasma concentration rapidly to the steady-state level. Therefore, if treatment with lidocaine ($t_{1/2}$~ 108 min) were initiated by infusion at only the maintenance dose level, it would take about 4 to 8 h before the drug's maximal effect was achieved. Because ventricular arrhythmias may be life-threatening, it is not reasonable to wait that long to achieve an effective steady-state drug level. Accordingly, it would be appropriate to administer one or more loading doses at the onset of therapy, together with infusion at the rate of the maintenance dose.

Loading may be accomplished by the administration of a single loading dose or, if that would create a risk of toxicity, by the administration of the loading dose in a series of fractions of that dose over time. The latter approach is particularly appropriate for most drugs that have a low therapeutic index. A divided loading dose strategy or the administration of the loading dose in a slow intravenous infusion are particularly

advisable when the drug is given intravenously. Thus, in the case of lidocaine, a common regimen is to administer an initial intravenous bolus of 1 mg/kg followed by up to three additional bolus injections of 0.5 mg/kg every 8 to 10 min as necessary, and a maintenance infusion of 2 mg/min.

Regardless of the size of the loading dose, *after maintenance therapy has been given for three to four half-lives, the amount of drug in the body is determined by the maintenance dose*. The independence of the steady state plasma levels from the loading dose is illustrated in Fig. 70-2, which shows that the elimination of the loading dose would be practically complete after three to four half-lives.

DETERMINANTS OF DRUG DISPOSITION

A number of physiologic and pathophysiologic factors determine the disposition of a drug and hence its pharmacokinetics in an individual patient. The three most important are *clearance*, a measure of the body's ability to eliminate drug; *volume of distribution*, an indication of the extent to which the drug is distributed outside of the blood compartment; and *bioavailability*, the fraction of the administered dose that reaches the systemic circulation. The elimination half-life ($t_{1/2}$), which measures the rate of drug removal from the body, is determined by the relationship between the physiologically determined clearance and volume of distribution.

Clearance The majority of drugs are given over a prolonged period of time according to a multiple dosage regimen, e.g., *x* mg every *y* h. The clinical goal is to maintain the drug's steady-state concentration within the therapeutic range for the individual patient; if the level is too low, reduced efficacy results, whereas if it is too high, the likelihood of adverse effects increases.

Steady state is achieved when the rate of drug elimination equals the rate of drug delivery into the systemic circulation, which, if bioavailability is complete, corresponds to the rate at which the drug dose is administered:

where Cl is clearance and C_{ss} is the steady-state concentration in plasma. Therefore, *at a given dosing rate the concentration of drug in plasma is completely dependent on its clearance*. If the drug is infused, the concentration remains constant so long as drug delivery continues; however, when the drug is given intermittently, the above relationship is expressed as:

where $C_{avg,ss}$ is the *average* value during the dosage interval and is equal to C_{ss} although the *actual* concentrations will be higher or lower at various points during this period. Thus, clearance determines the rate at which a drug should be administered in order to obtain a desired steady-state concentration; stated in a different fashion, steady-state drug levels can be modified either up or down by changing the dosage rate. *The clearance of the vast majority of drugs is constant over the therapeutic range of concentrations*.

Clearance is a measure of the rate at which the organs that eliminate drug from the body remove drug from the blood.

Accordingly, clearance reflects the volume of blood (or plasma) from which the drug would have to be removed per unit time to account for the elimination; it can be related to either total or unbound drug.

Drug elimination generally occurs as a result of metabolism and/or excretion in the liver, kidney, and possibly other organs. Clearance of drug from the body, therefore, reflects the overall contribution of each of these organs, as indicated by their individual rates of elimination normalized to the concentration of drug, and is additive.

Clearance of a drug is usually estimated following administration of an intravenous dose ($dose_{iv}$) and measurement of the resulting total area under the curve (AUC) for the blood or plasma concentration-time curve (AUC_{iv}) from zero to infinite time.

Table 70-2 indicates the marked differences in plasma clearance for some commonly used drugs. Some drugs such as phenobarbital and valproic acid have relatively low values (<10 mL/min), whereas others such as procainamide and lidocaine have much larger clearances (>500 mL/min). Such differences mainly reflect different rate-limiting determinants such as blood flow through the organ(s) of clearance, the extent of binding of the drug to plasma proteins, and the efficiency of the clearance process to remove drug from tissue water by metabolism and/or excretion. The data inTable 70-2 also demonstrate that the relative contributions of the two major routes of elimination, i.e., renal and nonrenal, also vary according to the individual drug. In some cases, such as amikacin, digoxin, gentamicin, lithium, and tobramycin, excretion by the kidneys is predominant. However, with many other drugs (e.g., carbamezipine, lidocaine), nonrenal elimination, which usually reflects metabolism in the liver, is more important.

Volume of Distribution The relationship between the amount of drug in the body and the concentration of drug in the plasma provides a measure of the apparent volume of distribution:

This volume does not, except in a limited number of special cases, reflect an identifiable physiologic volume but corresponds to the virtual volume of fluid that would be required to contain all of the drug in the body at the same concentration as in the plasma. In a typical 70-kg human, plasma volume is about 3 L, blood volume around 5.5 L, and extracellular water outside the vasculature is approximately 42 L. The volume of distribution of drugs that are extensively bound to plasma proteins but are not bound to tissue components approaches plasma volume. However, for most drugs, the volume of

distribution is far greater than any physiologic space. For example, the volume of distribution of digoxin is about 700 L, which obviously exceeds total body volume. This simply indicates that digoxin is largely distributed outside the vascular system and hence the proportion of the drug present in the plasma compartment is low.

The volume of distribution may be estimated by back-extrapolation of the plasma concentration-time curve to zero time (C_0) (Fig. 70-1) and dividing this into the dose of drug administered intravenously.

When distribution of the drug is not instantaneous, a more useful volume estimate is based on the area under the plasma-concentration time curve (*AUC*) and the terminal elimination half-life of the drug ($t_{1/2}$).

Extent and Rate of Bioavailability After intravenous administration, all of the administered dose reaches the systemic circulation. In contrast, with all other routes of administration, such as oral, intramuscular, and subcutaneous, there is the potential for only a part of the dose to be absorbed; this fraction (*F*) is termed the drug's *bioavailability*. Lack of complete bioavailability may reflect the inability of the drug to be completely released from the dosage form or vehicle, chemical destruction at the site of administration, incomplete absorption into the vascular system, and metabolism and/or excretion during translocation of the drug from its site of administration to the systemic circulation. In the case of oral dosing, this would include the intestinal epithelium and the liver and lungs. Metabolism and/or excretion by the gastrointestinal tract (F_{GI}) and liver (F_L) are collectively referred to as the *first-pass effect*, since the resulting drug elimination only occurs during drug delivery to the systemic circulation. Loss of drug because of a first-pass effect thus requires that the dosing rate appropriately take into account bioavailability. For example, after oral drug administration:

Bioavailability and the first-pass effect are important with respect to possible differences in drug responsiveness dependent on the route of administration. For example, glyceryl trinitrate has such a large oral first-pass effect (>99%) that systemic concentrations after an oral dose are negligible and no antianginal effect is present. Giving the drug by the sublingual or transdermal routes bypasses the splanchnic organs and allows essentially all of the drug to reach the systemic circulation. For drugs that are efficiently metabolized by the intestinal epithelium and/or liver, i.e., drugs with high extraction ratios in either of these organs, differences in the extent of the first-pass effect between individuals frequently explain variability in drug response. With propranolol, for example, the 15-fold variability in plasma concentrations after the same oral dose results from differences in the individual hepatic extraction ratios reflective of different levels of drug metabolizing activity.

Drug administration by nonintravenous routes involves an absorption process characterized by the plasma level increasing to a maximum value at some time after

administration and then declining as the rate of drug elimination exceeds the rate of absorption. Thus, the peak concentration is lower and occurs later than after the same dose given by rapid intravenous injection. The rate of absorption can be an important consideration during the initial period after drug administration, especially for drugs with a narrow *therapeutic index* -- the ratio of the toxic dose to the therapeutic dose. If absorption is too rapid, then the resulting high concentration may cause adverse effects not observed with a more slowly available formulation. At the other extreme, slow absorption is deliberately designed into "slow-release" or "sustained-release" drug formulations in order to maintain plasma concentrations essentially constant during the dosage interval, because the drug's rate of elimination is offset by an equivalent rate of absorption controlled by formulation factors.

Half-Life The organs of elimination can only clear drug from the blood. Thus, the rate at which drug is eliminated from the body is a function of both clearance and the extent to which drug is distributed outside of the vascular compartment. The fraction of total drug in the body that is eliminated in a given time is designated the *fractional elimination constant* (*k*).

For example, if the volume of distribution is 10 L and clearance is 1 L/min, then one-tenth of the drug is eliminated per minute. If *k* is multiplied by the total amount of drug in the body, the actual rate of elimination at any given time can be determined:

This relationship, indicating that the rate of drug elimination is proportional to the drug concentration, describes a first-order, or monoexponential, process. With a few notable exceptions, the elimination of drugs used clinically is first-order.

Half-life ($t_{1/2}$) is the time that it takes for the plasma concentration or amount of drug in the body to decline by 50%. This parameter is related to *k* as follows:

where 0.693 is the natural logarithm of 2(C_0/0.5 C_0).

Because

then

This is an important relationship since it indicates that the rate of drug elimination, reflected by $t_{1/2}$, is dependent on both the efficiency of drug removal (*Cl*) and the drug's volume of distribution (*V*). When *V* remains constant, $t_{1/2}$is a reflection of clearance. Thus, $t_{1/2}$is shortened when rifampin induces the enzymes responsible for a drug's

hepatic clearance and is lengthened when a drug's renal clearance is impaired in renal failure. However, when there are concomitant alterations in *V*, as occurs for some drugs in cardiac failure, $t_{1/2}$is not an accurate measure of *Cl* or drug dose.

DESIGNING DOSAGE REGIMENS

Most drugs are administered as part of long-term therapy involving multiple dosing, and it is critical that the dosage regimen be optimized to the individual patient. With some drugs, the desired response, e.g., coagulation or blood pressure, is readily measurable and an individualized dosage regimen can be developed with dosage titration. However, dosage changes should be conservative (<50% for drugs with a low therapeutic index) and not more frequent than every three to four half-lives. Other drugs have little dose-related toxicity so the therapeutic window is large, e.g., penicillins andb-adrenoceptor antagonists. In these situations, effective and prolonged drug effects may be obtained by a "maximal dose" strategy. It is also possible to use this strategy to extend the duration of action of a drug, especially one that is eliminated rapidly from the body. Thus, 75 mg of captopril will result in reduced blood pressure for up to 12 h, even though the elimination half-life of this angiotensin-converting enzyme (ACE) inhibitor is about 2 h; this is because the dose raises the concentration of drug in plasma many times higher than the threshold for its pharmacologic effect.

Determination of the Maintenance Dose The relationship between the maintenance dose and the final steady-state concentration is

Thus, steady-state concentrations can be predictably increased or decreased by appropriate modification of the maintenance dosing rate to achieve a desired target value:

In most cases, this is best achieved by changing the drug dose but not the dosing interval, e.g., by giving 250 mg every 8 h instead of 200 mg every 8 h. However, this approach is acceptable only if the resulting maximum concentration is not toxic and the trough value does not fall below the minimum effective concentration for an undesirable period of time. Alternatively, the steady state may be changed by altering the frequency of intermittent dosing but not the size of each dose. In this case, the magnitude of the fluctuations around the average steady-state level will change -- the shorter the dosing interval, the smaller the difference between peak and trough levels (Fig. 70-3).

The extent of fluctuation is determined by the relationship between the dosing interval and the drug's half-life. For example, if the dosing interval is equal to the drug's half-life, then the fluctuation would be twofold, which is usually a tolerable variation. If a longer dosing interval is used, then the difference between the maximum and minimum plasma levels will be greater (Fig. 70-3). Marked fluctuations increase the likelihood of increased concentration-dependent drug effects early during the dosing interval and possible ineffectiveness at the end of the period, even though the average steady-state drug concentration is the same as that following administration at the same dosing rate but at

shorter intervals.

Determination of the Loading Dose The loading dose can be estimated if both the desired plasma level (*C*) and the apparent volume of distribution (*V*) are known:

The loading amount required to achieve steady-state plasma levels can also be determined from the fraction of drug eliminated during the dosing interval and the maintenance dose. For example, if the fraction of digoxin eliminated daily is 35% and the planned maintenance dose is 0.25 mg daily, then the loading dose to achieve steady-state levels would be (100/35) times the maintenance dose, or approximately 0.75 mg. Thus,

NONLINEAR DRUG ELIMINATION

The elimination of some drugs (e.g., phenytoin, salicylate, propafenone, and theophylline) does not follow first-order kinetics because the clearance of these drugs changes as levels in the body fall during elimination or change after alterations in dose. Such elimination is called *concentration-dependent* or *dose-dependent*. Accordingly, the time for the concentration to fall to one-half becomes less as plasma levels fall. (This halving time is not truly a half-life, because the term *half-life* applies to first-order kinetics and is a constant.) When a drug is eliminated by first-order kinetics, the plasma level at steady state is directly related to the amount of the maintenance dose, and a doubling of the dose should lead to doubling of the steady-state plasma level. However, for drugs with dose-dependent kinetics, an increase in the dose may be accompanied by a disproportionate increase in the plasma level. For example, a threefold increase in the dose of propafenone (from 300 mg to 900 mg daily) leads to a tenfold increase in the concentration of propafenone in plasma. Changes in dosage regimens for drugs with dose-dependent kinetics should always be accompanied by surveillance for adverse effects and by measurement of the concentration of the drug in plasma during the time of transition to the new steady-state, if this is feasible.

INDIVIDUALIZATION OF DRUG THERAPY

EFFECTS OF RENAL DISEASE

Whether a drug's dosing rate needs to be modified in patients with renal dysfunction depends on whether the drug is primarily excreted through the kidneys and whether increased drug levels, secondary to impaired renal clearance, will be associated with adverse effects. If both of these factors are present, it is likely that with decreased renal clearance the drug will accumulate to a greater extent than in patients with normal renal function and toxicity will result. This is especially true for drugs with long half-lives and narrow therapeutic indexes (e.g., digoxin). In general, over 60 to 70% of the drug must be renally excreted for dosage modification to be necessary and then only when renal function is less than about 30 to 50% of normal.

The goal of any dosing rate adjustment is to modify the dosing schedule so that the drug's plasma concentration-time profile is as similar to the desired one as possible and that the steady state is reached in about the same time as in a patient with normal renal function. To obtain the desired profile, a modification may be made by decreasing the dose while maintaining the dosage interval, keeping the dose the same but increasing the dosing interval, or a combination of these two approaches.

A drug's renal clearance is proportional to creatinine's clearance (Cl_{CR}), which may be measured directly or estimated from the serum creatinine level (C_{CR}). In men:

For women, the estimate by the above equation should be multiplied by 0.85 to reflect their smaller muscle mass. It should also be noted that this equation is not valid for patients with severe renal insufficiency (C_{CR}< 5 mg/dL) or when renal function is changing rapidly. For simplicity, normal creatinine clearance is conveniently considered to be 100 mL/min. Thus, if the relative contributions of renal and nonrenal elimination to systemic clearance are known, an appropriate modification of the dose in a patient with a given level of insufficiency can be estimated. For example, if the fraction of drug excreted unchanged is 0.9 and creatinine clearance is reduced to 10% of normal, the dosing rate should be reduced to 19% of normal. This modification, which in practice would be rounded to 20%, is based on the fact that nonrenal clearance is unchanged (10% of normal clearance); renal clearance is reduced from 90% to 9% of normal *Cl*; thus systemic clearance is reduced to 10 + 9 = 19% of normal *Cl*.

In clinical practice today, most decisions involving dosing adjustment in patients with renal failure use published tables of recommended dosage reduction or dosing interval lengthening based on the level of renal function indicated by Cl_{CR}, or similar information provided in the drug "label" (Table 70-3). Such modifications are, however, rigorously based on pharmacokinetic principles and are best used when resulting plasma concentration data and clinical observation are used, as necessary, to further optimize therapy for the individual patient.

Often metabolites of the drug are pharmacologically active or cause toxicity, and renal insufficiency may result in their unanticipated accumulation. Meperidine, for example, is extensively metabolized, and renal failure has little effect on its plasma concentration; however, its metabolite, normeperidine, accumulates above its usual level when renal function is impaired. Because normeperidine has greater convulsant activity than meperidine, this accumulation probably accounts for the signs of central nervous system (CNS) excitation, such as irritability, twitching, and seizures, that appear when multiple doses of meperidine are administered to patients with renal disease.

EFFECTS OF LIVER DISEASE

In contrast to the predictable decline in renal clearance of drugs in renal insufficiency, it is not possible to make a general prediction of the effect of liver disease on hepatic biotransformation of drugs (Chap. 292). Rather, the possible effects of hepatitis or cirrhosis range from impaired to increased drug clearance. Even in advanced hepatocellular disease, drug clearance is usually impaired only about two- to fivefold.

The extent of such changes, however, cannot be predicted by the common tests of liver function. Consequently, even when it is suspected that drug elimination is altered in liver disease, there is no quantitative basis on which to adjust the dosage regimen other than assessment of clinical response and the concentration of the drug in plasma.

A drug's oral bioavailability may markedly increase in patients with liver disease. This is particularly the case for those drugs that normally are very well extracted by the liver and thus have a high first-pass effect. In addition, the presence of portacaval shunts may further reduce first-pass elimination and lead to higher drug concentrations reaching the systemic circulation, with the increased risk of adverse effects. For example, the oral availability for high first-pass drugs such as morphine, meperidine, midazolam, and nifedipine is almost doubled in patients with cirrhosis, compared to those with normal liver function. The size of the oral dose of such drugs should, therefore, be reduced in such patients.

EFFECTS OF CIRCULATORY INSUFFICIENCY -- CARDIAC FAILURE AND SHOCK

Under conditions of decreased tissue perfusion, the cardiac output is redistributed to preserve blood flow to the heart and brain at the expense of other tissues (Chap. 38). As a result, the drug may be distributed into a smaller volume of distribution, higher drug concentrations will be present in the plasma, and the tissues that are best perfused will be exposed to these higher concentrations. If either the brain or heart is sensitive to the drug, an alteration in response will occur.

Furthermore, the decreased perfusion of the kidney and liver may impair drug clearance by these organs, directly or indirectly. Thus, in severe congestive heart failure, in hemorrhagic shock, and in cardiogenic shock, the response to the usual dose of drug may be excessive, and dosage modification may be necessary. For example, the clearance of lidocaine is reduced by about 50% in cardiac failure, and therapeutic plasma levels are achieved at infusion rates only about half those usually required. The volume of distribution of lidocaine is also reduced, meaning that the correct loading dose will be smaller than usual. Similar situations are thought to exist for procainamide, theophylline, and possibly quinidine. Unfortunately, predictors of these types of pharmacokinetic alterations are unavailable. Therefore, loading doses should be conservative, and continued therapy should be monitored closely, following clinical indicators of toxicity and plasma levels.

DISEASE-INDUCED CHANGES IN PLASMA BINDING

Many drugs circulate in the plasma partly bound to plasma proteins. Since only the unbound (free) drug can distribute to the site of pharmacologic action, the therapeutic response should be related to the free rather than the total circulating plasma drug concentration. In most cases, the degree of binding is fairly constant across the therapeutic concentration range, so that the total drug levels in plasma can be used as a basis for adjusting dosage without resulting in significant error. However, conditions such as hypoalbuminemia, liver disease, and renal disease can decrease the extent of drug binding, particularly of acidic and neutral drugs so that at any total plasma level there is a greater concentration of free drug than usual and thus a risk of increased response and toxicity. By contrast, conditions that lead to an increased plasma

concentration of the acute-phase reactant α_1-acid glycoprotein -- such as myocardial infarction, surgery, neoplastic disease, rheumatoid arthritis, and burns -- cause an increase in drug binding for the basic drugs, e.g., lidocaine and quinidine, that bind to this macromolecule, resulting in an opposite set of effects. The drugs for which changes in binding are important are those that are normally highly bound to plasma proteins (>90%), because a small alteration in the extent of binding produces a large change in the amount of unbound drug.

For many drugs, elimination and distribution are restricted largely to the unbound fraction, and so a decrease in binding leads to an increase in the clearance and distribution of the drug. The relative magnitudes of these changes are such that the net effect is a shortened half-life.

GENETIC DETERMINANTS OF THE RESPONSE TO DRUGS

Knowledge of the enzyme that catalyzes the predominant pathway of metabolism of a drug provides a basis for understanding the therapeutic consequences of variations in the genotype of that enzyme. For a number of the enzymes that metabolize drugs, there are differences (polymorphisms) in catalytic function that are genetically determined (Chap. 65). *A phenotypic trait or its corresponding gene is said to be polymorphic if there is more than one form of the trait or gene in the population*. Polymorphisms in the function of an enzyme are determined by allelic variants in its gene. Increasingly it is possible to individualize treatment based on analysis of the phenotype and/or genotype of the relevant drug-metabolizing enzyme.

Similarly, polymorphism in the receptor for a drug can determine variability in its pharmacologic effect. Genotyping those drug receptors for which polymorphisms influence response may also assist in individualizing drug therapy.

THIOPURINE *S*-METHYLTRANSFERASE (TPMT)

The metabolism of azathioprine provides an example of the importance of genetic polymorphisms of enzymes. Azathioprine exerts its immunosuppressive action via an active metabolite, 6-mercaptopurine. Within target cells, the major pathway of inactivation of 6-mercaptopurine is by TPMT. Genetic polymorphisms in this enzyme lead to differences in inactivation of 6-mercaptopurine, with corresponding vast differences in the sensitivity of patients to the toxic and therapeutic effects of azathioprine. Homozygotes for alleles encoding inactive TPMT (0.3 to 1% of the population) predictably exhibit severe pancytopenia on standard doses of azathioprine. Heterozygotes for alleles encoding enzymes with deficient TPMT activity also experience more bone marrow suppression on "usual" doses. From a therapeutic standpoint it is likely that the bone marrow suppression in the heterozygotes has influenced the empiric determination of the "usual" dose range of azathioprine and that this results in undertreatment of some of the patients homozygous for the allele encoding a TPMT with full catalytic activity. To detect the TPMT deficient phenotype in patients anticipating therapy with azathioprine, the catalytic function of TPMT may be measured in red blood cells (if no blood or red cell transfusions have been given within 2 months). A high concordance of genotype with phenotype (~95%) suggests that analysis of genotype may be used to individualize dosing and therefore improve

treatment with azathioprine (and 6-mercaptopurine) in the future.

ACETYLATION

Isoniazid, hydralazine, sulfonamides, procainamide, and a number of other drugs are metabolized by acetylation of a hydrazino or amino group. This reaction is catalyzed by *N*-acetyl transferase-2 (NAT-2), an enzyme in the liver cytosol that transfers an acetyl group from acetyl coenzyme A to the drug. Individuals differ markedly in the rate at which drugs are acetylated, because of polymorphisms in the NAT-2 gene, resulting in a bimodal distribution of the population into "rapid acetylators" and "slow acetylators."

Acetylation phenotype can be determined by measuring the ratio of acetylated to nonacetylated forms of the probe drugs, dapsone, caffeine, or sulfamethazine, in plasma or urine following administration of a test dose of these acetylation substrates. Slow, intermediate, and rapid acetylators may be identified by these methods for phenotyping. It is also possible to identify slow acetylators by genotyping, using genomic DNA obtained from blood leukocytes.

METABOLISM BY CYTOCHROME P450 MONOOXYGENASES

In healthy individuals taking no other medications, the major determinant of the rate of metabolism of drugs by the cytochrome P450 monooxygenases is genetic. Hepatic endoplasmic reticulum contains a family of cytochrome P450 (CYP) isoforms with different substrate specificities. Many drugs undergo oxidative metabolism by more than one isoform, and the steady-state concentrations of such drugs in the plasma is a function of the sum of the activities of these and other metabolizing enzymes. When a drug is metabolized by multiple pathways, the catalytic activities of the participating enzymes are regulated by a number of genes, so that the clearance rates and steady-state concentrations of the drug tend to distribute unimodally within the population. The range of activity may differ markedly (³tenfold) between different individuals, as is the case for chlorpromazine, and there is no way to predict the rate before beginning therapy.

Certain metabolic pathways show a bimodal or trimodal distribution of activity, suggesting control by a single gene, and polymorphisms in these genes have been identified. Most individuals are extensive metabolizers (EM phenotype); a smaller group have a lower ability to metabolize the drug (or no ability at all) and are called poor metabolizers (PM phenotype). Heterozygotes for genes encoding the enzymes lacking catalytic activity may be intermediate metabolizers (IM phenotype). And patients with duplicate or multiple copies of the gene may exhibit ultrarapid metabolism. These polymorphisms are of greatest clinical relevance during administration of substrate drugs for which there are no major alternative routes of elimination. The clinical consequences of the PM phenotype will then depend on the resultant accumulation of the drug or occasionally on the absence of generation of active metabolites.

The cytochrome P450 isoform CYP2D6 is polymorphically distributed in the population, and about 8 to 10% of Caucasians are deficient in this enzyme. CYP2D6 represents the main metabolic pathway for a number of drugs, including antiarrhythmic agents (propafenone, flecainide), b-adrenoceptor blockers (timolol, metoprolol, and alprenolol),

tricyclic antidepressants (nortriptyline, desipramine, imipramine, clomipramine), neuroleptic drugs (perphenazine, thioridazine, and possibly haloperidol), selective serotonin reuptake inhibitors (fluoxetine and paroxetine), and certain opiates, such as codeine and dextromethorphan. Thus, codeine has a much lower analgesic effect inPMpatients because of impaired production of the active metabolite, morphine. Conversely, a patient with duplicate or multiple copies of CYP2D6 will exhibit an exaggerated response to codeine. Patients with the PM phenotype experience more pronounced systemic b-adrenoceptor blockade after the administration of timolol ophthalmic solution. The catalytic activity of CYP2D6 in humans may be assessed by using a test drug, debrisoquin, which is eliminated almost entirely via hydroxylation by CYP2D6. Individuals with the PM phenotype can be identified by genotyping for the alleles that encode proteins with loss of catalytic function. There are ethnic variations in the frequency of the PM phenotype, which occurs in 5 to 10% of Caucasians but with a lesser frequency in Asians (1 to 2%).

The isoform CYP2C19 also exhibits polymorphism; it was initially detected with the hydroxylation of mephenytoin, which is used as a probe drug for the function of this P450 isoform. This enzyme catalyzes the major metabolic pathway of omeprazole, proguanil, diazepam, and citalopram. The impact of the polymorphism in CYP2C19 on treatment outcome is clearly illustrated by omeprazole. The efficacy of omeprazole (20 mg in combination with amoxicillin) in eradicating *Helicobacter pylori* is markedly reduced in persons with the homozygousEMgenotype (29% cured) as compared with 100% cure in those with homozygousPMgenotype. This reflects the relative lack of effect of the recommended dose of omeprazole (20 mg) on gastric acid secretion and ulcer healing in patients with the CYP2C19 EM genotype. Certainly knowledge of a patient's CYP2C19 genotype would improve therapy with this proton pump inhibitor. Impaired hydroxylation of mephenytoin is present in only 3 to 5 percent of Caucasians, but the incidence is about 20 percent in individuals of Japanese and Chinese descent.

CYP2C9 catalyzes the major pathways of metabolism of warfarin and phenytoin. There are allelic variants of the gene for this enzyme that encode proteins with loss of catalytic function. These variant alleles are associated with requirement for a very low dose of warfarin, difficulties in initiating warfarin therapy, and an increased risk of bleeding complications. Similarly, high concentrations of phenytoin in plasma and resulting adverse effects of phenytoin occur in patients with loss of function alleles for CYP2C9.

Polymorphisms in drug-metabolizing ability may be associated with large differences in the disposition of a drug among individuals, especially when the involved pathway makes a major contribution to the elimination of the drug. For example, the clearance of mephenytoin given orally differs 100- to 200-fold between individuals of theEM andPMphenotypes. As a result, the peak plasma concentrations and bioavailability after oral administration are much higher, and the rate of drug elimination much lower, in PM than in EM individuals. In PM individuals, the result is excessive drug accumulation and exaggerated pharmacologic responses, including toxicity, when usual drug dosages are administered. Individualization of drug therapy is especially critical for drugs that exhibit polymorphic drug metabolism. The increasing availability of laboratory methods to identify the PM phenotype for NAT-2, CYP2D6, and CYP2C19 by genotyping should be useful for this purpose.

INTERINDIVIDUAL VARIABILITY IN THE MOLECULAR TARGETS WITH WHICH DRUGS INTERACT

The increasing emphasis on identifying molecular mechanisms of disease (Chap. 65) has important consequences for further understanding a genetic basis for individual variability in drug actions. As molecular approaches identify the role of specific gene products in human physiology, polymorphisms that alter expression or function of those gene products are being recognized; it is estimated that such polymorphisms occur in 1 in 1000 bp in the human genome. These genes in turn, are now being recognized as the molecular targets with which available and new drugs interact to produce beneficial and adverse effects.

Genome-wide searches in families with premature Alzheimer's disease identified the *APOE* locus as linked to the disease (Chap. 362). Specifically, the *E4* allele of the *APOE* gene appears associated with a worse prognosis, and this is thought to relate to reduced expression of choline acetyl transferase. Further, a therapeutic response to the choline acetyl transferase inhibitor, tacrine, appears to be more common with the prognostically more benign *APOE2* or *APOE3* alleles. Multiple polymorphisms identified in theβ_2-adrenergic receptor appear to be linked to specific phenotypes in asthma and congestive heart failure, diseases in whichβ_2-receptor function might be expected to determine prognosis. It has been suggested that polymorphisms in the$\beta_2$receptor may be a determinant of response to inhaledβ_2-receptor agonists.

The development of marked QT prolongation and the polymorphic ventricular tachycardia, *torsade de pointes* (Chap. 230), in response to certain action potential-prolonging drugs such as quinidine used to be characterized as an "idiosyncratic" response. Advances in understanding the molecular basis of normal cardiac repolarization have resulted in identification of genes encoding ion channel proteins, the molecules whose normal function results in physiologic cardiac repolarization. Mutations in these genes cause congenital arrhythmia syndromes, such as the long QT syndrome, and block of ion channels is a common mechanism whereby drugs prolong QT intervals. Patients with mutations in these genes that remain subclinical until challenge with drugs are now recognized. In summary, continuing efforts to unravel the molecular basis of disease are likely also to provide insights into determinants of the response to drug therapy.

DRUG USE IN THE ELDERLY (See also Chap. 9)

Aging results in changes in organ function, especially of the organs involved in drug disposition, as well as alterations in body size and composition. Not surprisingly, therefore, pharmacokinetics are often different in elderly individuals than in younger adults. Also, elderly patients often have multiple diseases and may therefore be taking a large number of drugs. Consequently, drug interactions, as well as an increased vulnerability to morbidity and mortality, contribute to the higher incidence of adverse drug reactions in elderly patients. Increased sensitivity of target organs and impairment of physiologic control systems, such as those involved in the regulation of the circulation, may also be a factor. Accordingly, optimization of drug therapy in the elderly, particularly in frail patients, is often difficult, as a variety of factors (often poorly defined) accentuate the usual interindividual variability in drug response.

Although many individuals preserve good renal function into old age, elderly patients as a group have an increased likelihood of impaired renal excretion of drugs. Even in the absence of kidney disease, renal clearance is generally reduced by about 35 to 50% in elderly patients. Dosage adjustments analogous to those in patients with renal dysfunction (see above) are therefore necessary for drugs that are eliminated mainly by the kidneys, such as digoxin, aminoglycosides, lithium, and other drugs listed in Table 70-3. In this regard, it is important to recognize that the reduced muscle mass of older individuals results in a reduced rate of creatinine production; thus, a normal serum creatinine concentration can be present even though creatinine clearance is impaired.

Aging also results in a decrease in the size of and blood flow to the liver and possibly in the activity of hepatic drug-metabolizing enzymes; accordingly, the hepatic clearance of some drugs is impaired in the elderly. Unfortunately, no consistent pattern of clinical application appears to be present. Moreover, the changes are often modest relative to other causes for interindividual variability in these patients. However, even a small reduction in hepatic extraction may significantly increase the oral bioavailability of drugs with a high first-pass effect, such as propranolol and labetalol.

Impaired clearance and/or increased distribution may cause the elimination half-life of a drug to increase with aging. Thus, if a dosage modification in an elderly patient is required, it is often possible to accomplish it by decreasing the frequency of drug administration, possibly along with a reduction in dose.

Even if the pharmacokinetics of a drug are not altered, an elderly patient may require a smaller dosage because of an increase in pharmacodynamic sensitivity. Examples include increased analgesic effects of opioids, increased sedation from benzodiazepines and otherCNSdepressants, and increased risk of bleeding while receiving anticoagulant therapy, even when clotting parameters are well controlled. Exaggerated responses to cardiovascular drugs are also common because of the impaired responsiveness of normal homeostatic mechanisms. Such age-related changes require close monitoring of the patient's clinical response and appropriate dosage titration. Accordingly, in the elderly, initial doses should be less than the usual adult dosage and should be increased slowly. The final therapeutic regimen should be as simple as possible, and the number of different drugs used should be kept as low as possible. Also, because interindividual variability in drug responsiveness is greater in geriatric patients than in younger adults, individualization of therapy is even more critical.

INTERACTIONS BETWEEN DRUGS

The effect of some drugs can be altered markedly by the administration of other agents. Such interactions can complicate therapy by adversely increasing or decreasing the action of a drug. Drug interactions must be considered in the differential diagnosis of unexpected responses to drugs, and it should be recognized that patients often come to the physician with a legacy of drugs acquired during previous medical experiences. A meticulous drug history will minimize such unknown elements. It should include examination of the patient's medications and, if necessary, calls to the pharmacist to identify prescriptions. It should also address the use agents not often volunteered on

initial questioning, such as over-the-counter drugs, health food supplements, and topical agents such as eye drops.

There are two principal types of interactions between drugs. In *pharmacokinetic interactions*, the delivery of a drug to its site of action is altered, whereas in *pharmacodynamic interactions*, the responsiveness of the target organ or system is modified.

An index of the drug interactions discussed in this chapter is provided inTable 70-4. The table includes interactions that have verified significance in patients, plus a few that are so potentially dangerous that cognizance should be taken of the experimental data or case reports suggesting they occur.

I. PHARMACOKINETIC INTERACTIONS CAUSING DIMINISHED DRUG DELIVERY

A. Impaired Gastrointestinal Absorption Examples include aluminum ions, present in antacids, which form insoluble chelates with the tetracyclines, preventing absorption of these drugs. Ferrous ions similarly block tetracycline absorption. Kaolin-pectin suspensions bind digoxin, and when these substances are administered together, digoxin absorption is reduced by about one-half. However, when kaolin-pectin is administered 2 h after digoxin, digoxin absorption is unaffected.

Ketoconazole is a weak base that dissolves well only at acidic pH. Histamine H_2receptor antagonists, such as ranitidine and cimetidine, reduce gastric acidity and thus impair the dissolution and absorption of ketoconazole. By contrast, the absorption of fluconazole is not impaired by an increase in gastric pH.

B. Induction of Hepatic Drug-Metabolizing Enzymes When a drug is eliminated largely by metabolism, an increase in the rate of its metabolism reduces its availability to sites of action. Most drugs are metabolized largely in the liver because of this organ's large mass, high blood flow, and high concentration of drug-metabolizing enzymes. The first step in the metabolism of many drugs is catalyzed by a group of cytochrome P450 mixed-function oxidases located in the endoplasmic reticulum (see "Metabolism by Cytochrome P450 Monooxygenases," above). These enzyme systems oxidize drug molecules by a variety of reactions, including aromatic hydroxylations, *N*-demethylations, *O*-demethylations, and sulfoxidations. The products of these reactions are usually more polar than the parent compound (and more readily excreted by the kidney).

The expression of some of the mixed-function oxidase (CYP) isoforms is regulated, and their content in the liver can be increased, by a number of drugs. Phenobarbital is the prototype of these inducers, and all the barbiturates in clinical use increase CYP enzyme activity. Induction with phenobarbital can occur with doses of as little as 60 mg daily. Mixed-function oxidases are also induced by rifampin, carbamazepine, phenytoin, and glutethimide and by smoking, exposure to chlorinated insecticides such as DDT, and chronic alcohol ingestion.

Phenobarbital, rifampin, and other inducers lower plasma levels of many drugs, including warfarin, quinidine, mexiletine, verapamil, ketoconazole, itraconazole,

cyclosporine, dexamethasone, methylprednisolone, prednisolone (the active metabolite of prednisone), oral contraceptive steroids, methadone, metronidazole, and metyrapone. These interactions all have obvious clinical significance. In the case of the coumarin anticoagulants, the patient is placed at major risk if the appropriate level of anticoagulation is achieved when an inducer is also being administered and the inducer is later discontinued (for example, at discharge from the hospital). The plasma levels of the coumarin anticoagulant will rise as the induction effect wears off, leading to excessive anticoagulation. There is considerable variation among individuals in the extent to which drug metabolism can be induced.

C. Inhibition of Cellular Uptake or Binding The guanidinium antihypertensive agents guanethidine and guanadrel are transported to their site of action in adrenergic neurons by an energy-requiring membrane transport system for biogenic monoamines; the physiologic function of this system is reuptake of the adrenergic neurotransmitter. Inhibitors of norepinephrine uptake prevent the uptake of the guanidinium antihypertensive agents into adrenergic neurons and thereby block their pharmacologic effects. The tricyclic antidepressants are potent inhibitors of norepinephrine uptake. Consequently, concomitant administration of clinical doses of tricyclic antidepressants, including desipramine, protriptyline, nortriptyline, and amitriptyline, almost totally abolishes the antihypertensive effects of guanethidine and guanadrel. Although they are less potent inhibitors of norepinephrine uptake, doxepin and chlorpromazine produce dose-related antagonism of the action of the guanidinium antihypertensives.

The antihypertensive effect of clonidine is partially antagonized by tricyclic antidepressants. Clonidine lowers arterial pressure by reducing sympathetic outflow from the blood pressure-regulating centers in the hindbrain (Chap. 246). This central hypotensive action is antagonized by the tricyclic antidepressants.

II. PHARMACOKINETIC INTERACTIONS CAUSING INCREASED DRUG DELIVERY

A. Inhibition of Drug Metabolism If the active form of a drug is eliminated largely by biotransformation, inhibition of its metabolism leads to reduced clearance, prolonged half-life, and accumulation of the drug during maintenance therapy. Excessive accumulation due to inhibited metabolism can lead to adverse effects.

Cimetidine is a potent inhibitor of the oxidative metabolism of many drugs, including warfarin, quinidine, nifedipine, lidocaine, theophylline, and phenytoin. Adverse reactions, many of them severe, have resulted from the administration of these drugs in conjunction with cimetidine. Cimetidine is a more potent inhibitor of mixed-function oxidases than ranitidine, whereas ranitidine is more potent as a histamine H_2 receptor antagonist. Famotidine and nizatidine are not known to produce clinically appreciable inhibition of drug metabolism.

Knowledge of the CYP isoforms that catalyze the main pathway of metabolism of a drug provides a basis for predicting and understanding drug interactions. For example, the CYP3A subfamily of isoforms catalyzes the metabolism of many drugs for which blockage of metabolism results in toxicity. Drugs that depend on CYP3A as a major route of metabolism include cyclosporine, quinidine, lovastatin, simvastatin, atorvastatin, nifedipine, lidocaine, cisapride, erythromycin, methylprednisolone, carbamazepine,

midazolam, and triazolam.

The antifungal agents ketoconazole and itraconazole are potent inhibitors of enzymes in the CYP3A family. When fluconazole levels are elevated as a result of higher doses and/or renal insufficiency, this drug can also inhibit CYP3A. The macrolide antibiotics erythromycin and clarithromycin inhibit CYP3A4 to a clinically significant extent, but azithromycin does not inhibit this enzyme. Some of the calcium antagonists, diltiazem, nicardipine, and verapamil can also inhibit CYP3A, as can some of its other substrates, such as cyclosporine.

Cyclosporine can cause serious toxicity when its metabolism is inhibited by erythromycin, ketoconazole, diltiazem, nicardipine, or verapamil. A serious complication of HMG-CoA reductase inhibitors is myopathy. Fortunately, this is infrequent except in the context of interactions of a subset of the HMG-CoA reductase inhbitors with other drugs, particularly those that inhibit CYP3A4. The disposition of lovastatin is reduced markedly by drugs that inhibit CYP3A4, causing increases in plasma levels by more than tenfold. As a consequence, lovastatin has produced severe myopathy with rhabdomyolysis when administered together with erythromycin or cyclosporine. Not all of the HMG-CoA reductase inhibitors are as dependent on CYP3A4 for disposition as is lovastatin. Blocking CYP3A4 causes moderate elevations of plasma levels of simvastatin and atorvastatin (increases of severalfold), whereas elevations of the levels of fluvastatin and cerivastatin are only slight. Pravastatin disposition and plasma levels are not altered by inhibitors of CYP3A4. Cisapride can cause polymorphic ventricular tachycardia (torsade de pointes) when its metabolism is blocked by inhibitors of CYP3A, such as ketoconazole, itraconazole, clarithromycin, and erythromycin.

Whenever an inhibitor of CYP3A4 is administered to a patient, the physician should be alert to the possibility of serious interactions with drugs that are metabolized by CYP3A.

The CYP2D6 isoform that catalyzes the polymorphic metabolism of debrisoquin is markedly inhibited by quinidine and is also blocked by a number of neuroleptic drugs, such as chlorpromazine and haloperidol, and by fluoxetine. The analgesic effect of codeine depends on its metabolism to morphine via CYP2D6 in individuals with theEMphenotype. Thus, quinidine reduces the analgesic efficacy of codeine in EMs. Since desipramine is cleared largely by metabolism via CYP2D6 in EMs, its levels are increased substantially by concurrent administration of quinidine, fluoxetine, or the neuroleptic drugs that inhibit CYP2D6.

Some drugs are inactivated by mechanisms other than the hepatic drug-metabolizing enzymes. Azathioprine is converted in the body to an active metabolite, 6-mercaptopurine, which in turn is oxidized by xanthine oxidase to 6-thiouric acid. When allopurinol, a potent inhibitor of xanthine oxidase, is administered concurrently with standard doses of azathioprine or 6-mercaptopurine, life-threatening toxicity (bone marrow suppression) can result.

Other drugs that inhibit biotransformation of pharmacologic compounds (with examples of drugs whose metabolism is blocked by the inhibitor listed in parenthesis) include:

· Amiodarone (warfarin, quinidine)

· Clofibrate (phenytoin, tolbutamide)

· Excessive ingestion of ethanol (warfarin)

· Isoniazid (phenytoin)

· Metronidazole, cotrimoxazole (warfarin)

· Phenylbutazone (warfarin, phenytoin, tolbutamide)

B. Inhibition of Drug Transport Specific molecules that transport drugs into and out of cells are increasingly recognized, and inhibition of their function can be a major cause of clinically important drug interactions. The best studied to date is P-glycoprotein, originally isolated from tumor cells displaying resistance to multiple, structurally unrelated anticancer agents. The mechanism underlying this "multidrug resistance" phenomenon is P-glycoprotein-mediated pumping of anticancer agents out of cells, thereby inhibiting their anticancer effects. P-glycoprotein is also expressed in normal tissues (the luminal aspect of intestinal and renal tubular cells, the canalicular aspect of hepatocytes, the capillary endothelium of the blood-brain barrier), where it is responsible for efflux of not only antineoplastics but also digoxin and HIV protease inhibitors. Quinidine inhibits P-glycoprotein function in vitro, and it now seems apparent that the widely recognized doubling of plasma digoxin when quinidine is coadministered reflects this action in vivo, particularly since the effects of quinidine (increased digoxin bioavailability and reduced renal and hepatic secretion) occur at the sites of P-glycoprotein expression. Many other drugs also elevate digoxin concentrations (e.g., amiodarone, verapamil, cyclosporine, itraconazole, and erythromcyin), and a similar mechanism seems likely. ReducedCNSpenetration of multiple HIV protease inhibitors (with the attendant risk of facilitating a sanctuary site for the virus) appears attributable to P-glycoprotein-mediated exclusion of the drug from the CNS.

A number of drugs are secreted by the renal tubular transport systems for organic anions. Inhibition of this tubular transport system can cause excessive accumulation of a drug. Phenylbutazone, probenecid, and salicylates competitively inhibit this transport system. Salicylate, for example, reduces the renal clearance of methotrexate, an interaction that may lead to methotrexate toxicity. Renal tubular secretion contributes substantially to the elimination of penicillin, which can be inhibited by probenecid.

Inhibition of the tubular cation transport system by cimetidine impedes the renal clearance of procainamide and its active metabolite *N*-acetylprocainamide.

III. PHARMACODYNAMIC AND OTHER INTERACTIONS BETWEEN DRUGS

Therapeutically useful interactions occur in which the effect of two drugs in combination is greater than the sum of their effects when used individually. Favorable drug combinations are described in specific therapeutic sections in this text, and this section focuses on interactions that create unwanted effects. Two drugs may act on separate components of a common process to yield effects greater than either has alone. For example, although small doses of aspirin (<1 g daily) do not alter the prothrombin time

appreciably in patients who are receiving warfarin therapy, aspirin nevertheless increases the risk of bleeding in these patients because it inhibits platelet aggregation. Thus the combination of impaired functions of platelets and the clotting system, while useful for some therapeutic purposes, also increases the potential for hemorrhagic complications in patients receiving warfarin therapy.

Nonsteroidal antiinflammatory drugs (NSAIDs) cause gastric and duodenal ulcers, and, in patients treated with warfarin, the risk of bleeding from a peptic ulcer is increased almost threefold by concomitant use of a NSAID. This clearly is a serious drug interaction.

Indomethacin, piroxicam, and probably other NSAIDs antagonize the antihypertensive effects of b-adrenergic receptor blockers, diuretics, ACE inhibitors, and other drugs. The resulting elevation in blood pressure ranges from trivial to severe. Aspirin and sulindac, however, do not elevate the blood pressure in treated hypertensive patients.

Polymorphic ventricular tachycardia (torsade de pointes) during quinidine administration occurs much more frequently in patients receiving diuretics, probably owing to potassium and/or magnesium depletion.

The administration of supplemental potassium leads to more frequent and more severe hyperkalemia when potassium elimination is reduced by concurrent treatment with ACE inhibitors, spironolactone, amiloride, or triamterene.

The pharmacologic effects of sildenafil result from inhibition of the phosphodiesterase type 5 isoform that inactivates cyclic GMP in the vasculature. Nitroglycerin and related nitrates produce vasodilation by elevating cyclic GMP. Thus, coadministration of these nitrates with sildenafil will cause profound and potentially catastrophic hypotension.

CONCENTRATION OF DRUGS IN PLASMA AS A GUIDE TO THERAPY

In many cases, the plasma concentration of a drug is measured as a guide in the individualization of therapy. Genetic variation in elimination rates, interactions with other drugs, disease-induced alterations in elimination and distribution, and other factors combine to yield a wide range of plasma levels in patients given the same dose. Furthermore, the problem of noncompliance with prescribed regimens during continuing therapy is an endemic and elusive cause of therapeutic failure (see below). Clinical indicators assist in the titration of some drugs into the desired range, but no chemical determination is a substitute for careful observations of the response to treatment. However, the therapeutic and adverse effects are not precisely quantifiable for all drugs, and, in complex clinical situations, estimates of the action of a drug may be misleading. For example, previously existing neurologic disease may obscure the neurologic consequences of intoxication with phenytoin. Because clearance, half-life, accumulation, and steady-state plasma levels are difficult to predict, the measurement of plasma levels is often useful as a guide to the optimal dose. This is particularly true when there is a narrow range between the plasma levels yielding therapeutic and adverse effects. For drugs having such characteristics -- e.g., digoxin, theophylline, lidocaine, aminoglycosides, cyclosporine, and anticonvulsants -- dose optimization should involve modification of the standard dose on the basis of the pharmacokinetic

principles described above. In certain instances, predictive nomograms and algorithms have been developed to facilitate the necessary modifications. However, the most flexible and accurate method for individualizing drug dosage appears to be a feedback approach using a small number of previously obtained plasma levels and Bayesian forecasting. In controlled studies, this type of computer-assisted dosing has been shown to improve patient care. However, the overall cost/benefit ratio of such methods in routine management still remains to be concusively demonstrated.

For drugs with a narrow therapeutic window that exhibit first-order elimination, then, dosage adjustments may be made on the assumption that the average, maximum, and minimum steady-state concentrations are related linearly to the dosing rate. Accordingly, the dose may be adjusted on the basis of the ratio between the desired and measured concentrations:

For drugs that have dose-dependent kinetics (e.g., phenytoin and theophylline), plasma concentrations change disproportionately more than the alteration in the dosing rate. Not only should changes in dose be small to minimize the degree of unpredictability, but plasma concentration monitoring is also critical to ensure appropriate modification.

The variability among individual responses to given plasma levels must be recognized. This is illustrated by a hypothetical population concentration-response curve (Fig. 70-4) and its relationship to the therapeutic range or therapeutic window of desired plasma levels. The defined therapeutic window should include the levels at which the intended pharmacologic effect is achieved in most patients. However, a few persons, who are sensitive to the therapeutic effects, respond to lower levels, whereas others are refractory enough to require levels that may cause adverse effects. For example, a few patients with strong seizure foci require plasma levels of phenytoin exceeding 20 ug/mL to control seizures. Dosages to achieve this effect may be appropriate if tolerated.

As also illustrated inFig. 70-4, some patients are prone to adverse effects at levels that are tolerated by most of the population. Therefore, raising the plasma concentration of a drug to a level that has a high probability of being therapeutically effective may bring on unwanted actions in an occasional patient. Table 70-2 presents for a number of drugs the plasma concentrations that are associated with adverse and therapeutic effects in most patients. Use of this information according to the guidelines discussed should permit more effective and safer therapy for those patients who are not "average."

EFFECTIVE PARTICIPATION OF THE PATIENT IN THERAPY

Measurement of the concentration of a drug in plasma is the most effective way to detect failure to take a drug. Such "noncompliance" is a frequent problem in the long-term treatment of diseases such as hypertension and epilepsy, occurring in 25% or more of patients in therapeutic environments in which no special effort is made to involve patients in the responsibility for their own health. Occasionally, noncompliance can be uncovered by sympathetic, nonincriminating questioning, but more often it is recognized only after determining that the concentration of drug in plasma is nil or is recurrently low. Because other factors can cause plasma levels to be lower than

expected, comparison with levels obtained during inpatient treatment may be required to confirm that noncompliance has occurred. Once the physician is certain of noncompliance, a nonaccusatory discussion of the problem with the patient may clarify the reason for the noncompliance and serve as a basis for more effective cooperation on the part of the patient. Many approaches have been tried to help patients exercise more responsibility for their own treatment, most based on better communication regarding the nature of the disease and the chances of success or failure of the treatment. The patient is given a chance to discuss problems associated with treatment. The process may be improved by the involvement of nurses and other paramedical personnel. Minimizing the complexity of the regimen is helpful in terms of both the number of drugs and the frequency of administration. Educating patients to assume the principal role in their own health care requires a blend of the art and science of medicine.

71. ADVERSE REACTIONS TO DRUGS - *Alastair J. J. Wood*

The beneficial effects of drugs are coupled with the inescapable risk of untoward effects. The morbidity and mortality from these untoward effects often present diagnostic problems because they can involve every organ and system of the body and are frequently mistaken for signs of underlying disease. Major advances in the investigation, development, and regulation of drugs ensure in most instances that they are uniform, effective, and relatively safe and that their recognized hazards are publicized. However, prior to regulatory approval and marketing, new drugs are tested in relatively few patients who tend to be less sick and to have fewer concomitant diseases than those patients who subsequently receive the drug therapeutically. Because of the relatively small number of patients studied in clinical trials, and the selected nature of these patients, rare adverse effects may not be detected prior to a drug's approval, and physicians therefore need to be cautious in the prescription of new drugs and alert for the appearance of previously unrecognized adverse events.

The large number and variety of drugs available over the counter (OTC), herbal preparations, and by prescription, make it impossible for patient or physician to obtain or retain the knowledge necessary to use all drugs well. It is understandable, therefore, that many OTC drugs are used unwisely by the public and that restricted drugs may be prescribed incorrectly by physicians.

Most physicians use no more than 50 drug products in their practice, gaining familiarity with their effectiveness and safety. Most patients probably use only a limited number ofOTCdrugs. Nevertheless, many patients receive care and drug prescriptions from more than one physician, and in any 30-day period, many patients consume more than three different OTC drug products containing nine or more different chemical agents.

Some 25 to 50% of patients make errors in self-administration of prescribed medicines, and these errors can be responsible for adverse drug effects. Elderly patients are the group most likely to commit such errors, perhaps in part because they consume more medicines. One- third or more of patients also may not take their prescribed medications. Similarly, patients commit errors in takingOTCdrugs by not reading or following the directions on the containers. Physicians must recognize that providing directions with prescriptions does not always guarantee compliance.

Every drug can produce untoward consequences, even when used according to standard or recommended methods of administration. When used incorrectly, the effectiveness may be reduced, and adverse reactions can be expected to occur more frequently. Also, the administration of several drugs concurrently may result in adverse drug interactions (Chap. 70). In the hospital, all drugs a patient is given should be under the control of a physician, and patient compliance is, in general, ensured. Errors may occur nevertheless -- the wrong drug or dose may be given, or the drug may be given to the wrong patient -- although improved drug distribution and administration systems have reduced this problem. On the other hand, there are no easy means for controlling how ambulatory patients take prescription orOTCdrugs.

EPIDEMIOLOGY

Epidemiologic studies of adverse drug reactions have been helpful in evaluating the magnitude of the overall problem, in calculating the rate of reactions to individual drugs, and in characterizing some of the determinants of adverse drug effects.

Patients receive, on average, 10 different drugs during each hospitalization. The sicker the patient, the more drugs are given, and there is a corresponding increase in the likelihood of adverse drug reactions. When fewer than 6 different drugs are given to hospitalized patients, the probability of an adverse reaction is about 5%, but if more than 15 drugs are given, the probability is over 40%. Retrospective analyses of ambulatory patients have revealed adverse drug effects in 20%.

Thus, the magnitude of drug-induced disease is large. Of patients admitted to the medical and pediatric services of general hospitals, 2 to 5% are admitted because of illnesses attributed to drugs. The case/ fatality ratio from drug-induced disease in hospitalized patients varies from 2 to 12%. Furthermore, some fetal or neonatal abnormalities are due to medicines taken by the mother during pregnancy or parturition.

A small group of widely used drugs accounts for a disproportionate number of reactions. Aspirin and other nonsteroidal anti-inflammatory drugs, analgesics, digoxin, anticoagulants, diuretics, antimicrobials, glucocorticoids, antineoplastics, and hypoglycemic agents account for 90% of reactions, although the drugs involved differ between ambulatory and hospitalized patients. Estimates of the cost of drug-related morbidity and mortality in the ambulatory setting range from $30 billion to $130 billion.

ADVERSE DRUG REACTIONS IN THE ELDERLY (See also Chap. 9)

The elderly as a group have a greater burden of disease and receive a greater number of medications than other persons. Thus, it is not surprising that adverse drug reactions occur frequently in elderly patients. The issue of whether an elderly individual is more likely to develop an adverse drug reaction than a young person with a similar number of concurrent diseases and taking the same number of drugs has not been answered unequivocally. However, in population surveys of the noninstitutionalized elderly, as many as 10% report having had at least one adverse drug reaction in the last year. The incidence appears to be even greater in hospitalized elderly patients. Although it is widely believed that the elderly are more sensitive to drugs than the young, that is not true for all drugs. For example, a consistent decrease in sensitivity to drugs acting at theb-adrenergic receptor has been demonstrated in the elderly. The consequences of adverse drug effects may differ in the elderly because of their greater likelihood of other disease. For example, use of long-half-life benzodiazepines is linked to the occurrence of hip fractures in elderly patients, perhaps reflecting both a risk of falls from these drugs and the increased incidence of osteoporosis in elderly patients. Even when a drug impairs function similarly in patients of different age groups, the poorer baseline function in elderly persons may put them at greater risk for an adverse drug reaction. When prescribing for an elderly patient, the possibility that hepatic or renal mechanisms of drug excretion may be impaired should be taken into account. Adverse drug effects in the elderly may be subtle and, as in all populations, the physician must be alert to the possibility that a patient's signs and symptoms reflect an adverse effect of medication.

ETIOLOGY

Most adverse drug reactions are preventable, and recent studies using a systems analysis approach suggest that the most common system failure associated with an adverse drug reaction is the failure to disseminate knowledge about drugs to individuals involved in prescribing and administering them. Most adverse reactions can be classified into two groups. The most frequent ones result from an exaggeration of a predicted pharmacologic action of the drug. Other adverse reactions ensue from toxic effects unrelated to the intended pharmacologic actions. The latter effects are often unpredictable, are frequently severe, and result from recognized as well as undiscovered mechanisms. Some mechanisms unrelated to the drug's primary pharmacologic activity may include direct cytotoxicity, initiation of abnormal immune responses, and perturbation of metabolic processes in individuals with genetic enzymatic defects. Further understanding of interindividual differences in the expression of the enzymes responsible for drug metabolism has contributed to the understanding of adverse drug reactions that previously were thought to be idiosyncratic (see below). Prior consideration of the factors known to modify drug action often make it possible to prevent adverse reactions of this type.

Genetic Variations in Drug Oxidation by Cytochromes There is considerable interindividual variability in drug metabolism, resulting in variability in drug concentrations (Chap. 70). The majority of drugs are oxidized by cytochrome P450s (CYP) in the liver and gut. Some of these enzymes exhibit genetic polymorphisms resulting in enzymes with absent or reduced drug metabolizing activity, which may result in concentration-dependent toxicity. Conversely, where toxicity or pharmacologic effect is produced by a metabolite, individuals with low enzyme activity may have reduced drug effect whereas those with genetically determined increased enzyme activity will have increased drug effect. Examples of such polymorphically distributed oxidation enzymes include CYP2D6, CYP2C9, and CYP2C19.

The clinical consequences of the poor metabolizer phenotype are now becoming clearer and depend on the specific consequences of excessive drug concentrations. For example, the more potent (S) isomer of warfarin is metabolized by the polymorphically distributed enzymeCYP2C9, resulting in lower (S) warfarin clearance and higher concentrations in both heterozygotes and homozygotes for the allelic variants associated with reduced enzyme activity. Recently, the clinical consequences of this polymorphism have been demonstrated in patients followed in an anticoagulant clinic. Patients who were stabilized on warfarin doses of 1.5 mg/d or less had an increased frequency of the genotypes associated with low warfarin metabolism compared to either community controls or patients requiring higher doses of warfarin (Table 71-1). In addition, the group stabilized on low-dose warfarin had a greater incidence of initial over-anticoagulation and hemorrhage than the group on the higher dose. This serves as an example of how genetic variations of a cytochrome P450 enzyme alter the response to a drug.

The oral hypoglycemic glipizide is also metabolized byCYP2C9, and excessively low blood glucose concentrations occur after usual doses in genetic CYP2C9 poor metabolizers. Another oral hypoglycemic, phenformin, produced lactic acidosis in some patients. It is now recognized that phenformin is metabolized by another polymorphically distributed oxidative enzyme, CYP2D6. Patients who have genetically determined low

activity of CYP2D6 may be at particular risk from phenformin-induced lactic acidosis.

Genotypically determined variability in drug toxicity may also occur with drugs metabolized by enzymes other than cytochrome P450s. Such toxicity can be severe with the clinical use of the antimetabolites azathioprine and 6-mercaptopurine (to which it is converted in vivo). The cytotoxic thioguanine nucleotides produced in vivo are detoxified by further metabolism by xanthine oxidase and thiopurine methyltransferase (TPMT). The latter enzyme shows a trimodal distribution (Fig. 71-1). In children receiving mercaptopurine for treatment of leukemia, low activity of this enzyme is associated with excessive myelosuppression, whereas children with high TPMT levels have a poor antileukemic response. Azathioprine is currently used as a disease-modifying agent in the treatment of rheumatoid arthritis. Individuals with mutant TPMT alleles that result in impaired metabolism developed toxicity rapidly after beginning azathioprine and were uniformly unable to take the drug chronically. Thus the genotypic basis for drug toxicity is beginning to emerge.

Pharmacokinetic Bases for Adverse Reactions *An abnormally high drug concentration at the receptor site* (site of action) owing to pharmacokinetic variability is the usual cause of these reactions (Chap. 70). For example, a reduction in the volume of distribution, in the rate of metabolism, or in the rate of excretion all result in higher than expected concentration of drug at the receptor site, with a consequent increase in the pharmacologic effect.

Alteration in the dose-response curve due to increased receptor sensitivity results in an increase in drug effect at a given drug concentration. An example is the excessive response of elderly persons to the anticoagulant warfarin at normal or lower than normal blood levels. Such alterations in the dose-response curve may reflect altered drug sensitivity due to receptor polymorphisms, which are now being recognized. One such example is the prolonged QT syndrome, which has both a genetic basis, in individuals with abnormal potassium channels involved in cardiac repolarization, and a pharmacologic basis in individuals who receive drugs known to prolong the QT interval. Such individuals may develop torsade de pointes (Chap. 230). A large number of drugs have now been identified that can produce this potentially lethal effect (Table 71-2; alsohttp://www.dml.georgetown.edu/depts/pharmacology/torsades.html).

The shape of the dose-response curve also determines the likelihood of adverse drug reactions. Drugs with a steep dose-response curve or a narrow therapeutic index (Chap. 70) are more likely to cause dose-related toxicity because a small increase in dose produces a large change in pharmacologic effect. An increase in the dose of drugs that exhibit nonlinear kinetics, such as phenytoin (Chap. 70), may produce a proportionately greater increase in the blood level, resulting in toxicity.

Concurrent administration of other drugs may affect pharmacokinetics or pharmacodynamics. Pharmacokinetics may be affected by alterations in bioavailability, protein binding, or the rate of metabolism or excretion. Pharmacodynamics may be altered by another drug that competes for the same receptor sites, that prevents the drug from reaching its site of action, or that antagonizes or enhances the drug's pharmacologic effect. Inhibition of the metabolism of one drug by another may occur when both drugs bind to the sameCYP. Therefore, as the specific CYPs responsible for

the metabolism of individual drugs become known, prediction of drug interactions is put on a more rational scientific basis. An important example of such a mechanism is the inhibition of terfenadine's metabolism by inhibitors of CYP3A, such as erythromycin and systemic antimycotics. Such inhibition has resulted in torsade de pointes and lethal cardiac arrhythmia (Chap. 70).

TOXICITY UNRELATED TO A DRUG'S PRIMARY PHARMACOLOGIC ACTIVITY

Cytotoxic Reactions The understanding of so-called idiosyncratic reactions has greatly improved with the recognition that many of them are due to irreversible binding of a drug or its metabolites to tissue macromolecules by covalent bonds. Some chemical carcinogens, such as the alkylating agents, combine directly with DNA. Usually, it is only after metabolic activation of a drug to reactive metabolites that covalent binding occurs. This activation usually occurs in the microsomal mixed-function oxidase system, the hepatic enzyme system responsible for the metabolism of many drugs (Chap. 70). During the course of drug metabolism, reactive metabolites may covalently bind to tissue macromolecules, causing tissue damage. Because of the reactive nature of these metabolites, covalent binding often occurs close to the site of production. Typically that is the liver, but the mixed-function oxidase system is found in other tissues as well.

An example of this type of adverse drug reaction is the hepatotoxicity associated with isoniazid. This drug is metabolized principally by acetylation to acetylisoniazid, which is then hydrolyzed to acetylhydrazine. The further metabolism of acetylhydrazine by the mixed- function oxidase system liberates reactive metabolites that covalently bind to hepatic macromolecules, causing hepatic necrosis. The administration of drugs known to increase the activity of the mixed-function oxidase system, such as phenobarbital or rifampin, together with isoniazid results in the production of increased amounts of reactive metabolites, increased covalent binding, and a greater risk of hepatic damage.

The hepatic necrosis produced by overdosage of acetaminophen is also caused by reactive metabolites. Normally these metabolites are detoxified by combining with hepatic glutathione. When glutathione becomes exhausted, the metabolites bind instead to hepatic protein, with resultant hepatocyte damage. The hepatic necrosis produced by the ingestion of acetaminophen can be prevented, or at least attenuated, by the administration of substances such as *N*-acetylcysteine that reduce the binding of electrophilic metabolites to hepatic proteins. The risk of hepatic necrosis is increased in patients receiving drugs such as phenobarbital that increase the rate of drug metabolism and the rate of production of toxic metabolite(s).

It is likely, though as yet not proved, that other idiosyncratic reactions are caused by the covalent binding of reactive metabolites to tissue macromolecules, resulting either in direct cytotoxicity or in the initiation of an immune response.

Immunologic Mechanisms Most pharmacologic agents are poor immunogens because they are small molecules with molecular weights of less than 2000. Stimulation of antibody synthesis or sensitization of lymphocytes by a drug or one of its metabolites usually requires in vivo activation and covalent linkage to protein, carbohydrate, or nucleic acid.

Drug stimulation of antibody production may mediate tissue injury by one of several mechanisms. The antibody may attack the drug when the drug is covalently attached to a cell, and thereby destroy the cell. This mechanism occurs in penicillin-induced hemolytic anemia. Antibody-drug-antigen complexes may be passively adsorbed by a bystander cell, which is then destroyed by activation of complement; this occurs in quinine- and quinidine-induced thrombocytopenia. Drugs or their reactive metabolites may alter a host tissue, rendering it antigenic and eliciting autoantibodies. For example, hydralazine and procainamide can chemically alter nuclear material, stimulating the formation of anti-nuclear antibodies and occasionally causing lupus erythematosus. Autoantibodies can be elicited by drugs that neither interact with the host antigen nor have any chemical similarity to the host tissue; for example, a-methyldopa frequently stimulates the formation of antibodies to host erythrocytes, yet the drug neither attaches to the erythrocyte nor shares any chemical similarities with the antigenic determinants on the erythrocyte.

Drug-induced pure red cell aplasia (Chap. 109) is due to an immune-based drug reaction. Red cell formation in bone marrow cultures can be inhibited by phenytoin and purified IgG obtained from a patient with pure red cell aplasia associated with phenytoin.

Serum sickness (Chap. 310) results from the deposition of circulating drug-antibody complexes on endothelial surfaces. Complement activation occurs, chemotactic factors are generated locally, and an inflammatory response develops at the site of complex entrapment. Arthralgias, urticaria, lymphadenopathy, glomerulonephritis, or cerebritis may result. Penicillin is the most common cause of serum sickness today. Many drugs, particularly antimicrobial agents, induce production of IgE, which binds to mast cell membranes. Contact with a drug antigen initiates a series of biochemical events in the mast cell and results in the release of mediators that can produce the urticaria, wheezing, flushing, rhinorrhea, and (occasionally) hypotension characteristic of anaphylaxis.

Drugs may also excite cell-mediated immune responses. Topically administered substances may interact with sulfhydryl or amino groups in the skin and react with sensitized lymphocytes to produce the rash characteristic of contact dermatitis. Other types of rashes may also result from the interaction of serum factors, drugs, and sensitized lymphocytes. The role of drug-activated lymphocytes in the immune mechanisms governing destruction of visceral tissue is unknown.

Toxicity Associated with Genetically Determined Enzymatic Defects In the porphyrias, drugs that increase the activity of enzymes proximal to the deficient enzyme in the biosynthetic pathway of porphyrins can increase the quantity of porphyrin precursors that accumulate proximal to the deficient enzyme (Chap. 346). These drugs are listed inTable 71-1.

Patients with a deficiency of glucose-6-phosphate dehydrogenase (G6PD) develop hemolytic anemia in response to primaquine and a number of other drugs (Table 71-1) that do not cause hemolysis in patients with adequate quantities of this enzyme (Chap. 108).

DIAGNOSIS

The manifestations of drug-induced diseases frequently resemble those of other diseases, and a given set of manifestations may be produced by different and dissimilar drugs. Recognition of the role of a drug or drugs in an illness depends on appreciation of the possible adverse reactions to drugs in any disease, on identification of the temporal relationship between drug administration and development of the illness, and on familiarity with the common manifestations of the drugs. Many associations between particular drugs and specific reactions have been described, but there is always a "first time" for a novel association, and any drug should be suspected of causing an adverse effect if the clinical setting is appropriate.

Illness related to a drug's pharmacologic action is often more easily recognized than illness attributable to immune or other mechanisms. For example, side effects such as cardiac arrhythmias in patients receiving digitalis, hypoglycemia in patients given insulin, and bleeding in patients receiving anticoagulants are more readily related to a specific drug than are symptoms such as fever or rash, which may be caused by many drugs or by other factors.

Once an adverse reaction is suspected, discontinuance of the suspected drug followed by disappearance of the reaction is presumptive evidence of a drug-induced illness. Confirming evidence may be sought by cautiously reintroducing the drug and seeing if the reaction reappears. However, that should be done only if confirmation would be useful in the future management of the patient and if the attempt would not entail undue risk. With concentration-dependent adverse reactions, lowering the dosage may cause the reaction to disappear, and raising it may cause the reaction to reappear. When the reaction is thought to be allergic, however, readministration of the drug may be hazardous, since anaphylaxis may develop. Readministration is unwise under these conditions unless no alternative drugs are available and treatment is necessary.

If the patient is receiving many drugs when an adverse reaction is suspected, the drugs likeliest to be responsible can usually be identified. All drugs may be discontinued at once, or, if that is not practical, they should be discontinued one at a time, starting with the one that is most suspect, and the patient observed for signs of improvement. The time needed for a concentration-dependent adverse effect to disappear depends on the time required for the concentration to fall below the range associated with the adverse effect, and that, in turn, depends on the initial blood level and on the rate of elimination or metabolism of the drug. Adverse effects of drugs with long half-lives, such as phenobarbital, take a considerable time to disappear.

Drugs recognized as producing a number of reactions are listed in Table 71-1. This table includes both well-documented and some less well-documented reactions, focusing on those that are sufficiently important to require consideration. This information should be used to suggest the drug likely to be causing a reaction; the absence of a drug from the table does not mean that it cannot be responsible for the reaction, however.

Serum antibody has been demonstrated in some persons with drug allergies involving cellular blood elements, as in agranulocytosis, hemolytic anemia, and thrombocytopenia. For example, both quinine and quinidine can produce platelet agglutination in vitro in the presence of complement and the serum from a patient who

has developed thrombocytopenia following use of this drug.

Eliciting a drug history from patients is important for diagnosis. Attention must be directed toOTCdrugs and herbal preparations as well as to prescription drugs. Each type can be responsible for adverse drug effects, and adverse interactions may occur between OTC drugs and prescribed drugs. In addition, it is common for patients to be cared for by several physicians, and duplicative, additive, counteractive, or synergistic drug combinations may therefore be administered if the physicians are not aware of the patients' drug histories. Every physician should determine what drugs a patient has been taking, at least during the preceding 30 days, before prescribing any medications. A frequently overlooked source of additional drug exposure is topical therapy; for example, a patient complaining of bronchospasm may not mention that an ophthalmic beta blocker is being used unless specifically asked. A history of previous adverse drug effects in patients is common. Since these patients have shown a predisposition to drug- induced illnesses, such a history should dictate added caution in prescribing drugs.

Patients with biochemical abnormalities such as erythrocyteG6PDdeficiency can be identified. Most patients with the G6PD defect are of African or Mediterranean descent. Drug-induced hemolytic crisis can be avoided by testing for the enzyme defect before administering drugs that could cause the reaction. Similarly, persons with an abnormal serum pseudocholinesterase level may have abnormally prolonged apnea when given succinylcholine.

GENERAL COMMENTS

No drug is completely without side effects, and a side effect in one patient may be the desired pharmacologic effect in another. Current drug regulations allow physicians to have considerable confidence in the purity, bioavailability, and effectiveness of the drugs they prescribe. However, physicians have to weigh potential toxicity against possible benefits. Toxicity that would be acceptable for an effective antineoplastic agent would not be permitted in an oral contraceptive, for example. Because of the necessarily small number of patients treated in premarketing studies, rare adverse reactions may not be identified, so the first responsibility for identifying and reporting these effects must rest with the practicing clinician through the use of the various national adverse reaction reporting systems, such as those operated by the Food and Drug Administration in the United States and the Committee on Safety of Medicines in Great Britain. The publication of a newly recognized adverse reaction can in a short time stimulate many similar such reports of reactions that previously had gone unrecognized.

The prevention of adverse drug reactions first involves a high index of suspicion that the development of a new symptom or sign may be drug-related. Reduction of the dose or discontinuation of the suspected agent usually clarifies the issue in concentration-dependent toxic reactions. Physicians should be familiar with the common adverse effects of the drugs they use and, when in doubt, should consult the literature.

72. PHYSIOLOGY AND PHARMACOLOGY OF THE AUTONOMIC NERVOUS SYSTEM - *Lewis Landsberg*, *James B. Young*

FUNCTIONAL ORGANIZATION OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system innervates vascular and visceral smooth muscle, exocrine and endocrine glands, and parenchymal cells throughout the various organ systems. Functioning below the conscious level, the autonomic nervous system responds rapidly and continuously to perturbations that threaten the constancy of the internal environment. The many functions governed by this system include the distribution of blood flow and the maintenance of tissue perfusion, the regulation of blood pressure, the regulation of the volume and composition of the extracellular fluid, the expenditure of metabolic energy and supply of substrate, and the control of visceral smooth muscle and glands.

ANATOMIC ORGANIZATION

The autonomic neurons, located in ganglia outside the central nervous system (CNS), give rise to the postganglionic autonomic nerves that innervate organs and tissues throughout the body (Fig. 72-1). The activity of autonomic nerves is regulated by central neurons responsive to diverse afferent inputs. After central integration of afferent information, autonomic outflow is adjusted to permit the functioning of the major organ systems in accordance with the needs of the organism as a whole. Connections between the cerebral cortex and the autonomic centers in the brainstem coordinate autonomic outflow with higher mental functions.

The Sympathetic and Parasympathetic Divisions The preganglionic neurons of the parasympathetic nervous system leave theCNS in the third, seventh, ninth, and tenth cranial nerves and in the second and third sacral nerves, while the preganglionic neurons of the sympathetic nervous system exit the spinal cord between the first thoracic and the second lumbar segments (Fig. 72-1). Responses to sympathetic and parasympathetic stimulation are frequently antagonistic, as exemplified by their opposing effects on heart rate and gut motility. This antagonism reflects highly coordinated interactions within the CNS; the resultant changes in parasympathetic and sympathetic activity, often reciprocal, provide more precise control of autonomic responses than could be achieved by the modulation of a single system. Moreover, both sympathetic and parasympathetic portions of the autonomic nervous system are composed of multiple function-specific subdivisions. Neurons with the various subdivisions differ neurochemically and neurophysiologically and are controlled by distinct regions within the CNS. This specialization within sympathetic and parasympathetic divisions contributes to the precision and specificity of autonomic regulation.

Neurotransmitters *Acetylcholine* (ACh) is the preganglionic neurotransmitter for both divisions of the autonomic nervous system as well as the postganglionic neurotransmitter of the parasympathetic neurons. Nerves that release ACh are said to be cholinergic. *Norepinephrine* (NE) is the neurotransmitter of the postganglionic sympathetic neurons; these nerves are said to be adrenergic. Within the sympathetic outflow, postganglionic neurons innervating the eccrine sweat glands (and perhaps

some blood vessels supplying skeletal muscle) are of the cholinergic type.

THE SYMPATHETIC NERVOUS SYSTEM AND ADRENAL MEDULLA

CATECHOLAMINES

All three of the naturally occurring catecholamines,NE, *epinephrine* (E), and *dopamine*, function as neurotransmitters within theCNS. NE, the neurotransmitter of postganglionic sympathetic nerve endings, exerts its effects locally, in the immediate vicinity of its release. Epinephrine, the circulating hormone of the adrenal medulla, influences processes throughout the body. A peripheral dopaminergic system also exists but has not been characterized in detail.

Biosynthesis (Fig. 72-2) Catecholamines are synthesized from the amino acid tyrosine, which is sequentially hydroxylated to form dihydroxyphenylalanine (dopa), decarboxylated to form dopamine, and hydroxylated on the b position of the side chain to formNE. The initial step, the hydroxylation of tyrosine, is rate-limiting and is regulated so that synthesis of dopa is coupled to NE release. This regulation is achieved by alterations in both the activity and the amount of tyrosine hydroxylase. In the adrenal medulla and in those central neurons utilizing epinephrine as neurotransmitter, NE is *N*-methylated to epinephrine by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT).

Catecholamine Metabolism The major metabolic transformations of catecholamines involve *O*-methylation at the meta-hydroxyl group and oxidative deamination. *O*-Methylation is catalyzed by the enzyme catechol-*O*-methyltransferase (COMT), and oxidative deamination is promoted by monoamine oxidase (MAO). COMT in liver and kidney is important in the metabolism of circulating catecholamines. MAO, a mitochondrial enzyme present in most tissues, including nerve endings, has a lesser role in the metabolism of circulating catecholamines but is important in regulating the catecholamine stores within the peripheral sympathetic nerve endings. The metanephrines and 3-methoxy-4-hydroxymandelic acid (vanilmandelic acid, VMA) are the major end products of E andNEmetabolism. Homovanillic acid (HVA) is the end product of dopamine metabolism.

STORAGE AND RELEASE OF CATECHOLAMINES

In both the adrenal medulla and sympathetic nerve endings catecholamines are stored in subcellular vesicles and released by exocytosis. The large stores of catecholamines in these tissues provide an important physiologic reserve that maintains an adequate supply of catecholamines in the face of intense stimulation. A variety of substances may be stored along with catecholamines in sympathetic nerve endings and adrenal medulla and released with catecholamines during exocytosis. These substances, which may function as cotransmitters or neuromodulators, include peptides such as neuropeptide Y, substance P, and enkephalins; purines such as ATP and adenosine; and other amines such as serotonin. At the neuroeffector junction, coreleased neuromodulators modify the response toNE, while cotransmitters exert physiologic effects independent of those induced by NE.

Adrenal Medulla The adrenal medullary chromaffin tissue in a pair of normal human adrenal glands weighs about 1 g and contains approximately 6 mg catecholamines, 85% of which is epinephrine.

Catecholamine secretion, stimulated byACh from the preganglionic sympathetic nerves, occurs after calcium influx triggers fusion of the chromaffin granule membrane and cell membrane; obliteration of the cell membrane at the point of fusion and extrusion of the entire soluble contents of the granule into the extracellular space complete the process of exocytosis (Fig. 72-2). Although the molecular mechanisms involved in the exocytotic process are only partially understood, evidence has accumulated that specific calcium-binding proteins are involved. Once bound, calcium induces a conformational change in these proteins that induces fusion of granules and docking of granules at the cell membrane.

Peripheral Sympathetic Nerve Endings The peripheral sympathetic nerve endings form a reticulum or ground plexus that brings the terminal fibers into close contact with effector cells. All theNE in peripheral tissues is in the sympathetic nerve endings, and heavily innervated tissues contain as much as 1 to 2 ug/g of tissue. NE stored in the nerve endings is in discrete subcellular particles analogous to the adrenal medullary chromaffin granules.MAO in the mitochondria of the nerve endings plays an important role in regulating the local concentration of NE (Fig. 72-2). Amines in storage vesicles are protected from oxidative deamination; amines within the cytoplasm, however, are deaminated to inactive metabolites. Release from the nerve ending occurs in response to action potentials propagated in terminal sympathetic fibers.

THE PERIPHERAL ADRENERGIC NEUROEFFECTOR JUNCTION

The peripheral sympathetic nerve endings possess an amine transport system that actively takes up amines from the extracellular fluid. Neuronal uptake or recapture of locally releasedNEterminates the action of the transmitter and contributes to the constancy of the NE stores.

A variety of factors alter the relationship between neuronal impulse traffic andNErelease. Diminished temperature and acidosis, for example, both decrease the amount of NE released in response to sympathetic impulses. Several chemical mediators operate at the peripheral sympathetic nerve ending (referred to as *prejunctional* or *presynaptic sites*) to modify sympathetic neurotransmission by influencing the amount of NE released in response to nerve impulses. Prejunctional modulation may be either inhibitory or facilitatory. Certain modulators, such as catecholamines andACh, may either inhibit or facilitate NE release, antagonistic effects that are mediated by different adrenergic or cholinergic receptors, respectively. Those compounds exerting an *inhibitory* effect on NE release at the prejunctional nerve ending include the following: catecholamines ($a_2$receptor), ACh (muscarinic receptor), dopamine (D_2receptor), histamine (H_2receptor), serotonin, adenosine, enkephalins, and prostaglandins.

Catecholamines reduceNErelease via prejunctional a receptors in a classic negative-feedback system. Feedback regulation is complicated by the fact thatb-receptor activation facilitates NE release.

Though both inhibitory and facilitatory effects ofACh onNErelease have been described, the inhibitory effect of ACh, mediated by the muscarinic cholinergic receptor, occurs at lower ACh concentrations and is probably of greater physiologic significance.

CENTRAL REGULATION OF SYMPATHOADRENAL OUTFLOW

Brainstem Sympathetic Centers Sympathetic outflow is initiated from the reticular formation of the medulla oblongata and pons and from centers in the hypothalamus. The rostral ventral portion of the medulla, particularly the area designated the rostral ventrolateral medulla (RVLM), appears to contain especially important sympathoexcitatory areas. Descending fibers originating from all these centers synapse in the intermediolateral cell column of the spinal cord with the preganglionic sympathetic neurons. Changes in the physical and chemical properties of the extracellular fluid, including the circulating levels of hormones and substrates, also affect sympathetic nervous system outflow. The area postrema, in the floor of the fourth ventricle, along with other circumventricular organs lie outside the blood-brain barrier and may play an important role in this regard. Although the hallmark of intense sympathoadrenal stimulation is a global response (the fight-or-flight reaction of Cannon), discrete changes in sympathetic outflow to different organ systems continuously regulate many autonomic functions.

Relationship Between the Sympathetic Nervous System and the Adrenal Medulla Sympathetic nervous system activity and adrenal medullary secretion are coordinated but not always congruent. During periods of intense sympathetic stimulation, such as cold exposure and exhaustive exercise, the adrenal medulla is progressively recruited, and circulating epinephrine reinforces the physiologic effects of sympathetic stimulation. In other situations, the sympathetic nervous system and the adrenal medulla are stimulated independently. The response to upright posture, for example, involves predominantly the sympathetic nervous system, while hypoglycemia stimulates only the adrenal medulla.

Sympathetic Regulation of the Cardiovascular System Stretch receptors in the systemic and pulmonary arteries and veins continuously monitor intravascular pressures; the resulting afferent impulses, after relay and integration in the brainstem, alter sympathetic activity in defense of blood pressure and blood flow to critical areas (Fig. 72-3).

Arterial Baroreceptors An increase in blood pressure stimulates receptors in the carotid sinus and aortic arch. The ensuing afferent impulses, after relay within the nucleus of the solitary tract (NTS) in the brainstem, suppress the brainstem sympathetic centers (Fig. 72-3). This baroreceptor reflex arc forms a negative-feedback loop in which a rise in arterial pressure results in the inhibition of central sympathetic outflow. A brainstem noradrenergic pathway interacts with the NTS to participate in suppression of sympathetic outflow. This noradrenergic inhibitory pathway is stimulated by centrally actinga-adrenergic agonists and may be involved in the action of certain antihypertensive drugs, such as clonidine, that potentiate the baroreceptor-mediated vasodepressor response (Chap. 246). In the opposite manner, when the blood pressure falls, decreased afferent impulses diminish central inhibition, resulting in an increase in

sympathetic outflow and a rise in arterial pressure.

Central Venous Pressure Receptors in the walls of the great veins and within the atria are also involved in the regulation of sympathetic outflow. Stimulation of these receptors by high venous pressure suppresses the brainstem sympathetic centers; when central venous pressure is low, sympathetic outflow increases. The central connections are poorly understood, but the afferent impulses are carried in the vagus (Fig. 72-3).

ASSESSMENT OF SYMPATHOADRENAL ACTIVITY

The clinical assessment of sympathoadrenal activity involves the measurement of catecholamines in plasma and of catecholamines and catecholamine metabolites in urine, and the assessment of sympathetic nerve impulse traffic by microneurography. Microneurography, utilizing microelectrodes implanted in nerves supplying skeletal muscle (such as the peroneal nerve), is primarily a research tool. Quantitation of urinary catecholamines and metabolites is useful in the diagnosis of pheochromocytoma (Chap. 332).

Plasma Catecholamines Catecholamines in human plasma may be measured by radioenzymatic isotope derivative techniques or by high-performance liquid chromatography in conjunction with electrochemical detection. Plasma catecholamine measurements provide an index of sympathetic nervous system and adrenal medullary activity and have been widely used to assess sympathoadrenal activity in clinical investigation in human subjects. The usefulness of plasma catecholamine measurements, however, is compromised by factors that alter the relationship between the plasma concentration of catecholamines and the functional state of the sympathoadrenal system, and also by important regional differences in sympathetic outflow. Techniques utilizing tracer infusions of tritiatedNE, which correct for changes in NE clearance when applied across a particular anatomic region, estimate regional sympathetic outflow with some precision and have helped to define differentiated sympathetic nervous system activity in the investigational setting. The clinical usefulness of plasma catecholamine levels remains limited to the evaluation of patients with autonomic insufficiency and, on occasion, patients with suspected pheochromocytoma (Chap. 332).

Basal plasmaNEconcentrations are in the range of 0.09 to 1.8 nmol/L (150 to 350 pg/mL); basal E levels are about 135 to 270 pmol/L (25 to 50 pg/mL). The half-time of disappearance of NE from the circulation is approximately 2 min. The plasma NE level is markedly affected by a variety of factors, including posture; accordingly, the conditions under which blood is obtained for assay must be controlled. By convention, basal plasma NE levels are those obtained through an indwelling intravenous line after the patient has rested supine in a relaxed environment for 30 min.

Plasma NE response to upright posture The predictable increase in circulating NE concentration during upright posture provides a convenient test of sympathetic nervous system function. Five minutes of quiet standing results in a two- to threefold increase in plasma NE level. A normal response requires an intact afferent system, appropriateCNSrelays, and an intact peripheral sympathetic nervous system; a defect of any of these components reduces the increment in circulating NE.

Plasma E levels are also dependent on the physical and mental state of the subject. Change in plasma E with upright posture is usually small. Hypoglycemia, strenuous exercise, and various types of mental stress, however, can cause large increases in the plasma E level.

PERIPHERAL DOPAMINERGIC SYSTEM

In addition to its role as neurotransmitter in theCNS, dopamine functions as an inhibitory transmitter in the carotid body and the sympathetic ganglia. A distinct peripheral dopaminergic system is also believed to exist. Dopamine elicits a variety of responses not attributable to stimulation of classic adrenergic receptors; it relaxes the lower esophageal sphincter, delays gastric emptying, causes vasodilation in the renal and mesenteric arterial circulation, suppresses aldosterone secretion, directly stimulates renal sodium excretion, and suppressesNErelease at sympathetic nerve terminals by a presynaptic inhibitory mechanism. The mediation of these dopaminergic effects in vivo is poorly understood. Dopamine does not appear to be a circulating hormone.

ADRENERGIC RECEPTORS

Catecholamines influence effector cells by interacting with specific surface *receptors* coupled to G proteins. Two major categories of response to catecholamines reflect the activation of two populations of adrenergic receptors, designateda and b. Botha and b receptors have been further divided into subtypes that serve different functions and are susceptible to differential stimulation and blockade.

a-ADRENERGIC RECEPTORS

a-Adrenergic receptors mediate vasoconstriction, intestinal relaxation, and pupillary dilatation. Epinephrine and NEare approximately equipotent as a-receptor agonists. Distincta$_1$- anda$_2$-receptor subtypes are also recognized. Originally the postsynaptic or postjunctionala-adrenergic receptors on effector cells were designateda$_1$, while the prejunctional a-adrenergic receptors on the sympathetic nerve endings were designateda$_2$. It is now recognized that nonneuronal (postsynaptic) processes are mediated by thea$_2$receptor as well. Thea$_1$receptor mediates the classic a effects, including vasoconstriction; phenylephrine and methoxamine are selectivea$_1$agonists, and prazosin is a selectivea$_1$antagonist. Thea$_2$receptor mediates presynaptic inhibition of NE release from adrenergic nerves and other responses, including inhibition ofAChrelease from cholinergic nerves, inhibition of lipolysis in adipocytes, inhibition of insulin secretion, stimulation of platelet aggregation, and vasoconstriction in some vascular beds. Specifica$_2$agonists include clonidine and a-methylnorepinephrine; these agents, the latter derived from a-methyldopa in vivo, exert an antihypertensive effect by interacting witha$_2$receptors within the brainstem sympathetic centers that regulate blood pressure. Yohimbine is a specifica$_2$antagonist.

b-ADRENERGIC RECEPTORS

Physiologic events associated with b-adrenergic receptor responses include stimulation of heart rate and contractility, vasodilation, bronchodilation, and lipolysis. b-Receptor

responses can also be divided into two types. Theb1receptor responds equally to E andNE and mediates cardiac stimulation and lipolysis. Theb2receptor is more responsive to E than to NE and mediates responses such as vasodilation and bronchodilation. Isoproterenol stimulates and propranolol blocks bothb1 andb2receptors. Other agonists and antagonists that have partial selectivity for theb1 orb2receptors have been used therapeutically where the desired response involves predominantly one of the two subtypes.

Both pharmacologic and molecular genetic studies have demonstrated an additional distinctb3-adrenergic receptor that subserves lipolysis in white and brown adipose tissue as well as the stimulation of heat production in brown adipose tissue. The humanb3-adrenergic receptor has been cloned, and a distinct polymorphism noted that may, in some populations, be associated with weight gain, insulin resistance, and type 2 diabetes mellitus. Theb3-adrenergic receptor has a much greater affinity forNE than E and, unlike theb1 andb2receptors, does not undergo desensitization. Synthetic agonists for theb3receptor, currently under development, have a potential role in the treatment of obesity by increasing metabolic rate.

DOPAMINERGIC RECEPTORS

Specific dopaminergic receptors, distinct from the classic a- andb-adrenergic receptors, are present in theCNS and peripheral nervous system and in several nonneural tissues. Two types of dopaminergic receptors serve different functions and have different second messengers. Dopamine is a potent agonist of both types of receptors; the action of dopamine is antagonized by phenothiazines and thioxanthenes. The D1receptor mediates vasodilation in the renal, mesenteric, coronary, and cerebral vascular beds. Fenoldopam is an agonist selective for the D1receptor. The D2receptor inhibits transmission in the sympathetic ganglia, inhibitsNErelease from sympathetic nerve endings by an effect on the presynaptic membrane (Fig. 72-2), inhibits prolactin release from the pituitary, and causes vomiting. Selective agonists of the D2receptor include bromocriptine, cabergoline, and apomorphine, while butyrophenones such as haloperidol (active within the CNS), domperidone (does not cross blood-brain barrier readily), and the benzamide sulpiride are relatively selective D2antagonists.

STRUCTURE AND FUNCTION OF ADRENERGIC RECEPTORS

Adrenergic receptors belong to a superfamily of related membrane proteins, including the visual protein rhodopsin and the muscarinic acetylcholine receptors, that interacts with G proteins. These proteins share significant sequence homologies and, as deduced from the properties of the constituent amino acids, a similar topographic structure in the cell membrane. The postulated structure of this family of receptor proteins is shown schematically inFig. 72-4. The characteristic features include seven membrane-spanning hydrophobic domains containing 20 to 28 amino acids each. The membrane-spanning domains, particularly M-7 (Fig. 72-4), appear to be important in determining the characteristic agonist binding.

Coupling of Receptor Occupancy with Cellular Response The major mediators of adrenergic (as well as many other) cellular responses are a family of regulatory proteins termed *G proteins* that, when activated, bind the nucleotide guanosine triphosphate

(GTP). The best-characterized G proteins are those that stimulate or inhibit adenylyl cyclase, designated G_s or G_i, respectively (Fig. 72-5). The b_1,b_2, and D_1receptors are coupled to G_s; receptor occupancy is therefore associated with stimulation of adenylyl cyclase and results in an increase in intracellular cyclic adenosine monophosphate (AMP), which in turn results in activation of protein kinase A and other cyclic AMP-dependent protein kinases. The resultant protein phosphorylation alters the activity of enzymes and the function of other proteins, culminating in a cellular response that is characteristic of the tissue being stimulated. The a_2, M_2subtype of the muscarinic acetylcholine receptor and the D_2receptor are coupled to G_i, resulting in diminished adenylyl cyclase activity and a fall in cyclic AMP. The subsequent alterations in enzyme activity and function of other proteins produce an alternate, frequently opposite, series of cellular responses. Although many$a_2$responses can be explained by inhibition of adenylyl cyclase, other mechanisms may be involved as well.

The a_1-adrenergic receptor (as well as the M_1subtype of the acetylcholine receptor) is coupled to a different G protein that activates phospholipase C; this G protein has not been as well characterized but is sometimes designated G_q. Receptor occupancy in this system stimulates phospholipase C, which catalyzes the breakdown of membrane-bound phospholipids, particularly phosphatidylinositol-4,5-bisphosphate (PIP_2) with the production of inositol-1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG), both of which act as second messengers (Fig. 72-5).IP_3rapidly mobilizes calcium from intracellular stores within the endoplasmic reticulum, producing an increase in free cytoplasmic calcium which by itself and via calcium-calmodulin-dependent protein kinases influences cellular processes appropriate to the stimulated cell. The transient rise in calcium induced by IP_3 from the intracellular stores is reinforced in the presence of continued agonist stimulation by alterations in membrane calcium flux that result eventually in net calcium uptake from the extracellular fluid by mechanisms that have been incompletely defined.

DAG, the other second messenger produced by the action of phospholipase C onPIP_2(as well as other membrane phospholipids), remains associated with the cell membrane and activates protein kinase C, which has different substrates than the calcium-calmodulin kinases stimulated byIP_3. Protein phosphorylation stimulated by protein kinase C contributes to the tissue-specific response in ways that remain poorly understood. Increases in intracellular calcium also potentiate the activation of protein kinase C (Fig. 72-5).

REGULATION OF ADRENERGIC RECEPTORS

Prolonged exposure to a- or b-adrenergic agonists decreases the number of corresponding adrenergic receptors on effector cells. Although the biochemical mechanisms involved are obscure, internalization of the b-adrenergic receptor within the cell occurs during agonist exposure in some systems, suggesting that internal translocation contributes to the decrease in receptor number under these circumstances.

Alteration in agonist concentration may also affect the affinity of the receptor for the agonist. Adrenergic receptors that utilize adenylyl cyclase for the second messenger (b receptors,$a_2$receptors) exist in high- and low-affinity states; exposure to agonist

diminishes the proportion of receptors in the high-affinity state. Such alterations in adrenergic receptors induced by adrenergic agonists are termed *homologous regulation*. Agonist-induced alterations in adrenergic-receptor density and affinity are believed to contribute to the diminished physiologic response that occurs after prolonged exposure of an effector tissue to adrenergic agonist, a phenomenon known as *tachyphylaxis* or *desensitization*.

Adrenergic receptors are also influenced by factors other than adrenergic agonists, so-called *heterologous regulation*. Enhanceda-adrenergic-receptor affinity, for example, may underlie the potentiation of a-adrenergic responses that occur in response to lowered environmental temperatures. Thyroid hormones potentiate b-receptor responses by alterations inb-receptor number and in the efficiency of coupling receptor occupancy with physiologic response. Estrogen and progesterone alter the sensitivity of the myometrium to catecholamines by effects ona-adrenergic receptors. Glucocorticoids may influence adrenergic function by antagonizing agonist-induced decreases in adrenergic receptors, thereby counteracting tachyphylaxis in response to intense adrenergic stimulation.

Alterations in sensitivity to catecholamines also occur as a consequence of postreceptor changes, although the latter remain poorly characterized.

PHYSIOLOGY OF THE SYMPATHOADRENAL SYSTEM

Catecholamines influence all of the major organ systems. The effects take place in seconds and may occur in anticipation of physiologic requirement. An increase in sympathoadrenal activity prior to strenuous exercise, for example, lessens the impact of exercise on the internal environment.

DIRECT EFFECTS OF CATECHOLAMINES

Cardiovascular System Catecholamines stimulate vasoconstriction in the subcutaneous, mucosal, splanchnic, and renal vascular beds bya-receptor-mediated mechanisms. Although vasoconstriction was originally considered ana$_1$-receptor response, vascular tone appears to be more complexly regulated and, in many areas, involvesa$_2$-mediated responses as well. The venous portion of the circulation, in particular, is endowed witha$_2$receptors. Differential regulation of the two types ofa receptors, under certain circumstances, contributes to an integrated physiologic response. Since vasoconstriction in the coronary and cerebral circulations is minimal, flow to these areas is maintained during sympathetic stimulation. Skeletal muscle vasculature containsb receptors sensitive to low circulating levels of epinephrine so that skeletal muscle blood flow is augmented during adrenal medullary activation.

The effects of catecholamines on the heart are mediated byb$_1$receptors and include increase in heart rate, enhancement of cardiac contractility, and increase in conduction velocity. The increase in myocardial contractility is illustrated by a leftward and upward shift of the ventricular function curve (see Fig. 231-6) that relates cardiac work to ventricular diastolic fiber length; at any initial fiber length, catecholamines increase cardiac work. Catecholamines also enhance cardiac output by stimulating venoconstriction, enhancing venous return, and increasing the force of atrial contraction,

thereby augmenting diastolic volume and hence fiber length. The acceleration of conduction in the junctional tissues results in a more synchronous, and hence more effective, ventricular contraction. Cardiac stimulation increases myocardial oxygen consumption, a major factor in the pathogenesis and treatment of myocardial ischemia.

Metabolism Catecholamines increase metabolic rate. In small mammals, mitochondrial respiration in brown adipose tissue is functionally uncoupled byNE. In a reaction unique to brown adipose tissue, NE stimulates theβ_3-adrenergic receptor that activates a specific mitochondrial uncoupling protein that dissipates the proton gradient between the inner mitochondrial matrix and the cytoplasm, thereby uncoupling substrate utilization and ATP synthesis. In humans, a functional role for brown adipose tissue has not been established with certainty.

Substrate Mobilization In a variety of tissues, catecholamines stimulate the breakdown of stored fuel with the production of substrate for local consumption; glycogenolysis in the heart, for example, provides substrate for immediate metabolism by the myocardium. Catecholamines also accelerate fuel mobilization in liver, adipose tissue, and skeletal muscle, liberating substrates (glucose, free fatty acids, lactate) into the circulation for use throughout the body.

Fluids and Electrolytes By a direct action on the renal tubule,NEstimulates sodium reabsorption, thereby defending extracellular fluid volume. Dopamine, in contrast, promotes sodium excretion. NE and E also promote cellular uptake of potassium.

Viscera Catecholamines affect visceral function by actions on smooth muscle and glandular epithelium. Urinary bladder and intestinal smooth muscle are relaxed while the corresponding sphincters are stimulated. Gallbladder emptying also involves sympathetic mechanisms. Catecholamine-mediated smooth-muscle contraction in the female aids ovulation and ovum transport along the fallopian tubes, and in the male provides propulsive force for the seminal fluid during ejaculation. Inhibitory$\alpha_2$receptors on cholinergic neurons within the gut contribute to intestinal relaxation. Catecholamines induce bronchodilation by aβ_2-receptor mechanism.

INDIRECT EFFECTS OF CATECHOLAMINES

The ultimate physiologic response induced by catecholamines involves changes in hormone secretion and in blood flow distribution, both of which support and amplify the direct effects of catecholamines.

Endocrine System Catecholamines influence the secretion of renin, insulin, glucagon, calcitonin, parathormone, thyroxine, gastrin, erythropoietin, progesterone, and, possibly, testosterone. Secretion of each of these hormones is governed by complex feedback loops. With the exception of thyroxine and the gonadal steroids, each is a polypeptide not under the direct control of the pituitary gland. Sympathoadrenal input into the secretion of these hormones provides a mechanism for regulation by theCNS and ensures a coordinated hormonal response in accord with the homeostatic needs of the organism.

Renin (See alsoChap. 246) Sympathetic stimulation increases renin release by a direct

b-receptor effect independent of vascular changes within the kidney. The renin response to volume depletion is sympathetically mediated and is initiated by a fall in central venous pressure. Since renin secretion activates the angiotensin-aldosterone system, angiotensin-induced vasoconstriction supports the direct effects of catecholamines on blood vessels, while aldosterone-mediated sodium reabsorption complements the direct increase in sodium reabsorption induced by sympathetic stimulation. b-receptor blocking agents suppress renin secretion.

Insulin and Glucagon Stimulation of pancreatic sympathetic nerves or an elevation in circulating catecholamines suppresses insulin and increases glucagon release. Inhibition of insulin secretion is mediated by the$a_2$receptor, and stimulation of glucagon is mediated by theb receptor. This combination of effects supports substrate mobilization, reinforcing the direct effects of catecholamines on hepatic glucose output and lipolysis. Althougha-receptor-mediated suppression of insulin release usually predominates, a b-receptor mechanism may augment insulin secretion under some circumstances.

SYMPATHOADRENAL FUNCTION IN SELECTED PHYSIOLOGIC AND PATHOPHYSIOLOGIC STATES

Support of the Circulation The sympathetic nervous system functions to maintain an adequate circulation. During upright posture and volume depletion, reduction of afferent venous and arterial baroreceptor impulse traffic diminishes an inhibitory input to the vasomotor center, thereby increasing sympathetic activity (Fig. 72-3) and reducing efferent vagal tone. As a result, heart rate is increased, and cardiac output is diverted from the skin, subcutaneous tissues, mucosa, and viscera. Sympathetic stimulation of the kidney increases sodium reabsorption, and sympathetically mediated venoconstriction enhances venous return (Fig. 72-6). With pronounced hypotension, the adrenal medulla is recruited and epinephrine reinforces the effects of the sympathetic nervous system.

The intense sympathoadrenal stimulation that accompanies severe volume depletion may contribute to the development of ketoacidosis in alcoholics as well as to the ketoacidosis sometimes seen in association with hyperemesis gravidarum. Catecholamine-mediated suppression of insulin and stimulation of glucagon markedly potentiate ketogenesis in these disease states. Volume resuscitation and provision of adequate glucose promptly reverse the ketoacidosis in most cases.

Congestive Heart Failure The sympathetic nervous system also provides circulatory support during congestive heart failure (Chap. 232). Venoconstriction and sympathetic stimulation of the heart increase cardiac output while peripheral vasoconstriction directs blood flow to the heart and brain. The afferent signals are less clear than in simple volume depletion because the venous pressure is usually elevated. In severe heart failure, depletion of cardiacNE may impair the effectiveness of sympathetic circulatory support. On the other hand, the possibility has been raised that intense sympathetic stimulation may further impair cardiac function, suggesting possible benefit fromb-adrenergic blockade. The use of beta blockers in the treatment of congestive heart failure, in fact, has increased in recent years.

Trauma and Shock In acute traumatic injury or shock, adrenal catecholamines support the circulation and mobilize substrates. In the chronic, reparative phase following injury, catecholamines also contribute to substrate mobilization and to the elevation in metabolic rate.

Exercise Sympathetic activation during exercise increases cardiac output and ensures sufficient substrate to meet the increased metabolic needs. Central neural factors, such as anticipation, and circulatory factors, such as fall in venous pressure, trigger the sympathetic response. Mild degrees of exercise stimulate the sympathetic nervous system alone; during more severe exertion the adrenal medulla is activated as well. Cardiovascular conditioning is associated with a decrease in sympathetic nervous system activity both at rest and during exercise, in comparison with the untrained state.

Hypoglycemia (See alsoChap. 334) Hypoglycemia causes a marked increase in adrenal medullary epinephrine secretion. When glucose concentrations fall below overnight fasting levels, regulatory glucose-sensitive neurons in theCNSinitiate a prompt increase in adrenal medullary secretion. The increase is especially intense at plasma glucose levels below 2.8 mmol/L (50 mg/dL), when plasma E levels increase 25 to 50 times above baseline, thereby increasing hepatic glucose output, providing alternative substrate in the form of free fatty acids, suppressing endogenous insulin release, and inhibiting insulin-mediated glucose utilization in muscle. Many clinical manifestations of hypoglycemia, such as tachycardia, palpitations, nervousness, tremor, and widened pulse pressure, are secondary to increased E secretion, and these manifestations constitute an "early warning" system in insulin-requiring diabetics. In patients with long-standing diabetes mellitus, however, the E response to hypoglycemia may be diminished or absent, leaving affected patients at greater risk to develop severe hypoglycemia.

Cold Exposure The sympathetic nervous system plays a critical role in the maintenance of normal body temperature during exposure to a cold environment. Receptors in the skin and CNSrespond to a fall in temperature by activating hypothalamic and brainstem centers that increase sympathetic activity. Sympathetic stimulation leads to vasoconstriction in the superficial vascular beds, thereby diminishing heat loss. The sympathetic response involves a complex interaction between lowered environmental temperatures anda_2-adrenergic receptors. Acclimatization during chronic cold exposure increases the capacity for metabolic heat production in response to sympathetic stimulation.

Dietary Intake Fasting suppresses and overfeeding stimulates the sympathetic nervous system. The reduction in sympathetic activity during fasting or starvation contributes to the decrease in metabolic rate, bradycardia, and hypotension in these states. Enhanced sympathetic activity during periods of increased caloric intake contributes to the elevation in metabolic rate associated with a chronic increase in dietary intake.

Hypoxia Chronic hypoxia is associated with stimulation of the sympathoadrenal system, and some of the cardiovascular changes attendant to hypoxia are dependent on catecholamines.

Orthostatic Hypotension The maintenance of arterial pressure during upright posture

depends on an adequate blood volume, an unimpaired venous return, and an intact sympathetic nervous system. Significant postural hypotension, therefore, often reflects extracellular fluid volume depletion or dysfunction of the circulatory reflexes. Diseases of the nervous system, such as tabes dorsalis, syringomyelia, or diabetes mellitus, may disrupt these sympathetic reflexes with resultant orthostatic hypotension. Although any antiadrenergic agent may impair the postural sympathetic response, orthostatic hypotension is most prominent with drugs that block neurotransmission within the ganglia or adrenergic neurons.

The term *idiopathic orthostatic hypotension* refers to a group of degenerative diseases involving either the pre- or postganglionic sympathetic neurons (Chaps. 21 and365).

Treatment of orthostatic hypotension is usually unsatisfactory except in the mildest cases. There is no way of reestablishing the normal relationship between fall in venous return and sympathetic neuronal activation. Volume expansion with fludrocortisone and a liberal salt diet in conjunction with fitted stockings to the waist, as well as elevation of the head of the bed to avoid recumbency, will maintain plasma volume and venous return and frequently provide symptomatic improvement.

PHARMACOLOGY OF THE SYMPATHOADRENAL SYSTEM

A variety of therapeutic agents affect sympathetic nervous system function or interact with adrenergic receptors, making it possible to stimulate or suppress effects mediated by catecholamines with some degree of specificity (Table 72-1).

SYMPATHOMIMETIC AMINES

Sympathomimetic amines may directly activate adrenergic receptors (direct acting) or releaseNE from the sympathetic nerve endings (indirect acting). Many agents have both direct and indirect effects.

Epinephrine and Norepinephrine The naturally occurring catecholamines act predominantly by the direct stimulation of adrenergic receptors.NE is employed to support the circulation and elevate the blood pressure in hypotensive states (Chap. 38). Peripheral vasoconstriction is the major effect, although cardiac stimulation occurs as well. Epinephrine, also employed as a pressor, has special usefulness in the treatment of allergic reactions, especially those associated with anaphylaxis. Epinephrine antagonizes the effects of histamine and other mediators on vascular and visceral smooth muscle and is useful in the treatment of bronchospasm.

Dopamine *Dopamine* is used in treating hypotension, shock (Chap. 38), and certain forms of heart failure (Chap. 232). At low infusion rates it exerts a positive inotropic effect both by a direct action on the cardiac$b_1$receptors and by the indirect release ofNE from sympathetic nerve endings in the heart. At low doses direct stimulation of dopaminergic receptors in the renal and mesenteric vasculature also results in vasodilation in the gut and kidney and facilitates sodium excretion. Athigher infusion rates interaction with a-adrenergic receptors results in vasoconstriction, an increase in peripheral resistance, and an elevation of blood pressure.

b-Receptor Agonists *Isoproterenol*, a direct-acting b-receptor agonist, stimulates the heart, decreases peripheral resistance, and relaxes bronchial smooth muscle. It raises the cardiac output and accelerates atrioventricular conduction while increasing the automaticity of ventricular pacemakers. Isoproterenol was formerly used in the treatment of heart block and bronchoconstriction. *Dobutamine*, a congener of dopamine with relative selectivity for the$\beta_1$receptor and with a greater effect on myocardial contractility than on heart rate, is also used in the treatment of congestive heart failure, often in combination with vasodilators (Chap. 232). In conjunction with radionuclide imaging or echocardiographic assessment of wall motion, dobutamine, as well as other investigational congeners that have a relatively greater effect on heart rate, is used in the diagnosis of demand-induced myocardial ischemia.

Selectiveβ_2-Receptor Agonists The cardiac stimulation caused by nonselectiveβ agonists, such as isoproterenol or epinephrine, is occasionally dangerous when these agents are used in the treatment of bronchoconstriction (Chap. 252). Selective$\beta_2$agonists, administered by inhalation for bronchoconstriction, include agents with an intermediate duration of action (*metaproterenol*, *albuterol*, *terbutaline*, *pirbuterol*, *isoetharine*, and *bitolterol*) and the newer long-acting agents (*salmeterol* and *formoterol*); these drugs improve the therapeutic ratio by achieving bronchial dilatation with less activation of the cardiovascular system (Chaps. 252 and258). Although selectivity is relative and cardiac stimulation may occur with these agents at higher dose levels, inhaled agonists at the usual doses result in relatively little cardiac stimulation. Oral administration, which is no longer preferred, is associated with more systemic b-agonist effects. *Ritodrine*, another selective$\beta_2$agonist, is used as a tocolytic agent (as is *terbutaline*) to relax the uterus and antagonize premature labor.

a-Adrenergic Agonists *Phenylephrine* and *methoxamine* are direct-actinga agonists that elevate blood pressure by increasing peripheral vasoconstriction. They are used primarily in the treatment of hypotension and paroxysmal supraventricular tachycardia (Chap. 230), in the latter case by increasing cardiac vagal tone through reflex baroreceptor stimulation. Phenylephrine and a related proprietary compound, *phenylpropanolamine*, are common constituents of decongestant medications (often combined with antihistamines) for the treatment of allergic rhinitis and upper respiratory infections.

Miscellaneous Sympathomimetic Amines with Mixed Actions *Ephedrine* has both directβ-receptor agonist properties and an indirect effect on sympathetic nerve endings, from which it releasesNE, and is used primarily as a bronchodilator. *Sudephedrine*, a congener of ephedrine, is less potent at dilating bronchi and serves as a nasal decongestant. *Metaraminol* has both direct and indirect effects on sympathetic nerve endings and is employed in the treatment of hypotensive states.

Dopaminergic Agonists The D_2-receptor agonists, *bromocriptine* and *cabergoline*, are used to suppress prolactin secretion (Chap. 328). *Apomorphine*, another D_2-receptor agonist, is used to induce emesis. The D_1receptor agonist, *fenoldapam*, has recently been approved for the short-term in-hospital treatment of severe hypertension.

ANTIADRENERGIC OR SYMPATHOLYTIC AGENTS (See alsoChap. 246)

Agents Inhibiting Central Sympathetic Outflow The antihypertensive agents *methyldopa*, *clonidine*, *guanabenz*, and *guanfacine* diminish central sympathetic outflow by stimulating a centrala-adrenergic pathway ($a_2$receptor) that diminishes vasomotor outflow.CNS side effects such as sedation are common. When administration of clonidine is stopped abruptly, a withdrawal syndrome characterized by rebound hyperactivity of the sympathetic nervous system can produce a state resembling the crises of patients with pheochromocytoma. *Opiates* also may exert a central sympatholytic effect; the sympathetic excitation of morphine withdrawal responds to clonidine and vice versa. *Propranolol* and *reserpine* may exert some sympatholytic effects at the level of the CNS.

Ganglionic Blocking Agents Ganglionic transmission may be antagonized by drugs that block the (nicotinic) cholinergic synapse between the pre- and postganglionic autonomic nerves. These agents inhibit the parasympathetic as well as the sympathetic nervous system. Only *trimethaphan* is in general clinical use; its major application is in the treatment of hypertensive crises, particularly aortic dissection, when controlled hypotension and decreased myocardial contractility are desirable (Chap. 246).

Agents Acting at the Peripheral Sympathetic Nerve Endings Adrenergic neuron-blocking agents depress the function of the peripheral sympathetic nerves by decreasing the amount of neurotransmitter released. *Guanethidine*, the prototype of this class of drugs, is concentrated in the sympathetic nerve endings by the amine-uptake mechanism. Within the terminal it blocks the release of NE in response to nerve impulses and eventually depletes the nerve of NE by displacing it from the intraneuronal storage granules. The drug was formerly useful in the management of severe hypertension, although orthostatic hypotension was a limiting side effect. *Bretylium*, an agent whose effects are similar to those of guanethidine, is employed in the treatment of ventricular fibrillation (Chap. 230). Both guanethidine and bretylium are antagonized by agents that affect the amine-uptake transport process such as sympathomimetic amines, tricyclic antidepressants, phenoxybenzamine, and phenothiazines. The antihypertensive action of guanethidine may be rapidly reversed by these drugs.

Reserpine depletes catecholamines from the peripheral sympathetic nerve endings, the brain, and the adrenal medulla. Its antihypertensive effect in humans is usually attributed to depletion of peripheralNEstores within sympathetic nerve endings. The sedation and occasionally morbid depression attending its use result from NE depletion within the CNS.

Adrenergic-Receptor Blocking Agents Adrenergic blocking agents antagonize the effects of catecholamines at the level of the peripheral tissue.

a-Adrenergic-receptor blocking agents *Phenoxybenzamine* and *phentolamine* are utilized principally in treating pheochromocytoma(Chap. 332). Phenoxybenzamine produces prolonged, noncompetitive alpha blockade, while phentolamine leads to reversible, competitive blockade. Because of its rapid action and short duration, phentolamine is commonly used in the treatment of acute hypertensive paroxysms secondary to catecholamine excess, such as occur with pheochromocytoma. Both phentolamine and phenoxybenzamine antagonizea_1 and$a_2$receptors, although phenoxybenzamine is more potent at thea_1-receptor site. *Prazosin*, an a-adrenergic

blocking agent with selectivity for the α_1 receptor, possesses properties that resemble those of primary vasodilators and has been used in the treatment of essential hypertension, as an afterload-reducing agent in congestive heart failure, and as an adjunct in the treatment of pheochromocytoma (Chap. 332). *Doxazosin* and *terazosin*, long-acting selective α_1 blockers, are more useful in the treatment of essential hypertension because of better dosing schedule and less orthostatic hypotension. These agents also lower triglyceride levels and raise high-density lipoprotein (HDL) cholesterol levels. These selective α_1 blockers, along with *tamsulosin* are useful in the symptomatic treatment of urinary outflow track obstruction and prostatism because they antagonize contraction of the sphincter at the bladder trigone and the prostate smooth muscle.

b-Adrenergic-receptor blocking agents These drugs antagonize the effects of catecholamines on the heart and are useful in the treatment of angina pectoris, hypertension, and cardiac arrhythmias. The benefit of beta blockade in angina derives from the decrease in myocardial oxygen consumption following reduction in heart rate and myocardial contractility (Chap. 244). The hypotensive effect of beta blockade is not clearly understood (Chap. 246). Diminished cardiac output, decreased NE release at postganglionic sympathetic nerve endings, reduced renin secretion, and suppressed central sympathetic outflow are possible mechanisms. The efficacy of b-blocking agents in the treatment of arrhythmias depends on reduction of the rate of spontaneous depolarization of pacemaker cells in the sinus node and junctional pacemakers and on slowing conduction within the atria and atrioventricular node. Beta blockade is also effective in the symptomatic management of hyperthyroidism and the control of tachycardia and arrhythmias in patients with pheochromocytoma.b-adrenergic blocking agents are also useful in the treatment of migraine, essential tremor, idiopathic hypertrophic subaortic stenosis, and aortic dissection. Several trials have demonstrated thatb-receptor blocking agents, administered long-term, diminish mortality following acute myocardial infarction. The mechanism of this cardioprotective effect may involve antiarrhythmic action, prevention of reinfarction, and reduction in infarct size (Chap. 243).

Pharmacologic Properties of b-Receptor Blocking Agents Fourteen beta-blocking agents (atenolol, acebutolol, betaxolol, bisoprolol, carvedilol, carteolol, esmolol, metoprolol, nadolol, pindolol, penbutolol, propranolol, sotalol, and timolol) are available for use in the United States. Other agents (alprenolol, bevantolol, dilevalol, oxprenolol, etc.) are in use in other countries and investigational within the United States. The utility of these agents is derived predominantly from blockade ofb-adrenergic receptors.

Although much has been written about other pharmacologic properties, including cardioselectivity, membrane-stabilizing (local anesthetic) effects, intrinsic sympathomimetic (partial-agonist) activity, and lipid solubility, the clinical significance of these additional properties is small. Local anesthetic properties are most prominent with propranolol; however, membrane stabilization probably does not contribute substantially to the clinical utility. The various beta blockers do differ in their water and lipid solubility. The lipophilic agents (propranolol, metoprolol, oxprenolol, bisoprolol, carvedilol) are readily absorbed from the gastrointestinal tract, metabolized by the liver, have large volumes of distribution, and penetrate the CNS well; the hydrophilic agents (acebutolol, atenolol, betaxolol, carteolol, nadolol, sotalol) are less readily absorbed, not extensively

metabolized, and have relatively long plasma half-lives. As a consequence, the hydrophilic agents may be administered once per day. Hepatic failure may prolong the plasma half-life of the lipophilic agents, whereas renal failure may prolong the action of the hydrophilic group. The degree of lipid solubility, therefore, provides a basis for choice of a particular agent in patients with hepatic or renal insufficiency. Although the hydrophilic agents penetrate the CNS less well, CNS side effects (sedation, depression, hallucinations) are well described with the hydrophilic as well as with the lipophilic agents.

Someb-adrenergic blocking agents possessb-agonist activity. This has been referred to as "intrinsic sympathomimetic activity" (ISA). Agents with partial agonist activity (pindolol, alprenolol, acebutolol, carteolol, dilevalol, oxprenolol) cause little or no depression of resting heart rate (partial agonist effect) while blocking the increase in heart rate that occurs in response to exercise or the administration of a beta agonist such as isoproterenol. The presence of partial agonist activity may be useful when bradycardia limits treatment in patients with slow resting heart rates. Pindolol also produces mild vasodilation, perhaps in part related to peripheral$b_2$stimulation. Agents with partial agonist activity cause less change in blood lipid levels than agents without agonist properties. On theoretical grounds, intrinsic sympathomimetic activity would be undesirable in the treatment of thyrotoxicosis, idiopathic hypertrophic subaortic stenosis, aortic dissection, and tachyarrhythmias.

Cardioselective (b_1) Adrenergic-Receptor Blocking Agents Propranolol, the prototype of the nonselective b-adrenergic blocking agent, induces a competitive blockade of bothb_1 and$b_2$receptors. Other nonselective beta-blocking agents include alprenolol, carteolol, dilevalol, nadolol, oxprenolol, penbutolol, pindolol, sotalol, timolol, and carvedilol. Metoprolol, esmolol, acebutolol, atenolol, and betaxolol possess relative selectivity for the$b_1$receptor. Althoughb_1-(cardio-) selective agents have the theoretical advantage of producing less bronchoconstriction and less peripheral vasoconstriction, a clear-cut clinical advantage of the cardioselective agents has not been decisively demonstrated, since the$b_1$selectivity is only relative. Bronchoconstriction may occur whenb_1-selective agents are administered in full therapeutic doses.

Adverse Effects ofb-Receptor Blocking Agents Aside from the effects on theCNS, most adverse reactions to beta-blocking agents are consequences ofb-adrenergic blockade. These include the precipitation of heart failure in patients in whom cardiac compensation depends on enhanced sympathetic drive; the aggravation of bronchospasm in patients with asthma; predisposition to the development of hypoglycemia in insulin-requiring diabetics (blockade of catecholamine-mediated counterregulation and antagonism of the adrenergic warning signs of hypoglycemia); the development of hyperkalemia in diabetic or uremic patients with impaired potassium tolerance; the enhancement of coronary or peripheral arterial vasospasm; and elevation in triglycerides and depression ofHDLlevels. The lipid (and perhaps the peripheral vascular) effects are less (or absent) in agents with partial (b_2) agonist activity or alpha-blocking properties (carvedilol).

Miscellaneous Adrenergic Blocking Agents Labetalol, approved for use in the United States as an antihypertensive agent, is a competitive antagonist of botha- and b-adrenergic receptors. Although labetalol induces relatively moreb- than a-receptor

blockade, fall in peripheral resistance may be marked following acute administration of the drug. Vasodilation may be mediated in part by a partial agonist effect on theb_2-adrenergic receptor; labetalol does not possess partial agonist activity for theb_1(cardiac) receptor.

Metoclopramide is a dopaminergic antagonist with cholinergic agonist properties. It enhances gastric emptying, increases the tone of the lower esophageal sphincter, increases prolactin and aldosterone secretion, and antagonizes emesis induced by apomorphine. It is useful clinically in enhancing gastric emptying (in the absence of organic obstruction such as in diabetic gastroparesis), in antagonizing gastroesophageal reflux, and as an antiemetic during cancer chemotherapy.

THE PARASYMPATHETIC NERVOUS SYSTEM

ACETYLCHOLINE

ACh serves as the neurotransmitter at all autonomic ganglia, at the postganglionic parasympathetic nerve endings, at the postganglionic sympathetic nerve endings innervating the eccrine sweat glands, and at the skeletal muscle end plate (neuromuscular junction). The enzyme choline acetyltransferase catalyzes the synthesis of ACh from acetyl coenzyme A (CoA) produced within the nerve ending and from choline, actively taken up from the extracellular fluid. Within the cholinergic nerve endings, ACh is stored in discrete synaptic vesicles and released in response to nerve impulses that depolarize the nerve terminals and increase calcium influx.

Cholinergic Receptors Different receptors for ACh exist on the postganglionic neurons within the autonomic ganglia and at the postjunctional autonomic effector sites. Those within the autonomic ganglia and adrenal medulla are stimulated predominantly by nicotine (*nicotinic receptors*) and those on autonomic effector cells by the alkaloid muscarine (*muscarinic receptors*). Ganglionic blocking agents antagonize the nicotinic receptors, while atropine blocks the muscarinic receptors. The muscarinic (M) receptor, furthermore, has been recently subdivided into additional types. The M_1 receptor is localized to the CNS and perhaps parasympathetic ganglia; the M_2 receptor is the nonneuronal muscarinic receptor on smooth muscle, cardiac muscle, and glandular epithelium. Bethanechol is a selective agonist of the M_2 receptor; pirenzepine, an investigational agent, is a selective antagonist of the M_1 receptor that markedly reduces gastric acid secretion. The M_2 receptor inhibits adenylyl cyclase and utilizes the regulatory G_i protein; the M_1 receptor interacts with G_q and stimulates phospholipase C (Fig. 72-5). The M_3 receptor, present on smooth muscle and secretory glands, is antagonized by atropine and utilizes phospholipase C, IP_3, and DAG as second messengers. Other subtypes have been identified by molecular biologic techniques but have not yet been fully characterized.

Acetylcholinesterase Hydrolysis of ACh by acetylcholinesterase inactivates the neurotransmitter at cholinergic synapses. This enzyme (also known as specific or true cholinesterase) is present within neurons and is distinct from butyrocholinesterase (serum cholinesterase or pseudocholinesterase). The latter enzyme is present in plasma and nonneuronal tissues and is not primarily involved in the termination of the effects of ACh at autonomic effector sites. The pharmacologic effects of

anticholinesterase agents are due to inhibition of neuronal (true) acetylcholinesterase.

PHYSIOLOGY OF THE PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system participates in the regulation of the cardiovascular system, the gastrointestinal tract, and the genitourinary system. Tissues such as liver, kidney, pancreas, and thyroid also receive parasympathetic innervation, suggesting a role for the parasympathetic nervous system in metabolic regulation as well, although cholinergic effects on metabolism are not well characterized.

Cardiovascular System Parasympathetic effects on the heart are mediated by the vagus nerve.ACh reduces the rate of spontaneous depolarization of the sinoatrial node and decreases heart rate. ACh also delays impulse conduction within the atrial musculature while shortening the effective refractory period, a combination of factors that may initiate or perpetuate atrial arrhythmias. At the atrioventricular node, ACh reduces conduction velocity, increases the effective refractory period, and thus diminishes the ventricular response during atrial flutter or fibrillation (Chap. 230). The decrease in inotropy induced by ACh is related to a prejunctional inhibitory effect on sympathetic nerve endings as well as to a direct inhibitory effect on the atrial myocardium. The ventricular myocardium is not much affected since innervation by cholinergic fibers is minimal. A direct cholinergic contribution to the regulation of peripheral resistance appears unlikely since parasympathetic innervation of the vasculature is not extensive. The parasympathetic nervous system, however, may influence peripheral resistance indirectly by inhibiting NE release from sympathetic nerves.

Gastrointestinal Tract Parasympathetic innervation of the gut is via the vagus nerve and the pelvic sacral nerves. The parasympathetic nervous system increases the tone of gastrointestinal smooth muscle, enhances peristaltic activity, and relaxes the gastrointestinal sphincters.ACh stimulates exocrine secretion from the glandular epithelium and enhances the secretion of gastrin, secretin, and insulin.

Genitourinary and Respiratory Systems Sacral parasympathetic nerves supply the urinary bladder and genitalia.ACh increases ureteral peristalsis, contracts the urinary detrusor muscle, and relaxes the trigone and sphincter, thereby playing a critical role in the coordination of urination. The respiratory tract is innervated with parasympathetic fibers derived from the vagus nerve. ACh increases tracheobronchial secretions and stimulates bronchial constriction.

PHARMACOLOGY OF THE PARASYMPATHETIC NERVOUS SYSTEM

Cholinergic Agonists ACh itself has no therapeutic role because of its widespread effects and short duration of action. Congeners of ACh are less susceptible to hydrolysis by cholinesterase and have a narrower range of physiologic effects. Bethanechol, the only systemic cholinergic agonist in general use, stimulates gastrointestinal and genitourinary smooth muscle with minimal effect on the cardiovascular system. It is used in the treatment of urinary retention in the absence of outflow tract obstruction and, less commonly, in gastrointestinal disorders such as postvagotomy gastric atony. Pilocarpine and carbachol are topical cholinergic agonists used in the treatment of

glaucoma.

Acetylcholinesterase Inhibitors Cholinesterase inhibitors enhance the effects of parasympathetic stimulation by diminishing the inactivation ofACh. The therapeutic application of reversible cholinesterase inhibitors depends on the role of ACh as neurotransmitter at the skeletal muscle neuroeffector junction and within theCNS and includes the treatment of myasthenia gravis (Chap. 380), the termination of neuromuscular blockade following general anesthesia, and the reversal of intoxication by agents with a central anticholinergic action. Physostigmine, a tertiary amine, penetrates the CNS well, while related quaternary amines (neostigmine, pyridostigmine, ambenonium, and edrophonium) do not. Organophosphorous cholinesterase inhibitors produce irreversible cholinesterase blockade; these agents are used principally as insecticides and are primarily of toxicologic interest. With regard to the autonomic nervous system, cholinesterase inhibitors are of limited use in the treatment of intestinal and bladder smooth-muscle dysfunction such as occurs in paralytic ileus and atonic urinary bladder. Cholinesterase inhibitors induce a vagotonic response in the heart and may be useful in terminating attacks of paroxysmal supraventricular tachycardia (Chap. 230).

Cholinergic-Receptor Blocking Agents *Atropine* blocks muscarinic cholinergic receptors, with little effect on cholinergic transmission at the autonomic ganglia and the neuromuscular junctions. Many of theCNSactions of atropine and atropine-like drugs are attributable to blockade of central muscarinic synapses. The related alkaloid, *scopolamine*, is similar to atropine but causes drowsiness, euphoria, and amnesia, effects that make it suitable as a preanesthetic medication.

Atropine increases heart rate and enhances atrioventricular conduction, actions that may be useful in combating the bradycardia or heart block associated with heightened vagal tone. In addition, atropine reverses cholinergically mediated bronchoconstriction and diminishes respiratory tract secretions. These effects contribute to its utility as a preanesthetic medication.

Atropine also decreases gastrointestinal tract motility and secretion. Although various derivatives and congeners of atropine (such as *propantheline*, *isopropamide*, and *glycopyrrolate*) have been advocated in patients with peptic ulcer or with diarrheal syndromes, the chronic use of such agents is limited by other manifestations of parasympathetic inhibition such as dry mouth and urinary retention. The investigational selective M_1inhibitor pirenzepine inhibits gastric secretion at doses that have minimal anticholinergic effects at other sites; this agent may be useful in the treatment of peptic ulcer. Atropine and its congener *ipratropium*, when given by inhalation, cause bronchodilation and have been used experimentally in the treatment of asthma.

PART FIVE -NUTRITION

73. NUTRITIONAL REQUIREMENTS AND DIETARY ASSESSMENT - *Johanna Dwyer*

Nutrients are substances that are not synthesized in the body in sufficient amounts and therefore must be supplied by the diet. Nutrient requirements for groups of healthy persons have been thoroughly defined on the basis of experimental evidence. For good health we require energy-providing nutrients (protein, fat, and carbohydrate), vitamins, minerals, and water. Specific nutrient requirements include 9 essential amino acids, several fatty acids, 4 fat-soluble vitamins, 10 water-soluble vitamins, and choline. Several inorganic substances, including four minerals, seven trace minerals, three electrolytes, and the ultratrace elements, must also be supplied in the diet (Chap. 75).

The required amounts of the essential nutrients differ by age and physiologic state. Conditionally essential nutrients are not required in the diet but must be supplied to individuals who do not synthesize them in adequate amounts, such as those with genetic defects, those having pathologic states with nutritional implications, and developmentally immature infants (Chap. 74). Many organic phytochemicals and zoochemicals present in foods have various health effects. For example, dietary fiber has been shown to have beneficial effects on gastrointestinal function.

ESSENTIAL NUTRIENT REQUIREMENTS

Energy For weight to remain stable, energy intake must match energy output (Chap. 77). The major categories of energy output are resting energy expenditure (REE) and physical activity; minor sources include the energy cost of metabolizing food (thermic effect of food or specific dynamic action) and shivering thermogenesis (e.g., cold-induced thermogenesis). The average energy intake is about 2800 kcal/d for American men and about 1800 kcal/d for American women, though these estimates vary with body size and activity level. Formulas for estimating REE are useful for assessing the energy needs of an individual whose weight is stable. Thus, for males, REE= 900 + 10*w*, and for females, REE = 700 +7*w*, where *w* is weight in kg. The calculated REE is then adjusted for physical activity level by multiplying by 1.2 for sedentary, 1.4 for moderately active, or 1.8 for very active individuals. The final figure provides an estimate of total caloric needs in a state of energy balance.

Illness often alters energy needs. Unstressed hospitalized patients at bed rest usually require 1.2 times theirREE, whereas those who are stressed, febrile, and catabolic require 1.5 to 2 times their REE (Chap. 74). Intestinal malabsorption may decrease net utilizable energy to as little as 25% of ingested energy and may necessitate feeding by parenteral routes (Chap. 76). Fever increases energy expenditure by 10 to 13% per degree Celsius above normal. Other diseases increase energy needs by varying amounts, such as burns (40 to 100%), trauma (40 to 100%), and hyperthyroidism (10 to 100%). Hypothyroidism and adrenal insufficiency decrease resting energy needs, but these alterations are corrected after adequate hormone replacement. In obese patients, weight reduction can be accomplished by reducing energy intakes by approximately 500 kcal/d to achieve a loss of 0.5 kg of fat per week, or 1000 kcal/d to lose 1 kg per week (Chap. 77).

Protein Dietary protein consists of both essential and nonessential amino acids that are required for protein synthesis, whereas certain amino acids can also be used for energy and gluconeogenesis (Chap. 334). The nine essential amino acids are histidine, isoleucine, leucine, lysine, methionine/cystine, phenylalanine/tyrosine, threonine, tryptophan, and valine. When energy intake is inadequate, protein intake must be increased, since ingested amino acids are diverted into pathways of glucose synthesis and oxidation. In extreme energy deprivation, protein-calorie malnutrition may ensue (Chaps. 74 and76).

For adults, the recommended dietary allowance (RDA) for protein is about 0.6 g/kg desirable body weight per day, assuming that energy needs are met and that the protein is of relatively high biologic value. Current recommendations for a healthy diet call for at least 10 to 14% of calories from protein. Biologic value tends to be highest for animal proteins, followed by proteins from legumes (beans), cereals (rice, wheat, corn), and roots. Combinations of plant proteins that complement one another in biologic value or combinations of animal and plant proteins can increase biologic value and lower total protein requirements.

Protein needs increase during growth, pregnancy, lactation, and rehabilitation during treatment of malnutrition. The tolerance of dietary protein is decreased in renal insufficiency and liver failure. Normal protein intake can precipitate encephalopathy in patients with cirrhosis of the liver (Chap. 299) or worsen uremia in those with renal failure (Chap. 270).

Fat and Carbohydrate Fats are a concentrated source of energy and constitute on average 34% of calories in U.S. diets. However, for optimal health, fat intake should total no more than 30% of calories. Saturated fat and trans-fat should be limited to <10% of calories, and polyunsaturated fats to <10% of calories, with monounsaturated fats comprising the remainder of fat intake. At least 55% of total calories should be derived from carbohydrates. The brain requires about 100 g/d of glucose for fuel; other tissues use about 50 g/d. Over time, adaptations in carbohydrate needs are possible in hypocaloric states. For example, reduced insulin levels lead to adipose tissue breakdown and cause the body to burn more fatty acids. However, some tissues (e.g., brain and red blood cells) rely on glucose supplied either exogenously or from muscle proteolysis (Chap. 334).

Water For adults, 1 to 1.5 mL water per kcal of energy expenditure is sufficient under usual conditions to allow for normal variations in physical activity levels, sweating, and solute load of the diet. Water losses include 50 to 100 mL/d in the feces, 500 to 1000 mL/d by evaporation or exhalation, and, depending on the renal solute load, ³1000 mL/d in the urine. If external losses increase, intakes must increase accordingly to avoid underhydration. Fever increases water losses by approximately 200 mL/d per°C; diarrheal losses vary but may be as great as 5 L/d in severe diarrhea. Heavy sweating and vomiting also increase water losses. When renal function is normal and solute intakes are adequate, the kidneys can adjust to increased water intake by excreting up to 18 L/d of excess water (Chap. 329). However, obligatory urine outputs can compromise hydration status when there is inadequate intake or when losses increase in disease or kidney damage.

Infants have high requirements for water because of their large ratio of surface area to volume, the limited capacity of the immature kidney to handle high renal solute loads, and their inability to communicate their thirst. Increased water needs during pregnancy are low, perhaps an additional 30 mL/d; but during lactation, milk production increases water requirements so that approximately 1000 mL/d of additional water is needed, or 1 mL for each mL of milk produced. Special attention must be paid to the water needs of the elderly, who have reduced total body water and blunted thirst sensation and may be taking diuretics.

Other Nutrients The vitamins and minerals required for health and the clinical disorders caused by vitamin deficiency or excess are discussed inChap. 75.

DIETARY REFERENCE INTAKES, RECOMMENDED ALLOWANCES, AND TOLERANCES

Fortunately, human life and well-being can be maintained within a fairly wide range for most nutrients. However, the capacity for adaptation is not infinite -- too much, as well as too little, intake of a nutrient may have adverse effects or alter the health benefits conferred by another nutrient (Chap. 75). Therefore, benchmark recommendations on nutrient intakes have been developed to guide clinical practice. These quantitative estimates of nutrient intakes are collectively referred to as the *dietary reference intakes* (DRIs). The DRIs supplant theRDAs, the single reference values used in the United States since 1989. DRIs include the estimated average requirement (EAR) for nutrients, as well as three other reference values used for dietary planning for individuals: the RDAs, the adequate intake (AI), and the safe upper level (UL). The current RDAs and AIs are provided in Tables 73-1 and73-2, respectively.

Estimated Average Requirement When florid dietary deficiency diseases such as rickets, scurvy, xerophthalmia, and protein-calorie malnutrition were common, nutrient adequacy was assumed by the absence of clinical signs of a dietary deficiency disease. Later, it was determined that biochemical and other changes were evident long before the clinical deficiency became apparent. Consequently, criteria of adequacy are chosen using such biologic markers when they are available. Current efforts focus on the amount of a nutrient that reduces the risk of chronic degenerative diseases. Priority is given to sensitive biochemical, physiologic, or behavioral tests that reflect early changes in regulatory processes or maintenance of body stores of nutrients.

TheEAR is the amount of a nutrient estimated to be adequate for half of the healthy individuals of a specific age and sex. The types of evidence and criteria used to establish nutrient requirements vary by nutrient, age, and physiologic group. The EAR is not an effective estimate of nutrient adequacy in individuals because it is a median requirement for a group, and the variation around this number is considerable. As the EAR specifies, 50% of individuals in a group fall below the requirement and 50% fall above it. Thus, a person with a usual intake at the EAR has a 50% risk of an inadequate intake during the reporting period. For these reasons, other standards, described below, are more useful for clinical purposes.

Recommended Dietary Allowances The RDAis the average daily dietary intake level

that meets the nutrient requirements of nearly all healthy persons of a specific sex, age, life stage, or physiologic condition (such as pregnancy or lactation). The RDA is commonly used as a nutrient-intake goal for planning diets of individuals.

TheRDA is defined statistically as 2 standard deviations (SD) above theEAR to ensure that the needs of any given individual are met. The RDAs are used to formulate food guides such as the U.S. Department of Agriculture (USDA) Food Guide Pyramid for individuals, food exchange lists for therapeutic diet planning, and as a standard for describing the nutritional content of processed foods and nutrient supplements. The nutrient content in a food is stated by weight or as a percent of the daily value (DV), a varient of the RDA which, for an adult, represents the highest RDA for an adult consuming 2000 kcal/d.

The risk of dietary inadequacy increases as intakes fall further below theRDA. However, the RDA is an overly generous criterion for evaluating nutrient adequacy. For example, by definition the RDA exceeds the actual requirements of all but about 2 to 3% of the population. Therefore, many people whose intakes fall below the RDA may still be getting enough of the nutrient.

Adequate Intake It is not possible to set anRDA for some nutrients that do not have an establishedEAR. In this circumstance, theAI is based on observed, or experimentally determined, approximations of nutrient intakes in healthy people. In theDRIsestablished to date, AIs rather than RDAs are proposed for infants up to age 1, as well as for calcium, vitamin D, fluoride, pantothenic acid, biotin, and choline for persons of all ages.

Tolerable Upper Levels of Nutrient Intake Excessive nutrient intake can disturb body functions and cause acute, progressive, or permanent disabilities (Chap. 75). Some diseases of nutritional excess include fluorosis, hypervitaminosis A, hypervitaminosis D, and obesity. The tolerableUL is the highest level of chronic nutrient intake (usually daily) that is unlikely to pose a risk of adverse health effects for most of the population. An uncertainty factor is applied to ensure that even very sensitive persons would not experience adverse effects at the UL dose chosen. For many nutrients, data on the adverse effects of large amounts of the nutrient are unavailable or too limited establish a UL. Therefore, the lack of a UL does *not* mean that the risk of adverse effects from high intakes is nonexistent; caution is warranted in those who consume large amounts of such nutrients. Healthy individuals derive no established benefit from consuming nutrient levels above the RDAor AI. Individual nutrients in foods that most people eat rarely reach levels that exceed the UL. However, nutritional supplements provide more concentrated amounts of nutrients per dose and, as a result, pose a potential risk of toxicity. Nutrient supplements are labeled with "supplement facts" that express the amount of nutrient in absolute units or as the percent of theDVprovided per recommended serving size. Those who use supplements should be advised that total nutrient consumption, including both food and supplements, should not exceed RDA levels.

FACTORS ALTERING NUTRIENT NEEDS

TheDRIs are affected by age, sex, rate of growth, pregnancy, lactation, physical activity, composition of diet, concomitant diseases, and drugs. When only slight differences exist

between the requirements for nutrient sufficiency and excess, dietary planning becomes more difficult. Renal insufficiency provides one example in which protein intakes must be sufficient to maintain protein nutritional status, while avoiding exacerbation of uremic symptoms because of protein excess.

Physiologic Factors Growth, strenuous physical activity, pregnancy, and lactation increase needs for energy and several essential nutrients. Energy needs rise during pregnancy, due to the demands of fetal growth, and during lactation, because of the increased energy required for milk production. Energy needs decrease with loss of lean body mass, the major determinant ofREE. Because both health and physical activity tend to decline with age, energy needs in older persons, especially those over 70, tend to be less than those of younger persons.

Dietary Composition Dietary composition affects the biologic availability and utilization of nutrients. For example, the absorption of iron may be impaired by high amounts of calcium or lead; non-heme iron uptake may be impaired by the lack of ascorbic acid and amino acids in the meal. The absorption of calcium and magnesium is decreased by large amounts of phytates in the diet. Protein utilization by the body may be decreased when essential amino acids are not present in sufficient amounts. Animal foods, such as milk, eggs, and meat, have high biologic values with most of the needed amino acids present in adequate amounts. Plant proteins in corn (maize), soy, and wheat have lower biologic values and must be combined with other plant or animal proteins to achieve optimal utilization by the body.

Route of Administration TheRDAsapply only to oral intakes. When nutrients are administered parenterally, similar values can sometimes be used for amino acids, carbohydrates, fats, sodium, chloride, potassium, and most of the vitamins, since their intestinal absorption is nearly 100% (Chap. 75). However, the oral bioavailability of most mineral elements may be only half that obtained by parenteral administration. For some nutrients that are not readily stored in the body, or cannot be stored in large amounts, timing of administration may also be important. For example, amino acids cannot be used for protein synthesis if they are not supplied together; instead they will be used for energy production.

Disease Specific dietary deficiency diseases include protein-calorie malnutrition; iron, iodine, and vitamin A deficiency; megaloblastic anemia due to vitamin B_{12} or folic acid deficiency; vitamin D deficiency rickets; and scurvy, beriberi, and pellagra (Chaps. 74 and75). Each deficiency disease is characterized by imbalances at the cellular level between the supply of nutrients or energy and the body's nutritional needs for growth, maintenance, and other functions. Imbalances in nutrient intakes are recognized as risk factors for certain chronic degenerative diseases, such as saturated fat and cholesterol in coronary artery disease; sodium in hypertension; obesity in hormone-dependent endometrial, breast, and prostate cancers; and ethanol in alcoholism. Since the etiology and pathogenesis of these disorders are multifactorial, diet is only one of many risk factors. Osteoporosis, for example, is associated with calcium deficiency, as well as risk factors related to environment (e.g., smoking, sedentary lifestyle), physiology (e.g., estrogen deficiency), genetic determinants (e.g., defects in collagen metabolism), and drug use (chronic steroids) (Chap. 342).

DIETARY ASSESSMENT

In clinical situations, nutritional assessment is an iterative process that involves: (1) screening for malnutrition, (2) assessing the diet and other data to establish either the absence or presence of malnutrition and its possible causes, and (3) planning for the most appropriate nutritional therapy. Some disease states affect the bioavailability, requirements, utilization, or excretion of specific nutrients. In these circumstances, specific measurements of various nutrients may be required to assure adequate replacement (Chap. 75).

Most health care facilities have a nutrition screening process in place for identifying possible malnutrition after hospital admission. Nutritional screening is required by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), but there are no universally recognized or validated standards, so techniques vary. The factors that are usually assessed include: abnormal weight for height or body mass index (e.g., BMI <19 or>25); reported weight change (involuntary loss or gain of >5 kg in past 6 months) (Chap. 43); diagnoses with known nutritional implications (metabolic disease, any disease affecting the gastrointestinal tract, alcoholism, and others); present therapeutic dietary prescription; chronic poor appetite; presence of chewing and swallowing problems or major food intolerances; need for assistance with preparing or shopping for food, eating, or other aspects of self care; and social isolation. Reassessment of nutrition status should occur periodically in hospitalized patients -- at least once every week.

A more complete dietary assessment is indicated for patients who exhibit a high risk of malnutrition on nutrition screening. The type of assessment varies based on the clinical setting, severity of the patient's illness, and stability of his or her condition.

Acute Care Settings In acute care settings, anorexia, various diseases, test procedures, and medications can compromise dietary intake. Under such circumstances, the goal is to identify and avoid inadequate intake and assure appropriate alimentation. Dietary assessment in acute care situations focuses on what patients are currently eating, whether they are able and willing to eat, and whether they experience any problems with eating. Dietary intake assessment is based on information from observed intakes; medical record; history; clinical examination; and anthropometric, biochemical, and functional status. The objective is to gather enough information to establish the likelihood of malnutrition due to poor dietary intake or other causes in order to determine whether nutritional therapy is indicated.

Simple observations may suffice to suggest inadequate oral intake. These include dietitians' and nurses' notes, the amount of food eaten on trays, frequent tests and procedures that are likely to cause meals to be skipped, nutritionally inadequate diet orders such as clear liquids or full liquids for more than a few days, fever, gastrointestinal distress, vomiting, diarrhea, or a comatose state. Patients with diseases or treatments that involve any part of the alimentary tract are at high nutritional risk. Acutely ill patients with diet-related diseases such as diabetes need assessment because an inappropriate diet may exacerbate these conditions and adversely affect other therapies. Abnormal biochemical values [serum albumin levels <35 g/L (<3.5 mg/dL); serum cholesterol levels <3.9 mmol/L (<150 mg/dL)] are nonspecific but may

also indicate a need for further nutritional assessment.

Most therapeutic diets offered in hospitals are calculated to meet individual nutrient requirements and theRDA. Exceptions include clear liquids, some full liquid diets, and test diets, which are inadequate for several nutrients and should not be used, if possible, for more than 24 h. As much as half of the food served to hospitalized patients is not eaten, and so it cannot be assumed that the intakes of hospitalized patients are adequate. The dietary assessment should therefore compare how much and what food the patient has consumed with the diet that has been provided in the hospital. Major deviations in intakes of energy, protein, fluids, or other nutrients of special concern for the patient's illness should be noted and corrected.

Nutritional monitoring is especially important for patients who are very ill and who have extended lengths of stay. Patients who are fed by special enteral and parenteral routes also require special nutritional assessment and monitoring by physicians with training in nutrition support and/or dietitians with certification in nutrition support (Chap. 76).

Ambulatory Settings The aim of dietary assessment in the outpatient setting is to determine whether the patient's usual diet is a health risk in itself or if it contributes to existing chronic disease-related problems. It also provides the basis for planning a diet that fulfills therapeutic goals while ensuring patient compliance. The outpatient dietary assessment should review the adequacy of present and usual food intakes, including vitamin and mineral supplements, medications, and alcohol, as all of these may affect the patient's nutritional status. The dietary assessment should focus on the dietary constituents that are most likely to be involved or compromised by a specific diagnosis, as well as any comorbidities that are present. More than one day's intake should be reviewed to provide a better representation of the usual diet.

There are many ways to assess the adequacy of the patient's habitual diet. These include a food guide, a food exchange list, a diet history, or a food frequency questionnaire. A commonly used food guide for healthy persons is theUSDA's food pyramid, which is useful as a basis for identifying inadequate intakes of essential nutrients, as well as likely excesses in fat, saturated fat, sodium, sugar, and alcohol (Table 73-3). The guide is calculated to provide approximately 1600 kcal for sedentary women and some older adults; 2200 kcal for most children, teenage girls, active women, and many sedentary men (women who are pregnant or breastfeeding may need somewhat more); and 2800 kcal for teenage boys, most active men, and some very active women. Results provide a rough guide to food groups that may be eaten either in excess of recommendations or in insufficient quantities. Respondents who follow ethnic or unusual dietary patterns may need extra instruction on how foods should be categorized, as well as the appropriate portion sizes that constitute a serving. The process of reviewing the guide with patients helps them transition to healthier dietary patterns. For those on therapeutic diets, assessment against food exchange lists may be useful. These include, for example, the American Diabetes Association food exchange lists for diabetes, or the American Dietetic Association food exchange lists for renal disease.

Nutritional Status Assessment Full nutritional status assessment is a complex, time-consuming, and expensive process that requires considerable expertise.

Candidates include seriously ill patients and those at very high nutritional risk when the cause of malnutrition is still uncertain after initial clinical evaluation and dietary assessment. Full nutritional status assessment involves multiple dimensions, including documentation of dietary intake, anthropometric measurements, biochemical measurements of blood and urine, clinical examination, health history, and functional.**For further discussion of Nutritional Assessment, see Chap. 74.*

74. MALNUTRITION AND NUTRITIONAL ASSESSMENT - *Charles H. Halsted*

Malnutrition is a frequent and integral component of acute and chronic illness. When recognized by appropriate clinical assessment, malnutrition is found in>50% of all hospitalized adults. It contributes to increased in-hospital morbidity and mortality in both medical and surgical patients, and leads to more frequent hospital admissions among the elderly. Malnutrition results from various combinations of starvation, including inadequate intake or abnormal gastrointestinal assimilation of the diet, the stress response to acute injury or chronic inflammation, and abnormal nutrient metabolism. Nutritional assessment should be considered an integral part of the clinical evaluation and be used as a basis for nutritional support in the overall therapeutic plan.

DEFINITIONS OF MALNUTRITION

In the strict sense, the term *malnutrition* includes extremes of underweight and overweight. The current chapter, however, focuses on the evaluation of the undernourished patient who presents with diminished body protein and energy stores and micronutrient deficiencies.

To the practicing physician, both outpatients and inpatients should be considered at risk for malnutrition if they meet one or more of the following criteria: (1) unintentional loss of>10% of usual body weight in the preceding 3 months, (2) body weight <90% of ideal for height, or (3) body mass index (BMI; the weight in kilograms divided by the height in square meters) <18.5. With regard to varying levels of severity, body weight <90% of ideal for height represents risk of malnutrition, body weight <85% of ideal constitutes *malnutrition,* <70% of ideal represents *severe malnutrition,* and<60% of ideal is usually incompatible with survival.

Malnutrition may be endemic in regions of famine, and two forms of severe malnutrition are recognized under conditions of inadequate food supply or distribution: *marasmus* refers to generalized starvation with loss of body fat and protein, whereas *kwashiorkor* refers to selective protein malnutrition with edema and fatty liver. The latter form occurs following restriction of dietary protein among children in settings of recurrent diarrheal illness. These distinctions, however, seldom apply to malnourished patients in more developed societies. In this setting, features of combined protein-calorie malnutrition (PCM) are more commonly seen in the context of a wide variety of acute and chronic illnesses that lead to depletion of body fat, muscle wasting, multiple signs of micronutrient deficiencies, decubitus ulcers, and life-threatening infections. An overview of the evaluation of malnutrition in the sick adult is depicted inFig. 74-1.

PATHOPHYSIOLOGY AND ETIOLOGIES OF MALNUTRITION

In simple terms, patients lose weight when: (1) the intake or gastrointestinal assimilation of dietary calories is insufficient to meet normal energy expenditure; (2) the expenditure of body energy stores is greater than energy normally consumed and assimilated by the body; or (3) the metabolism of energy supplies, protein, and other nutrients is significantly impaired by the intrinsic disease process.

Body Composition As depicted in Fig. 74-2, the human body stores between 15 and

25% of its energy as fat (greater in women than men), which is available for the metabolism of endogenous fatty acids during starvation. The remaining fat-free mass (FFM) is composed of extracellular and intracellular water, the bony skeleton, glycogen, and skeletal and visceral protein. Aside from body fat, energy reserves are also provided by intracellular glycogen and protein, which, together with intracellular water, constitute the body cell mass (BCM). Thus, in addition to the enzymes that support the normal metabolic machinery of the body, the BCM provides reserve protein for energy production by gluconeogenesis during the stress response.

The Metabolic Response to Starvation and Stress The expenditure of body stores of energy (as fat, glycogen, and protein) is different during *starvation* (due to decreased intake and/or assimilation of the diet) and *stress* (due to excessive expenditure of energy and body protein). Consequently, these events affect body compartments differently. Starvation decreases the size of all body compartments, whereas stress reducesBCM, increases extracellular water, and has variable effects on body fat.

A normal 70-kg man stores fuel at about 15 kg as fat, 6 kg as protein, and 0.4 kg as glycogen. During a 24-h fast, energy needs are met by the consumption of liver glycogen stores and the conversion of up to 75 g of body protein to glucose (by gluconeogenesis). During prolonged starvation, metabolism is supported by stores of body fat (about 150 g/d), which provides fatty acid-derived ketones, and muscle protein (about 20 g/d), which is used for gluconeogenesis. Under these conditions, total energy expenditure is decreased in order to conserve energy. While normal-weight individuals can sustain total fasting for about 2 months, obese individuals can fast for periods>12 months, depending on their fat stores.

The metabolic responses to the stress of acute critical illness (e.g., following accidental or surgical trauma or sepsis) significantly modify this sequence of events. In contrast to the hypometabolism, protein conservation, and reliance on body fat stores for energy needs during starvation, the acute stress response is characterized by hypermetabolism, in which the demands of accelerated energy expenditure are met by skeletal and visceral proteolysis to provide amino acid substrate for gluconeogenesis. Muscle proteolysis and gluconeogenesis are promoted by high levels of circulating catecholamines, glucagon, cortisol, and cytokines, including tumor necrosis factor (TNF) a and interleukins 1 and 6, in the setting of insulin resistance. When untreated, body protein catabolism is accelerated to 240 g/d, which is sufficient to deplete 50% of body protein stores within 3 weeks.

A more common clinical situation is the malnourished patient with chronic illness in whom acute trauma or sepsis superimposes cytokine-mediated proteolysis with increased metabolic demands. If unchecked by appropriate therapy, the process of progressivePCM in such patients is associated with decreased cardiac and renal function, fluid retention, intestinal mucosal atrophy, loss of intracellular minerals (zinc, magnesium, and phosphorus), diminished cell-mediated immune functions, increased risk of infection, and eventual death (Fig. 74-3).

Etiologies of Malnutrition The causes of decreased dietary intake are diverse and include social and economic conditions, psychiatric diseases, neurodegenerative dementias, cytokine-mediated appetite suppression in chronic infections such as AIDS

or in disseminated cancer, and self-limited food intake in abdominal pain syndromes (Table 74-1;Chap. 43). Given the central role of the gastrointestinal tract in the assimilation of nutrients,PCM is a predictable component of many chronic gastrointestinal diseases. These diseases promote starvation through decreased assimilation of the diet by: (1) blocking the transit of dietary constituents to the intestinal absorbing surface, (2) impairing normal processes of pancreatic or biliary digestion, or (3) preventing the intestinal mucosal transport of dietary constituents. Diseases that are characterized by increased catabolism of stored energy and protein include acute surgical or medical critical illness and acute or chronic inflammatory or infectious disorders affecting diverse organ systems. Other chronic diseases promote malnutrition through mixed mechanisms that contribute to abnormal nutrient metabolism. Both AIDS and disseminated malignancy, for example, cause progressive malnutrition through combinations of anorexia and futile cycles of fatty acid and glucose metabolism. Chronic obstructive pulmonary disease increases risk of malnutrition through the increased energy expenditure of labored respiration, chronic indolent bronchial infection, and the anorexic side effects of many bronchodilating drugs. Chronic liver disease is often associated with PCM caused by the cumulative effects of anorexia; decreased biliary circulation; and abnormal lipid, carbohydrate, and protein metabolism. The chronic intestinal inflammation of Crohn's disease or ulcerative colitis accelerates fecal losses of protein, electrolytes, and zinc.

CLINICAL EVALUATION OF THE MALNOURISHED PATIENT

THE PATIENT HISTORY

The clinical nutritional history should include diet and weight change, socioeconomic conditions, and symptoms unique to each clinical setting (Table 74-2). Social and economic conditions that may lead to poverty include inadequate income, homelessness, and activities that restrict real income and promote involuntary diet restriction, such as drug abuse or chronic alcoholism. Anorexia, or loss of appetite, is a feature of psychiatric disorders, such as anorexia nervosa and neurodegenerative dementia in the elderly. Many self-selected, inadequate diets may promote malnutrition. During binge drinking, chronic alcoholics typically substitute more than half their daily food calories with excessive amounts of ethanol, the metabolism of which consumes energy and promotes unbalanced metabolism of fat and carbohydrates. Other inadequate diets include unbalanced and commercially promoted formulas for rapid weight loss and strict vegetarianism, which may lead to selective deficiencies of specific nutrients such as vitamin B_{12} and iron.

Digestive diseases are major causes of malnutrition, both in the inpatient and outpatient settings. The malnourished patient with digestive disease may present with symptoms of: (1) dysphagia or recurrent vomiting due to benign or malignant esophageal or gastrointestinal obstruction; (2) chronic diarrhea due to abnormal pancreatic or biliary digestion, intestinal mucosal malabsorption, or protein-losing enteropathy; or (3) recurrent abdominal pain exacerbated by eating, as occurs in patients with chronic pancreatitis, inflammatory bowel disease, or intestinal ischemia.

On the general medical service,PCM is prevalent in patients with multiple chronic illnesses that are associated with anorexia, recurrent stress, and abnormal nutrient

metabolism. In addition, PCM is comorbid with chronic recurrent pancreatitis, renal failure, chronic liver disease, chronic obstructive pulmonary disease, disseminated cancer, and chronic infections such as AIDS and tuberculosis. Depending on the severity of injury or illness, critically ill surgical and medical patients predictably develop stress-related PCM if increased nutritional needs are not met after 5 to 10 days.

THE PHYSICAL EXAMINATION

A careful physical examination can both characterize and define the extent of malnutrition. Measurements of unclothed weight and height are essential for establishing the severity of malnutrition in all patients but may be confounded by the effects of fluid overload as a result of edema and ascites. The normal values for weight (in kg) and height (in cm) in men and women are provided inTable 74-3. These values can be adjusted by±10% to account for variability in body frame.

Anthropometry Measurements of subcutaneous fat and skeletal muscle are important to determine the severity ofPCM. Using specialized calipers and a tape measure, anthropometry estimates body fat from the thickness of the skin-fold of the posterior mid-upper arm. Anthropometric measurements in healthy and malnourished adults are shown inTable 74-4. Mid-arm muscle circumference is estimated from the equation:

The use of anthropometry is limited by the requirement for specialized calipers, the experience of the observer, and potential confounding effects of edema or dehydration.

Specific Physical Findings of Malnutrition During the conventional physical examination, the observant and experienced clinician can identify multiple and specific findings ofPCM and its associated micronutrient deficiencies (Chap. 75). A variety of nutritional deficiencies can be identified by examination of the patient's general appearance, including skin, hair, nails, mucus membranes, and neurologic system (Table 74-5). Initially, a pinch of the posterior upper arm may reveal loss of subcutaneous fat in the malnourished patient. Hollowing of the temporal muscles, wasting of upper arms and thigh muscles, easily plucked hair, and peripheral edema are all consistent with protein deficiency. Examination of the skin may reveal the papular keratitis ("goose bump rash") of vitamin A deficiency, perifollicular hemorrhages of vitamin C deficiency, ecchymoses of vitamin K deficiency, the "flaky paint" lower extremity rash of zinc deficiency, hyperpigmentation of skin-exposed areas from niacin deficiency, seborrhea of essential fatty acid deficiency, spooning of nails in iron deficiency, and transverse nail pigmentation in protein deficiency. The eye examination yields conjunctival pallor of anemia, pericorneal and corneal opacities of severe vitamin A deficiency ("Bitot spots"), and nystagmus and isolated ocular muscle paresis of thiamine deficiency. The oral examination may reveal angular stomatitis and cheilosis of either riboflavin or niacin deficiency; glossitis with smooth and red tongue of riboflavin, niacin, vitamin B_{12}, or pyridoxine deficiency; and hypertrophied bleeding gums of vitamin C deficiency. Examination of the neurologic system, particularly in the setting of chronic alcohol abuse, may detect memory loss with confabulation, a wide-based gait, and past pointing, which, together with ophthalmoplegia and peripheral neuropathy, constitute the Wernicke-Korsakoff syndrome of thiamine deficiency. Other neurologic causes of

dementia include pellagra due to niacin and/or tryptophan deficiency. Additional causes of peripheral neuropathy include deficiencies of pyridoxine or vitamin E; loss of distal vibratory and position sense is characteristic of the subacute combined degeneration of vitamin B_{12}deficiency.

LABORATORY ASSESSMENT

Selected use of laboratory tests, most of which are widely available, is essential for characterizing and quantifying malnutrition. Laboratory findings that are often attributed to chronic disease may, in actuality, reflect the response toPCM or selected micronutrient deficiencies in the setting of chronic illness.

Serum Visceral Proteins Serum albumin, which has a 2- to 3-week half-life, is a highly sensitive but nonspecific measure ofPCM. A normal serum albumin level in a well-hydrated patient is inconsistent with PCM. On the other hand, a low serum albumin level must be interpreted in its clinical context, since the concentration of albumin is decreased in the setting of increased plasma volume (as seen in acute trauma or sepsis and in chronic liver, renal, or cardiopulmonary failure). The acute stress of surgery, sepsis, or other acute inflammatory illness lowers the serum albumin level because of a combination of increased circulating extracellular volume andTNF-a-mediated inhibition of albumin synthesis. Hepatic albumin synthesis is inhibited in the setting of liver cirrhosis, AIDS, and disseminated cancer, whereas albumin loss from the body is accelerated in inflammatory bowel diseases, including ulcerative colitis, Crohn's disease, and radiation enteritis. Several shorter-lived visceral proteins can also be measured for estimation of the severity of PCM. These include transferrin (1-week half-life), prealbumin or retinol-binding protein complex (2-day half-life), and fibronectin (1-day half-life). However, like the serum albumin level, the circulating level of each of these proteins is affected by the changes in extracellular volume that occur in acute and chronic illnesses.

Vitamin and Mineral Assays Specific micronutrient deficiencies can be measured by a variety of serum and red blood cell assays, often utilizing high-performance liquid chromatography or enzyme or microbiologic assays (Chap. 75). Commonly available assays and their interpretations are listed in Table 74-6.PCM is typically associated with low serum levels of vitamin A, zinc, and magnesium. Abnormal digestion and absorption of dietary fat are associated with deficiencies of fat-soluble vitamins A, D, and E, whereas intestinal mucosal malabsorption (as in celiac disease) is commonly associated with additional deficiencies of iron and folic acid. Chronic alcoholism is frequently associated with thiamine, folate, vitamin A, and zinc deficiencies. Vitamin B_{12}deficiency due to achlorhydria occurs in up to 15% of elderly individuals as well as in those with pernicious anemia or with diseases involving the terminal ileum. As described in Chap. 105, both folate and vitamin B_{12}deficiencies are associated with elevations in plasma homocysteine; vitamin B_{12}deficiency can also elevate the plasma level of methylmalonic acid.

Assessment of Immune Function PCM is associated with atrophy of thymic-dependent lymphoid structures and reduced T cell-mediated immunity. Conversely, B cell-mediated production of immunoglobulins is usually unaffected. Total lymphocyte count (total white cell count ´ fraction as lymphocytes) is often<1000/uL in

PCM and may be accompanied by anergy to common skin test antigens. While sensitive for PCM, these measures of cell-mediated immunity are nonspecific and can be affected by other disorders such as acute or chronic infections, uremia, or immunosuppressive therapy.

SPECIALIZED PROCEDURES FOR NUTRITIONAL ASSESSMENT

Several specialized procedures are used to assess energy and protein stores and energy expenditure in malnourished patients. These procedures may be employed during the initial nutritional assessment or may serve as an index of the efficacy of nutritional support during the treatment of malnourished patients.

Bioelectric Impedance Analysis Bioelectric impedance analysis (BIA) is a simplified and portable method for measurement of body fat,FFM, and total-body water. BIA is based on differences in the electric conductivity of a weak current between electrodes placed on the dorsal surfaces of the hands and feet. The measurement reflects differences in the impedance to electric current, which is greatest through fat and least through water. Lean body mass can be calculated as the difference between fat mass and body weight or as total-body water divided by 0.73.

Overall,BIA is most useful in assessing body fat andFFM in stable patients and in those who suffer from conditions leading to relative starvation. However, BIA can also be used to assess critically ill patients with decreased intracellular water space andBCM and expanded extracellular compartment size. Reduced BCM correlates inversely with increased metabolic rate. BIA may be confounded in AIDS patients receiving protease-inhibitor therapy, if they exhibit lipodystrophy with associated redistribution of interscapular, abdominal, and breast fat (Chap. 309).

Energy Expenditure Body weight and energy balance are sustained in health by the consumption of dietary calories in an amount equal to the daily expenditure of energy. Therefore, caloric needs can be determined from the estimated daily total energy expenditure (TEE), which is composed of basal or resting energy expenditure (REE, about 75% of total), the thermic expenditures of digestion (about 10% of total), and modest physical activity (about 15% of total). The REE is directly proportional to both theFFM andBCM and can be estimated in healthy people using the Harris and Benedict formula on the basis of weight in kg (*W*), height in cm (*H*), and age in years (*A*):

A simplified bedside estimation forTEE in sick patients is 25 kcal/kg of body weight, to which is added 10% for digestion or metabolism of intravenous or enteral nutrition. In the acutely ill patient, one should include an additional 12.5% for each degree of fever over 37°C, as well as an additional multiplier commensurate with the severity of illness (e.g., 25% for general surgery, 50% for sepsis, and 100% for extensive third-degree burns).

WhileREE can be predicted by the Harris-Benedict equations in healthy persons, it is

decreased in starvation because of hypometabolism. In contrast, REE is increased in the hypermetabolic stress that accompanies critical illness. REE and caloric requirements cannot be predicted in certain clinical conditions. These include the relatively starved, chronically ill patient admitted with a critical illness, the obese patient who develops a critical illness on the background of both increased body fat andFFM, or the patient with chronic liver disease accompanied by combinations of anorexia and ongoing hepatic inflammation. In these situations, REE can be measured accurately by the gas-exchange method of indirect calorimetry. In practice, indirect calorimetry is performed at the bedside using a mobile metabolic cart. This procedure is applicable to ventilator-independent and -dependent patients whose fractional intake of oxygen is less than 0.45. Because the goal is to reach an accurate approximation of the 24-h energy requirement, measurements must be taken at intervals during the day and must account for several variables, including food intake and activity. To calculate the energy cost of metabolism by indirect calorimetry, the volumes (*V*) of oxygen consumed and carbon dioxide produced are measured over a given period of time, according to the modified Weir equation where

Indirect calorimetry also provides the respiratory quotient (RQ), which is the ratio of carbon dioxide produced to oxygen consumed during the process of gas collection. The RQ decreases when fat is the predominant substrate for metabolism (as in starvation) and increases when the contribution of carbohydrate increases (as during stress with gluconeogenesis). In healthy individuals, the RQ usually falls between 0.80 and 0.90. A RQ <0.7 is consistent with active ketogenesis from endogenous fatty acid metabolism with limited generation of carbon dioxide. An RQ >1.0 indicates net lipogenesis, or the conversion of substrate carbohydrate to fat, a situation that occurs with overfeeding. Values that fall outside the range of 0.65 to 1.25 suggest an error in measurement technique.

Creatinine Excretion in the 24-h Urine Creatinine, the metabolic product of skeletal muscle creatine, is produced at a constant rate and in an amount directly proportional to skeletal muscle mass. With steady-state day-to-day renal function, each gram of creatinine in the 24-h urine collection represents 18.5 g of fat-free skeletal muscle. Since skeletal muscle is the major component ofFFM andBCM, measurement of creatinine in the 24-h urine collection can be used as a relative measure of these body compartments during the initial assessment and/or during the course of nutritional support. The *creatinine coefficient* represents the amount of creatinine excreted per kilogram of body weight; it is equal to 23 mg/kg of ideal body weight in men and 18 mg/kg of ideal body weight in women. The *creatinine-height index* represents the ratio of the measured 24-h urine creatinine excretion to the value predicted by the creatinine coefficient for the patient's ideal body weight. These values can be calculated from estimation of the patient's ideal body weight (Table 74-3) or from tables that relate creatinine excretion to height in men and women (Table 74-7). In practice, the accuracy of the 24-h urine creatinine depends primarily on completeness of the urine collection. Together with variations due to fever and fluctuations in dietary intake, inaccuracies of urine collections may result in as much as 10% error in the quantitative 24-h urine creatinine measurement. The constancy of creatinine excretion depends on steady-state renal function, and unpredictable creatinine excretion may occur through

feces or skin in patients with serum creatinine levels>530 umol/L (>6 mg/dL). The presence of ascites, however, apparently does not compromise the accuracy of the 24-h urine creatinine as a reflection of FFM or BCM in patients with chronic liver disease.

Urine Nitrogen Excretion and Nitrogen Balance Nitrogen balance provides an index of protein gain or loss: 1 g nitrogen is equivalent to 6.25 g protein. Nitrogen balance can be assessed by measuring the difference between nitrogen consumed through the mouth, enteral tube, or intravenous sources and nitrogen excreted in the urine, feces, and other intestinal sources. Protein requirements to achieve zero or positive balance are less in starvation states, where daily protein losses are minimized because of hypometabolism, than in clinical states of stress, where the catabolism of skeletal muscle is accelerated for gluconeogenesis. Accurate measurement of nitrogen balance requires complete measurement of nitrogen losses from all possible excretory routes. In most cases, total urine nitrogen can be calculated by dividing 24-h urinary urea nitrogen by 0.85 and assuming approximately 2 g/d for nitrogen losses in feces and sweat. On the other hand, when the clinical condition includes extensive diarrhea and/or protein losses from pancreatic or enterocutaneous fistulas, the accuracy of nitrogen balance requires measurement of total nitrogen by the modified Kjeldahl technique in both urine and enteric sources. Total nitrogen measurements are also advisable in patients with liver failure, where urinary ammonia becomes a major and alternative source of nitrogen.

INTEGRATED BEDSIDE NUTRITIONAL ASSESSMENT

Several different approaches have been developed in order to simplify the process of nutritional assessment by using selective measurements that relate malnutrition to the specific medical condition and the severity of the underlying disease process.

Subjective Global Assessment This approach incorporates historic and physical findings as a basis for nutrition assessment by the trained physician. Major components in the history include evaluation of the extent of recent weight loss, changes in dietary intake, presence of significant gastrointestinal symptoms persisting more than 2 weeks, alterations in functional status, and the metabolic demand of the patient's underlying disease. Emphasis in the physical examination is placed on findings of depletion of subcutaneous body fat; skeletal muscle wasting; typical changes in skin, mucus membranes, and neurologic examination; as well as the presence of edema. Integration of the historic and physical data permits ranking of patients according to the following categories: adequate nutrition, moderate malnutrition, or severe malnutrition. Though the developers of the subjective global assessment have reported good sensitivity and specificity, the approach is still quite dependent on the training and experience of the clinician.

Prognostic Nutritional Assessment Several paradigms have been developed to link different parameters of nutritional assessment with clinical prognosis. Each approach links specific features of malnutrition with certain measurements of cell-mediated immunity, since abnormal immune function is a common pathway for increased risk in the malnourished patient (Fig. 74-3). A surgical prognostic nutritional index predicts morbidity based on preoperative measurements of serum albumin, transferrin, triceps skin-fold thickness, and delayed hypersensitivity to skin-test antigens.

AnotherPCMscore was developed to link survival in alcoholic liver disease to both skin-fold and mid-arm muscle measurements; the creatinine-height index; values for serum albumin, transferrin, prealbumin, and retinol-binding protein; the total lymphocyte count; and the skin-test response to a series of antigens. The Maastricht index predicts survival in patients with serious gastrointestinal diseases on the basis of factors related to serum albumin, retinol-binding protein, lymphotyce count, and deviation from the patient's ideal body weight.

75. VITAMIN AND TRACE MINERAL DEFICIENCY AND EXCESS- *Robert M. Russell*

Vitamins and trace minerals are required constituents of the human diet since they are either inadequately synthesized or not synthesized in the human body. Only small amounts of these substances are needed for carrying out essential biochemical reactions (e.g., acting as coenzymes or prosthetic groups). Overt vitamin or trace mineral deficiencies are rare in western countries due to a plentiful, varied, and inexpensive food supply; however, multiple nutrient deficiencies may appear together in persons who are ill or alcoholic. Moreover, subclinical vitamin and trace mineral deficiencies, as diagnosed by laboratory testing, are quite common in the normal population -- especially the geriatric population.

Body stores of vitamins and minerals vary tremendously. For example, vitamin B_{12} and vitamin A stores are large, and an adult may not become deficient for 1 or more years after being on a depleted diet. However, folate and thiamine may become depleted within weeks when eating a deficient diet. Therapeutic modalities can deplete essential nutrients from the body; for example, hemodialysis removes water-soluble vitamins, which must be replaced by supplementation.

There are several roles for vitamins and trace minerals in diseases: (1) deficiencies of vitamins and minerals may be caused by disease states such as malabsorption; (2) both deficiency and excess of vitamins and minerals can cause disease in and of themselves (e.g., vitamin A intoxication and liver disease); and (3) vitamins and minerals in high doses may be used as drugs (e.g., niacin for hypercholesterolemia). The hematologic-related vitamins and minerals (Chaps. 105,107) are not considered in this chapter, nor are the bone-related vitamins and minerals (vitamin D, calcium, phosphorus; Chap. 340), as they are covered elsewhere.

VITAMINS

THIAMINE (VITAMIN B_1)

Thiamine was the first B vitamin to be identified and is therefore also referred to as vitamin B_1. Thiamine pyrophosphate, the coenzyme form of thiamine, is required for branched-chain amino acid metabolism and carbohydrate metabolism (Fig. 75-1). Thiamine functions in the decarboxylation of a-ketoacids, such as pyruvate anda-ketoglutarate, and branched-chain amino acids and thus is a source of energy generation. In addition, thiamine pyrophosphate acts as a coenzyme for a transketolase reaction that mediates the conversion of hexose and pentose phosphates. It has also been postulated that thiamine plays a role in peripheral nerve conduction, although the exact chemical reactions underlying this function are unknown.

Absorption and Requirements At high doses, thiamine is absorbed by a passive mechanism; at low doses, it is absorbed by a carrier-mediated, active transport system and becomes phosphorylated in the process. Once absorbed, thiamine circulates bound to plasma proteins (mainly albumin) and erythrocytes. Storage sites for thiamine include muscle, heart, liver, kidney, and brain, although muscle is the principal storage site. The total body store of thiamine, mainly in the form of thiamine pyrophosphate, is approximately 30 mg, and its biologic half-life ranges between 9 and 18 days.

Given the fact that thiamine is involved in carbohydrate metabolism and energy generation, the Recommended Dietary Allowance (RDA) for males has been adjusted upward to account for increased energy utilization. Experiments have shown that heavy athletic training also increases thiamine utilization slightly. The RDA for thiamine is 1.2 mg/d for males and 1.1 mg/d for females. The median intake of thiamine in the United States from food alone is 2 mg/d. There is a 10% increase in the need for thiamine in pregnancy, and a small further increase in lactating females.

Primary food sources for thiamine include yeast, pork, legumes, beef, whole grains, and nuts. Milled and polished rice contain little, if any, thiamine. Thiamine deficiency is therefore more common in cultures that rely heavily on a rice-based diet. The molecule is heat-sensitive and is destroyed at pH > 8. Tea, coffee (caffeinated and decaffeinated), raw fish, and shellfish contain thiamineases, which can destroy the vitamin. Thus, drinking large amounts of tea or coffee can theoretically lower thiamine body stores.

Deficiency Most dietary deficiency of thiamine worldwide is the result of poor dietary intake. In western countries, the primary causes of thiamine deficiency are alcoholism and chronic illness, such as cancer. Alcohol is known to interfere directly with the absorption of thiamine and with the synthesis of thiamine pyrophosphate. Malnourished individuals with alcoholic liver disease are also at increased risk of thiamine deficiency because of diminished storage sites in liver and muscle. Thiamine should always be replenished when refeeding a patient with alcoholism, as carbohydrate repletion without adequate thiamine can precipitate acute thiamine deficiency.

Thiamine deficiency in its early stage induces anorexia, irritability, apathy, and generalized weakness. Prolonged thiamine deficiency causes beriberi, which is classically categorized as wet or dry, although there is considerable overlap. In either form of beriberi, patients may complain of pain and parathesia. *Wet beriberi* presents primarily with cardiovascular symptoms, due to impaired myocardial energy metabolism and dysautonomia, and can occur after 3 months of a thiamine-deficient diet. Patients present with an enlarged heart, tachycardia, high-output congestive heart failure, peripheral edema, and peripheral neuritis. Patients with *dry beriberi* present with a symmetric peripheral neuropathy of the motor and sensory systems with diminished reflexes. The neuropathy affects the legs most markedly, and patients have difficulty rising from a squatting position.

Alcoholic patients with chronic thiamine deficiency may also have central nervous system manifestations known as *Wernicke's encephalopathy*, consisting of horizontal nystagmus, ophthalmoplegia (due to weakness of one or more extraocular muscles), cerebellar ataxia, and mental impairment (Chap. 387). When there is an additional loss of memory and a confabulatory psychosis, the syndrome is known as *Wernicke-Korsakoff syndrome*. Although this syndrome is generally described in alcoholic patients, there may be a genetic predisposition to Wernicke-Korsakoff that involves a variant transketolase isozyme.

In severely malnourished infants 2 to 3 months old, thiamine deficiency may occur precipitously with sudden cardiovascular failure and collapse, resulting in death within

hours. In addition, infants with thiamine deficiency may present with features suggesting meningitis, including vomiting, nystagmus, and convulsions. An aphonic presentation has also been described in which there is extreme irritability and either a very hoarse cry or total inability to emit any noise whatsoever (a silent scream).

The laboratory diagnosis of thiamine deficiency is usually made by a functional enzymatic assay of transketolase activity measured before and after the addition of thiamine pyrophosphate. A >25% stimulation by the addition of thiamine pyrophosphate (an activity coefficient of 1.25) is taken as abnormal. Thiamine or the phosphorylated esters of thiamine in serum or blood can also be measured by high-performance liquid chromatography (HPLC) to detect deficiency. Moreover, a urinary level of thiamine<27 ug per gram of creatinine per day is abnormal. In measuring urinary excretion of thiamine, one should make sure the patient is not taking diuretics, which increase thiamine excretion.

TREATMENT

In acute thiamine deficiency with either cardiovascular or neurologic signs, 100 mg/d of thiamine should be given parenterally for 7 days, followed by 10 mg/d orally until there is complete recovery. Cardiovascular improvement occurs in£12 h, and ophthalmoplegic improvement occurs within 24 h. Other manifestations gradually clear, although psychosis in the Wernicke-Korsakoff syndrome may be permanent or persist for several months. Consistent with this, pathologic changes occur in the cortex, cerebellum, and mammillary bodies of the thalamus. Parenteral thiamine should be given prophylactically to all chronic alcoholic patients in the emergency room, or as soon as they are admitted, to prevent precipitation of thiamine deficiency after the provision of glucose-containing solutions.

Thiamine-responsive conditions requiring pharmacologic doses of thiamine include branched-chain ketoaciduria (maple sugar urine disease), subacute necrotizing encephalopathy due to thiamine triphosphate deficiency in the brain (Leigh syndrome), thiamine-responsive lactic acidosis, and thiamine-responsive megaloblastic anemia associated with diabetes mellitus and deafness (Chap. 353). The gene for this recessive disorder, *SLC19A2*, encodes a thiamine transporter.

Toxicity Although anaphylaxis has been reported after high doses of thiamine, no adverse effects have been recorded from either food or supplements at high doses. Thiamine supplements may be bought over the counter in doses of up to 50 mg/d.

RIBOFLAVIN (VITAMIN B_2)

Riboflavin is important for the metabolism of fat, carbohydrate, and protein, reflecting its role as a respiratory coenzyme and an electron donor. Riboflavin is esterified with phosphoric acid in the body to form two coenzymes, flavin-mononucleotide (FMN) and flavin adenine dinucleotide (FAD) which are involved in a variety of cellular oxidation-reduction processes. Enzymes that contain FAD or FMN as prosthetic groups are known as *flavoenzymes* (e.g., succinic acid dehydrogenase, monoamine oxidase, glutathione reductase). Riboflavin plays an important role in niacin metabolism, since flavoenzymes act as intermediaries in the oxidation of the reduced forms of

nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP).

Riboflavin is normally absorbed by active and carrier-mediated saturable mechanisms, whereas diffusion is the principal mechanism of absorption at high concentrations. Riboflavin phosphorylation takes place mainly in the wall of the small intestine. BothFMN andFAD are bound to immunoglobulins and albumin in the circulation, and both forms are stored to some degree in liver and muscle.

Although much is known about the chemical and enzymatic reactions of riboflavin, the clinical manifestations of riboflavin deficiency are nonspecific and similar to those of other B vitamin deficiencies. Further, riboflavin deficiency usually occurs in combination with other water-soluble vitamin deficiencies (Chap. 74). Riboflavin deficiency is manifested principally by lesions of the mucocutaneous surfaces of the mouth (angular stomatitis, cheilosis, atrophic glossitis, magenta tongue, pharyngitis) and skin (seborrhea, genital dermatitis). In addition to the mucocutaneous lesions, corneal vascularization, anemia, and personality changes have been described with riboflavin deficiency.

Deficiency and Excess Riboflavin deficiency is almost always due to dietary deficiency. The requirement for riboflavin is increased during pregnancy and lactation and possibly by heavy exercise. The use of phenothiazines and antibiotics also appears to increase the need for riboflavin. Milk, other dairy products, and enriched breads and cereals are the most important dietary sources of riboflavin in the United States, although lean meat, fish, eggs, broccoli, and legumes are also good sources. Riboflavin is extremely sensitive to light, and milk should be stored in containers that protect against photodegradation. In non-milk-drinking societies (e.g., Central America), the laboratory diagnosis of riboflavin deficiency is common. Laboratory diagnosis of riboflavin deficiency can be made by measurement of red blood cell or urinary riboflavin concentrations or by measurement of erythrocyte glutathione reductase activity, with and without addedFAD. A stimulation (activity coefficient) of >1.4 is diagnostic of a deficient state. TheRDA for riboflavin is 1.1 to 1.3 mg/d in adults, with slightly higher recommendations for lactating and pregnant women. Rare genetic defects of flavoprotein synthesis may require pharmacologic doses of riboflavin for treatment. Because the capacity of the gastrointestinal tract to absorb riboflavin is limited (~20 mg if given in one oral dose), riboflavin toxicity has not been described. Thus, the most recent revision of the RDAs did not set an upper limit for this nutrient.

NIACIN (VITAMIN B_3)

The term *niacin* refers to nicotinic acid and nicotinamide and their biologically active derivatives. Nicotinic acid and nicotinamide serve as precursors of two coenzymes,NAD andNADP. These coenzymes are important in numerous oxidation and reduction reactions in the body. NAD and NADP serve as cofactors for dehydrogenases and are involved in the transfer of the hydride ion in many redox reactions. Thus, niacin is important in pentose, steroid, and fatty acid biosynthesis; glycolysis; protein metabolism; and the oxidation of fuels such as lactate, pyruvate, and alcohol. In addition, NAD and NADP are active in adenine diphosphate-ribose transfer reactions involved in DNA repair and calcium mobilization.

Absorption, Metabolism, and Requirements Nicotinic acid and nicotinamide are absorbed well from the stomach and small intestine. Both forms of niacin are absorbed by a sodium-dependent, facilitated diffusion mechanism at low doses, whereas passive diffusion occurs at high doses. Some storage ofNADtakes place in the liver. The amino acid tryptophan can be converted to niacin with an efficiency of 60:1 by weight. Thus, theRDA for niacin is expressed in niacin equivalents. Greater conversion of tryptophan to niacin occurs in niacin-deficient states, pregnancy, and in women using oral contraceptives. However, a lower conversion efficiency occurs if a patient is vitamin B_6- or riboflavin-deficient. The drug isoniazid inhibits the conversion of tryptophan to niacin. The urinary excretion products of niacin include nicotinic acid and niacin oxide; however, the major urinary metabolites are 2-pyridone and 2-methyl nicotinamide, measurements of which are used in diagnosis of niacin deficiency.

TheRDA for niacin is 16 niacin equivalents per day for men and 14 niacin equivalents for women. Median intakes of niacin in the United States considerably exceed these values. Diets that are corn-based can predispose to niacin deficiency due to the low tryptophan and niacin content. Niacin bioavailability is high from beans, milk, meat, and eggs; bioavailability from cereal grains is lower. Since flour is enriched with the "free" niacin (i.e., non-coenzyme form), bioavailability is excellent.

Deficiency Niacin deficiency causes *pellagra*, which is mostly found among people eating corn-based diets in parts of China, Africa, and India. Pellagra in North America is found mainly among alcoholics; in patients with congenital defects of intestinal and kidney absorption of tryptophan (Hartnup's disease;Chap. 352); and in patients with carcinoid syndrome (Chap. 93), in which there is increased conversion of tryptophan to serotonin. The early symptoms of pellagra include loss of appetite, generalized weakness and irritability, abdominal pain, and vomiting. Epithelial cell changes then ensue with stomatitis and bright-red glossitis, followed by a characteristic skin rash that is pigmented and scaling, particularly in skin areas exposed to sunlight. This rash is known as "Casal's necklace," when it rings the neck, and is seen in advanced cases. Vaginitis and esophagitis may also occur. Diarrhea (in part due to proctitis and in part due to malabsorption), depression, seizures, and dementia are also part of the pellagra syndrome -- the four D's: *d*ermatitis, *d*iarrhea, and *d*ementia leading to *d*eath.

The diagnosis of niacin deficiency is based on low levels of the urinary metabolites 2-methyl nicotinamide and 2-pyridone. Treatment of pellagra consists of oral supplementation of 100 to 200 mg of nicotinamide or nicotinic acid three times daily for 5 days. High doses of nicotinic acid (^{3}3 g nicotinic acid per day) are used for the treatment of elevated cholesterol levels and in the treatment of types 2, 4, and 5 hyperlipidemias (Chap. 344).

Toxicity Prostaglandin-mediated flushing has been observed at daily doses as low as 50 mg of niacin when taken as a supplement or as therapy for hypertriglyceridemia. No toxicity has been seen from niacin derived from food sources. Flushing may be accompanied by skin dryness, itching, and headache. Premedication with aspirin may alleviate these symptoms. Nausea, vomiting, and abdominal pain also occur at similar doses of niacin. Hepatic toxicity is the most serious toxic reaction due to niacin and may present as jaundice with elevated AST and ALT levels. A few cases of fulminant hepatitis requiring liver transplantation have been reported at doses of 3 to 9 g/d. Other

toxic reactions include glucose intolerance, macular edema, and macular cysts. It is not clear whether sustained-release forms of nicotinic acid are more toxic than regular forms. The upper limit for daily niacin intake has been set at 35 mg. However, this upper limit does not pertain to the therapeutic use of niacin.

PYRIDOXINE (VITAMIN B_6)

Vitamin B_6 refers to a family of compounds including pyridoxine, pyridoxal, pyridoxamine, and their 5¢-phosphate derivatives. 5¢-Pyridoxal phosphate (PLP) is a cofactor for more than 100 enzymes involved in amino acid metabolism (e.g., 5¢-PLP is a cofactor for the transulfuration enzymes involved in the conversion of homocysteine to cystathionine; Chap. 352). Vitamin B_6 is also involved in heme and neurotransmitter synthesis and in the metabolism of glycogen, lipids, steroids, sphingoid bases, and several vitamins, including the conversion of tryptophan to niacin.

Absorption and Metabolism Approximately 75% of vitamin B_6 is absorbed from a mixed diet by a nonsaturable, passive process. Much of dietary vitamin B_6 is in the phosphorylated form, and the phosphate must be removed by intestinal alkaline phosphatase before absorption takes place. Once absorbed, the vitamin becomes rephosphorylated in the liver, where the various forms can be interconverted. In the liver, PLP binds avidly to cellular proteins and albumin. Since these binding proteins protect it from phosphatase activity, tissue levels of PLP can become quite high with continuous supplementation. Sixty mg of vitamin B_6 is stored in the body, and much is in the form of PLP bound to phosphorylase A in muscle. The biologic half-life of vitamin B_6 is 25 days.

Dietary Sources Plants contain vitamin B_6 in the form of pyridoxine, whereas animal tissues contain PLP and pyridoxamine phosphate. The vitamin B_6 contained in plants is less bioavailable than that from animal tissues. All forms of vitamin B_6 are labile in alkaline conditions. Rich food sources of vitamin B_6 include legumes, nuts, wheat bran, and meat, although the vitamin is present in all food groups. The RDA for young adults (both males and females) has been set at 1.3 mg/d. For older adults, the RDA is slightly higher (1.5 mg/d for women, 1.7 mg/d for men).

Deficiency Symptoms of vitamin B_6 deficiency include seborrheic dermatitis, glossitis, stomatitis, and cheilosis, as frequently seen with other B vitamin deficiencies (Chap. 74). In addition, severe vitamin B_6 deficiency can lead to generalized weakness, irritability, peripheral neuropathy, abnormal electroencephalograms, and personality changes including depression and confusion. In infants, diarrhea, seizures, and anemia have been reported. Microcytic, hypochromic anemia is due to diminished hemoglobin synthesis, since the first enzyme involved in heme biosynthesis (amino-levulinate synthase) requires PLP as a cofactor (Chap. 104). In some case reports, platelet dysfunction has also been reported. Since vitamin B_6 is necessary for the conversion of homocysteine to cystathionine, it is possible that chronic low-grade vitamin B_6 deficiency may result in hyperhomocystinemia and increased risk of cardiovascular disease (Chaps. 242 and 352).

Certain medications such as isoniazid, L-dopa, penicillamine, and cycloserine interact with PLP due to a reaction with carbonyl groups. Oral contraceptives have been reported

to decrease vitamin B_6 status indicators, although the mechanism for this is uncertain. Alcoholism also decreases vitamin B_6 status due to poor diet, liver disease, and the fact that acetaldehyde can compete with PLP for protein binding, leading to increased degradation and excretion. The increased ratio of aspartate aminotransferase (AST or SGOT) to alanine aminotransferase (ALT or SGPT) seen in alcoholic liver disease reflects the relative vitamin B_6 dependence of ALT. Vitamin B_6 requirements are higher in preeclampsia, eclampsia, and hemodialysis. Vitamin B_6 dependency syndromes that require pharmacologic doses of vitamin B_6 are rare, but include cystathionine b-synthase deficiency, pyridoxine-responsive (primarily sideroblastic) anemias, and gyrate atrophy with chorioretinal degeneration due to decreased activity of the mitochondrial enzyme ornithine aminotransferase. In these situations, 100 to 200 mg/d of oral vitamin B_6 are required for treatment.

High doses of vitamin B_6 have been used to treat carpal tunnel syndrome, premenstrual tension, schizophrenia, autism, and diabetic neuropathy but have not been found to be effective.

The laboratory diagnosis of vitamin B_6 deficiency is generally made on the basis of low plasma PLP values (<20 nmol/L). Other measures of vitamin B_6 deficiency include low erythrocyte levels of PLP, low plasma pyridoxal, and low urinary levels of 4-pyridoxic acid. Treatment of vitamin B_6 deficiency is 50 mg/d; higher doses of 100 to 200 mg/d are given if vitamin B_6 deficiency is related to medication use. Vitamin B_6 should not be given with L-dopa, since the vitamin interferes with the action of this drug.

Toxicity The safe upper limit for vitamin B_6 has been set at 100 mg/d, although the lowest dose at which toxicity (sensory neuropathy) has been seen is 500 mg/d. No adverse effects have been associated with high intakes of vitamin B_6 from food sources only. When toxicity occurs, it causes a severe sensory neuropathy, leaving patients unable to walk. Some cases of photosensitivity and dermatitis have also been reported.

VITAMIN C

Both ascorbic acid and its oxidized product dehydroascorbic acid are biologically active. Vitamin C participates in oxidation-reduction reactions and hydrogen ion transfer reactions. As an antioxidant, vitamin C donates electrons to quench reactive free radical and oxygen species. It also acts to regenerate other antioxidants such as vitamin E, flavonoids, and glutathione. Other actions of vitamin C include promotion of nonheme iron absorption, carnitine biosynthesis, and the conversion of dopamine to norepinephrine. Vitamin C is also important for connective tissue metabolism and cross-linking and is a component of many drug-metabolizing enzyme systems, particularly the mixed-function oxidase systems. As such, the vitamin participates in the synthesis of corticosteroids, aldosterone, and the metabolism of cholesterol. Vitamin C also participates in enzymatic reactions requiring a reduced metal, although the exact molecular basis for this role has not been delineated.

Absorption and Physiology Vitamin C is absorbed by an energy-dependent, saturable transport system, and a progressively smaller proportion of the vitamin is absorbed with increasing dose. Almost complete absorption of the vitamin occurs if <100 mg is administered in a single dose; however, only 50% or less is absorbed at doses >1 g.

Enhanced degradation and fecal and urinary excretion of vitamin C occur at higher intake levels. High levels of the reduced form of vitamin C are contained in white blood cells, lens tissue, and brain. The maximum body pool in adult males is approximately 1500 mg, and 3% of this body pool is turned over each day, resulting in a half-life of approximately 18 days.

Dietary Sources and Requirements Good dietary sources of vitamin C include citrus fruits, green vegetables (especially broccoli), tomatoes, and potatoes. Appreciable amounts of vitamin C may be consumed as an antioxidant food additive, and the consumption of five servings of fruits and vegetables a day provides vitamin C in excess of theRDA of 60 mg/d for males and females. Moreover, approximately 40% of the U.S. population takes vitamin C as a dietary supplement. Vitamin C requirements are increased slightly to 70 mg in pregnancy and are increased further to 90 to 95 mg/d during lactation. Smoking, hemodialysis, and stress (e.g., infection, trauma) appear to increase vitamin C requirements. "Natural forms" of vitamin C are no more bioavailable than synthetic forms.

Deficiency Vitamin C deficiency causes scurvy; in the United States, this is seen primarily among poor and elderly people and alcoholics who consume <10 mg/d of vitamin C. Vitamin C deficiency has also been described among individuals consuming macrobiotic diets. Scurvy occurs when the body pool for vitamin C drops to <300 mg/d and plasma levels drop to<11 umol/L. Symptoms of scurvy primarily reflect impaired formation of mature connective tissue and include bleeding into skin (petechiae, ecchymoses, perifollicular hemorrhages); inflamed and bleeding gums; and manifestations of bleeding into joints, the peritoneal cavity, pericardium, and the adrenal glands. Other generalized symptoms include weakness, fatigue, and depression. In children, vitamin C deficiency may cause impaired bone growth. Laboratory diagnosis of vitamin C deficiency is made on the basis of low plasma or leukocyte levels.

Administration of vitamin C (200 mg/d) results in marked improvement in the symptoms of scurvy in a matter of several days. High-dose vitamin C supplementation (e.g., 1 to 2 g/d) has been shown to slightly decrease the symptoms and duration of upper respiratory tract infections and to improve glycemic control. Vitamin C supplementation has also been reported to be useful in Chediak-Higashi syndrome (Chap. 64) and osteogenesis imperfecta (Chap. 351). It has been claimed that foods high in vitamin C may lower the incidence of certain cancers, particularly esophageal and gastric cancers. If proven, this effect may be due to the fact that vitamin C can prevent the conversion of nitrites and secondary amines to carcinogenic nitrosomines. However, one intervention study from China did not show vitamin C to be protective. Other chronic diseases for which diets high in vitamin C have been reported to be protective include cardiovascular disease, stroke, and cataracts. However, these studies are correlational, and no large-scale intervention studies have been reported.

Toxicity Taking>2 g of vitamin C in a single dose may result in abdominal pain, diarrhea, and nausea; doses >3 g have been reported to elevate blood levels of alanine aminotransferase, lactic acid dehydrogenase, and uric acid. Since vitamin C may be metabolized to oxalate, it has been feared that chronic, high-dose vitamin C supplementation could result in an increased prevalence of kidney stones. However, this has not been borne out in several trials, except in individual patients with preexisting

renal disease. Thus, it is reasonable to advise patients with a past history of kidney stones not to take large doses of vitamin C. There is also an unproven, but possible risk that chronic high doses of vitamin C could promote iron overload in patients taking supplemental iron. High doses of vitamin C can induce hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and doses >1 g/d can cause false-negative guaiac reactions as well as interfering with tests for urinary glucose.

BIOTIN

Biotin is a water-soluble vitamin with a bicyclic structure. The vitamin plays an important role in gluconeogenesis and fatty acid synthesis and serves as a CO_2carrier on the surface of both cytosolic and mitochondrial carboxylase enzymes. The vitamin also functions in the catabolism of specific amino acids (e.g., leucine).

Biotin in food sources is bound to protein from which it must be cleaved in order to be absorbed. The enzyme biotinidase dissociates the vitamin and facilitates its subsequent transport. Excellent food sources of biotin include liver, soy, beans, yeast, and egg yolks, although egg white contains the protein avidin that strongly binds the vitamin and reduces its bioavailability. Biotin is contained in moderate amounts in legumes, nuts, mushrooms, cauliflower, and certain cereals. Although biotin is synthesized by intestinal bacteria, the relative importance of this source in humans is uncertain. The recommended intake of biotin for adults is 30 ug/d and 35 ug/d in lactating women.

Biotin deficiency has been induced by experimental feeding of egg white diets and in patients with short bowels who received biotin-free parenteral nutrition. In the adult, biotin deficiency results in mental changes (depression, hallucinations), paresthesia, anorexia, and nausea. A scaling, seborrheic, and erythematous rash may occur around the eyes, nose, and mouth as well as on the extremities. In infants, biotin deficiency presents as hypotonia, lethargy, and apathy. In addition, the infant may develop alopecia and a characteristic rash that includes the ears. Two types of inherited infantile biotin deficiency states have been described. Multiple carboxylase deficiency syndrome is an autosomal recessive disorder that is expressed during the first week of life and is characterized by severe metabolic ketoacidosis and dermatitis. Treatment requires pharmacologic doses of biotin, using up to 10 mg/d. Late-onset infantile biotin deficiency due to absorptive and transport defects occurs between 3 and 6 months with dermatitis, seizures, ataxia, hypotonia, and variable metabolic acidosis. The laboratory diagnosis of biotin deficiency can be established based on a decreased urinary concentration.

PANTOTHENIC ACID

Pantothenic acid is a component of coenzyme A and phosphopantetheine, which are involved in fatty acid metabolism and the synthesis of cholesterol, steroid hormones, and all compounds formed from isoprenoid units. In addition, pantothenic acid is involved in the acetylation of proteins. Pantothenic acid is actively transported when given at low doses, but it is passively absorbed when given at high doses. The vitamin is excreted in the urine, and the laboratory diagnosis of deficiency is made on the basis of low urinary vitamin levels.

The vitamin is ubiquitous in the food supply. Liver, yeast, egg yolks, and vegetables are

particularly good sources. The recommended adequate intake for adults is 5 mg/d. Human pantothenic acid deficiency has only been demonstrated in experimental feeding of diets low in pantothenic acid or by giving a specific pantothenic acid antagonist. The symptoms of pantothenic acid deficiency are nonspecific and include gastrointestinal disturbance, depression, muscle cramps, paresthesia, ataxia, and hypoglycemia. Pantothenic acid deficiency was thought to cause the burning feet syndrome seen in prisoners of war during World War II. No toxicity of this vitamin has been reported.

CHOLINE

Choline is a precursor for acetylcholine, phospholipids, and betaine. Choline is necessary for the structural integrity of cell membranes, cholinergic neurotransmission, lipid and cholesterol metabolism, and transmembrane signaling. Recently, a recommended adequate intake was set at 550 mg/d for adult males and 425 mg/d for adult females. Choline is thought to be a "conditionally essential" nutrient, in that de novo synthesis occurs in the liver and is less than the vitamin's utilization only under certain stress conditions. Choline deficiency has occurred in patients receiving parenteral nutrition devoid of choline. Deficiency results in fatty liver and elevated transaminase levels. The diagnosis of choline deficiency is made on the basis of low plasma levels.

Toxicity from choline results in hypotension, cholinergic sweating, diarrhea, salivation, and a fishy body odor. The upper limit for choline has been set at 3.5 g/d. Therapeutically, choline has been suggested for patients with dementia and for patients at high risk of cardiovascular disease, due to its ability to lower cholesterol and homocysteine levels. However, such benefits have yet to be documented.

VITAMIN A

Vitamin A, in the strictest sense, refers to retinol. However, the oxidized metabolites, retinaldehyde and retinoic acid, are also biologically active compounds. The term *retinoids* includes synthetic molecules that are chemically related to retinol. Retinaldehyde is the essential form of vitamin A that is required for normal vision, whereas retinoic acid is necessary for normal morphogenesis, growth, and cell differentiation. Retinoic acid does not function in vision and, in contrast to retinol, is not involved in reproduction. Vitamin A also plays a role in iron utilization, humoral immunity, T cell-mediated immunity, natural killer cell activity, and phagocytosis. Vitamin A is commercially available in esterified forms (e.g., acetate, palmitate) since it is more stable as an ester.

There are over 600 carotenoids in nature, and approximately 50 of these can be metabolized to vitamin A.b-Carotene is the most prevalent carotenoid in the food supply that has provitamin A activity. Although the breakdown ofb-carotene should theoretically yield two molecules of vitamin A, the conversion of carotenoids to vitamin A, in fact, is much less efficient. It is estimated that 6 ug or greater of dietaryb-carotene is equivalent to 1 ug of retinol, whereas 12 ug or greater of other dietary provitamin A carotenoids (e.g., cryptoxanthin,a-carotene) is equivalent to 1 ug of retinol.

Absorption and Metabolism Approximately 80% of preformed vitamin A is absorbed

from food, and absorption is via a carrier-mediated mechanism at low concentrations and passive diffusion at high concentrations. Approximately 15 to 30% of provitamin A carotenoids are absorbed passively from the diet, and the absorption becomes much less efficient at high dosage. The absorption of both vitamin A and carotenoids are partially dependent on an adequate bile concentration within the intestinal lumen for the formation of micelles. Once a provitamin A carotene is absorbed into the epithelial cell, a small proportion of it is split to form vitamin A. At higher doses of b-carotene, the conversion to vitamin A is less efficient, thereby preventing vitamin A toxicity. The absorption of both vitamin A and intact b-carotene is via the lymphatics after chylomicron formation.

Hepatic clearance of vitamin A in chylomicrons is efficient, and the liver contains approximately 90% of the vitamin A reserves. Approximately 10 to 40% of a vitamin A dose is oxidized or conjugated in the liver and excreted in urine or bile. Of a given dose of vitamin A, approximately 50% enters the liver storage pool. Storage of vitamin A takes place in the lipid storage (Ito) cell of the liver, which is also a collagen-producing cell. The liver secretes vitamin A in the form of retinol, which is bound to retinol-binding protein. Once this has occurred, the retinol-binding protein complex interacts with a second protein, transthryetin. This trimolecular complex functions to prevent vitamin A from being filtered by the kidney glomerulus, to protect the body against the toxicity of retinol and to allow retinol to be taken up by specific cell-surface receptors that recognize retinol-binding protein. A certain amount of vitamin A enters peripheral cells even if it is not bound to retinol-binding protein. After retinol is internalized by the cell, it becomes bound to a series of cellular retinol-binding proteins, which function as sequestering and transporting agents as well as coligands for enzymatic reactions. Certain cells also contain retinoic acid-binding proteins, which have the same sequestering functions as well as enabling retinoic acid metabolism.

11-*cis*-Retinaldehyde functions as a visual pigment chromophore to capture light. Rhodopsin is composed of the protein opsin and retinaldehyde and is contained in the rod cells, whereas iodopsin is contained in cones. When the dark-adapted retina is exposed to light, the 11-*cis*-retinaldehyde contained in rhodopsin isomerizes to an all-*trans* form. This conformational change causes dissociation from the opsin, resulting in a nerve impulse and a visual response. Once the retina returns to dim light conditions, rhodopsin is regenerated.

Retinoic acid is a ligand for certain nuclear receptors that act as transcription factors. Two families of receptors (RAR and RXR receptors) are active in retinoid-mediated gene transcription. Retinoid receptors regulate transcription by binding as dimeric complexes to specific DNA sites, the retinoic acid response elements, in target genes (Chap. 327). The receptors can either stimulate or repress gene expression in response to their ligands. RAR binds all-*trans* retinoic acid and 9-*cis* retinoic acid, whereas RXR binds only 9-*cis* retinoic acid.

The retinoid receptors play an important role in controlling cell proliferation and differentiation. Retinoic acid is useful in the treatment of promyeolcytic leukemia (Chap. 111). In this case, a gene rearrangement fuses the RAR to one of several other genes [e.g., t(15;17)], causing an apparent block in cell differentiation. Treatment with retinoic acid activates the RAR, dissociating repressor complexes and leading to cell

differentiation and more normal cell turnover. Retinoic acid is also used in the treatment of cystic acne because it inhibits keratinization, decreases sebum secretion, and possibly alters the inflammatory reaction (Chap. 56). RXRs dimerize with other nuclear receptors to function as coregulators of genes responsive to retinoids, thyroid hormone, and calcitriol. RXR agonists induce insulin sensitivity experimentally, perhaps because RXR is a cofactor for the peroxisome-proliferator-activated receptors (PPARs), which are targets for the thiazolidinedione drugs such as rosiglitazone and troglitazone (Chap. 333).

Dietary Sources The retinol equivalent (RE) is used to express the vitamin A value of food. One RE is defined as 1 ug of retinol (0.003491 mmol). In the past, 1 RE was considered to be equal to 6 ug of b-carotene, but additional studies indicate that 1 RE may, in fact, be equal to 12 to 20 ug ofb-carotene from a dietary source. In older literature, vitamin A was often expressed in international units (IU), with 1 RE being equal to 3.33 IU of retinol and 12 IU of b-carotene, but these units are no longer in current medical or scientific use. The RDA for vitamin A is set at 1000 RE for adult males and 800 RE for adult females.

Liver and fish are excellent food sources for preformed vitamin A; vegetable sources of provitamin A carotenoids include dark-green and -colored fruits and vegetables. Diets consisting mainly of rice, wheat, maize, and tubers can produce vitamin A deficiency, as few carotenoids are contained in these foods. In areas where these foods are staples, children are particularly susceptible to vitamin A deficiency because neither breast nor cow's milk supplies enough vitamin A to prevent deficiency. Areas of the world where vitamin A deficiency is particularly prevalent include parts of Africa, South America, and Southeast Asia. Vitamin A deficiency occurs in more than 250,000 children each year, resulting in blindness and a 50% mortality rate within the year. In western countries, vitamin A deficiency is seen primarily among patients with diseases associated with fat malabsorption (e.g., celiac sprue, short-bowel syndrome). Concurrent zinc deficiency can interfere with the mobilization of vitamin A from liver stores as well as the synthesis of rhodopsin in the eye; thus vitamin A deficiency is exacerbated by concurrent zinc deficiency. Alcohol also interferes with the conversion of retinol to retinaldehyde in the eye by competing for alcohol (retinol) dehydrogenase. Drugs that interfere with the absorption of vitamin A include mineral oil, neomycin, and cholestyramine.

Deficiency Symptoms of vitamin A deficiency include hyperkeratotic skin lesions, night blindness (inability to see in dim light), dryness of the eyes, xerosis, and Bitot spots, which are white patches of keratinized epithelium appearing on the sclera (Fig. 75-CD1). Aggressive xerophthalmia can result in corneal ulceration. If untreated, proteolytic destruction and rupture of the cornea ensues with permanent blindness, although vitamin A treatment of patients with corneal ulcers can also result in blindness due to permanent corneal scarring. Children with vitamin A deficiency have increased mortality, primarily from infectious diseases, measles, respiratory diseases, and diarrhea. Extremely low birth weight infants (<1000 g) should be treated parenterally with 5000 IU (1500 ug or RE) of vitamin A three times a week for 4 weeks.

There are no specific deficiency signs or symptoms that result from carotenoid deficiency. However, dietary carotenoids have been suggested to protect against cataract formation, low-density lipoprotein (LDL) oxidation, and certain cancers. It was

hoped thatb-carotene would be an effective chemopreventive for cancer because numerous epidemiologic studies had shown that diets high inb-carotene were associated with lower incidences of cancers of the respiratory and digestive system. However, intervention studies using high doses of b-carotene actually resulted in more lung cancers than in placebo-treated groups. Non-provitamin A carotenoids, such as lutein and zeaxanthin, have been suggested to protect against macular degeneration. The non-provitamin A carotenoid lycopene has been suggested to protect against prostate cancer. However, the effectiveness of these agents has not been proven by intervention studies, and the mechanisms underlying these purported biologic actions are unknown.

The diagnosis of vitamin A deficiency is made by measurement of serum retinol (normal range, 30 to 65 ug/dL), tests of dark adaptation, impression cytology of the conjunctiva (decreased numbers of mucous-secreting cells), or measurement of body storage pools, either directly by liver biopsy or by isotopic dilution after administering a stable isotope of vitamin A.

Vitamin A deficiency with ocular changes should be treated by administering 100,000 IU (30 mg) of vitamin A intramuscularly, or 200,000 IU (60 mg) orally. In areas of endemic vitamin A deficiency, this is followed by vitamin A capsules of 200,000 IU at 6-month intervals. Vitamin A deficiency in patients with malabsorptive diseases, who have abnormal dark adaptation or symptoms of night blindness without ocular changes, should be treated for 1 month with 50,000 IU/d (15 mg/d) orally of a water micelle preparation of vitamin A. This is followed by lower maintenance doses with the exact amount determined by monitoring serum retinol.

Toxicity Acute toxicity of vitamin A was first noted in Arctic explorers after eating polar bear liver and has been seen after administration of 150 mg in adults or 100 mg in children. Acute toxicity is manifest by increased intracranial pressure, vertigo, diplopia, bulging fontanels in children, seizures, and exfoliative dermatitis; it may result in death. Chronic vitamin A intoxication has been seen in normal adults who ingest 50,000 IU/d (15 mg/d) of vitamin A for a period of several months and in children who ingest 20,000 IU/d (6 mg/d). Manifestations include dry skin, cheilosis, glossitis, vomiting, alopecia, bone pain, hypercalcemia, lymph node enlargement, hyperlipidemia, amenorrhea, and features of pseudotumor cerebri with increased intracranial pressure and papilledema. Liver fibrosis with portal hypertension and bone demineralization may also result from chronic vitamin A intoxication. When vitamin A is provided in excess of pregnant women, congenital malformations have included spontaneous abortions, craniofacial abnormalities, and valvular heart disease. In pregnancy, the daily dose of vitamin A should not exceed 10,000 IU (3 mg). Elderly individuals appear to be more prone to vitamin A intoxication, as are alcoholics and patients with liver disease. In fact acute hepatitis may precipitate vitamin A intoxication in patients who have extremely high vitamin A stores in the liver. It should be noted that the commercially available retinoid derivatives are also toxic, including 13-*cis*-retinoic acid, which has been associated with birth defects. As a result, contraception should be continued for a least 1 year, and possibly longer, in women who have taken 13-*cis* retinoic acid.

High doses of carotenoids do not result in toxic symptoms. However, carotenemia, which is characterized by a yellowing of the skin (creases of the palms and soles) but

not the sclerae, may be seen after ingestion of >30 mg ofb-carotene on a daily basis. Hypothyroid patients are particularly susceptible to the development of carotenemia due to impaired breakdown of carotene to vitamin A. Reduction of carotenes from the diet results in the disappearance of skin yellowing and carotenemia over a period of 30 to 60 days.

VITAMIN D (SeeChap. 340).

VITAMIN E

Vitamin E is a collective name for a group of tocopherols and tocotrionols, the latter having an unsaturated sidechain. There are eight naturally occurring plant compounds with vitamin E activity. RRR-a tocopherol is the most active, while synthetic stereoisomers of vitamin E are less biologically active. Vitamin E acts as a chain-breaking antioxidant and is an efficient pyroxyl radical scavenger, which protectsLDLs and polyunsaturated fats in membranes from oxidation. A network of other antioxidants (e.g., vitamin C, glutathione) and enzymes maintains vitamin E in a reduced state. Vitamin E also inhibits prostaglandin synthesis and the activities of protein kinase C and phospholipase A_2.

Absorption and Metabolism Vitamin E is a fat-soluble vitamin and requires all the processes needed for micelle formation to be absorbed. About 15 to 40% is absorbed passively from a single physiologic dose, and there is less efficient absorption at high doses. Polyunsaturated fat may inhibit absorption. Vitamin E is taken up from chylomicrons by the liver, and an hepatica tocopherol transport protein is involved in intracellular vitamin E transport and incorporation into very low density lipoprotein (VLDL). The transport protein has particular affinity for the RRR isomeric form of a tocopherol; thus this natural isomer has the most biologic activity. In the circulation, vitamin E is bound to all lipoprotein classes and becomes widely distributed in tissues, with fat and muscle being the most important storage depots. Vitamin E metabolites are mainly excreted in feces, although some are also excreted in urine.

Requirement TheRDA for vitamin E is currently 10 mg for adults. Additional vitamin E is recommended during pregnancy (12 mg/d) and lactation (14 mg/d). Vitamin E is widely distributed in the food supply. The RRR-a isomers are particularly high in sunflower oil, safflower oil, and wheat germ oil;g tocotrionols are notably present in soybean and corn oils. Vitamin E is also found in meats, nuts, and cereal grains, and small amounts are present in fruits and vegetables. Vitamin E pills containing doses of 50 to 1000 mg are ingested by a large fraction of the U.S. population. In the older literature, 1 IU of vitamin E is equal to 1 mg *all*-racemica tocopherol acetate. Diets high in polyunsaturated fats may necessitate a slightly higher requirement for vitamin E.

Dietary deficiency of vitamin E does not exist. Vitamin E deficiency is seen only in severe and prolonged malabsorptive diseases, such as celiac disease, or after small-intestinal resection, leading to short-bowel syndrome. Children with cystic fibrosis or prolonged cholestasis may develop vitamin E deficiency characterized by areflexia and hemolytic anemia. Children with abetalipoproteinemia cannot absorb or transport vitamin E and become deficient quite rapidly. A familial form of isolated vitamin E deficiency also exists, which is due to a defect in thea tocopherol transport protein.

Vitamin E deficiency causes axonal degeneration of the large myelinated axons and results in posterior column and spinocerebellar symptoms. Peripheral neuropathy is initially characterized by areflexia, with progression to an ataxic gait, and by decreased vibration and position sensations. Ophthalmoplegia, skeletal myopathy, and pigmented retinopathy may also be features of vitamin E deficiency. The laboratory diagnosis of vitamin E deficiency is made on the basis of low blood levels of a tocopherol (<5 ug/mL, or <0.8 mg of a tocopherol per gram of total lipids).

TREATMENT

Symptomatic vitamin E deficiency should be treated with 800 to 1200 mg ofa tocopherol per day. Patients with abetalipoproteinemia may need as much as 5000 to 7000 mg/d. Children with symptomatic vitamin E deficiency should be treated with 400 mg/d orally of water-soluble esters; alternatively, 2 mg/kg per day may be administered intramuscularly. Vitamin E in high doses may protect against oxygen-induced retrolental fibroplasia and bronchopulmonary dysplasia in prematurity, as well as intraventricular hemorrhage of prematurity. Vitamin E has been suggested to increase sexual performance, to treat intermittent claudication, and to slow the aging process, but evidence for these properties is lacking. High doses (60 to 800 mg/d) of vitamin E have been shown in controlled trials to improve parameters of immune function, and there are two intervention studies showing that vitamin E at 400 to 800 mg/d may be protective against cardiovascular disease, possibly by inhibitingLDLoxidation. Also, supplemental intake of vitamin E (100 to 200 mg/d) has been associated with a decreased risk of cataracts.

Toxicity High doses of vitamin E (>800 mg/d) may reduce platelet aggregation and interfere with vitamin K metabolism and are therefore contraindicated in patients taking coumadin. Nausea, flatulence, and diarrhea have been reported at doses >1 g/d.

VITAMIN K

There are two natural forms of vitamin K: vitamin K I, also known as *phylloquinone*, from vegetable and animal sources, and vitamin K II, or *menaquinone*, which is synthesized by bacterial flora and found in hepatic tissue. *Menadione*, or vitamin K III, is a chemically synthesized pro-vitamin that can be converted to menaquinone by the liver. Phylloquinone and menaquinones differ only in their lipophilic sidechains, and both are destroyed in an alkaline pH and by ultraviolet light.

Absorption and Physiology As with other fat-soluble vitamins, vitamin K absorption is dependent on normal pancreatic function and the presence of bile salts. Phylloquinones are absorbed by a saturable energy-dependent mechanism in the proximal small intestine, whereas menaquinones are absorbed by passive diffusion in the small intestine and colon. Approximately 100 ug of vitamin K is stored in the liver as well as in lung, bone marrow, kidneys, and adrenal glands. Most vitamin K circulates bound toVLDL, although it is also carried byLDL and high-density lipoprotein (HDL). The half-life of vitamin K is only $1_{1/2}$days, despite the presence of a vitamin K regeneration cycle.

Vitamin K is necessary for the posttranslational carboxylation of glutamic acid, which is

necessary for calcium binding to g-carboxylated proteins such as prothrombin (factor II); factors VII, IX, and X; protein C; protein S; and proteins found in bone (bone gla, matrix gla protein, and osteocalcin). The importance of vitamin K for bone mineralization is not known. Warfarin-type drugs inhibitg carboxylation by preventing the conversion of vitamin K to its active hydroquinone form. Vitamin E, at high doses, may act as a vitamin K antagonist.

Dietary Sources Vitamin K is found in green leafy vegetables such as kale and spinach, but appreciable amounts are also present in butter, margarine, liver, milk, ground beef, coffee, and pears. Vitamin K is present in vegetable oils and is particularly rich in olive oil and soybean oil. The recommended intake of vitamin K is 70 ug/d in adults. The average daily intake by Americans is estimated to be approximately 100 ug/d.

Deficiency The symptoms of vitamin K deficiency are due to hemorrhage, and newborns are particularly susceptible because of low fat stores, low breast milk levels of vitamin K, sterility of the infantile intestinal tract, liver immaturity, and poor placental transport. Intracranial bleeding, as well as gastrointestinal and skin bleeding, can be seen in vitamin K-deficient infants 1 to 7 days after birth. Thus, vitamin K (1 mg intramuscularly) is given prophylactically at the time of delivery.

Vitamin K deficiency in adults may be seen in patients with chronic small-intestinal disease (e.g., celiac disease, Crohn's disease), obstructed biliary tracts, or after small-bowel resection. Broad-spectrum antibiotic treatment can precipitate vitamin K deficiency by reducing gut bacteria, which synthesize menaquinones, as well as by inhibiting the metabolism of vitamin K. The diagnosis of vitamin K deficiency is usually made on the basis of an elevated prothrombin time or reduced clotting factors. Vitamin K may also be measured directly byHPLC. In addition, undercarboxylated prothrombin and low gla levels in urine are indicative of vitamin K deficiency. Vitamin K deficiency is treated using a parenteral dose of 10 mg. For patients with chronic malabsorption, 1 to 2 mg/d of vitamin K may be given orally, or 1 to 2 mg/week can be taken parenterally. Patients with liver disease may have an elevated prothrombin time because of liver cell destruction as well as vitamin K deficiency. If an elevated prothrombin time does not improve on vitamin K therapy, it can be assumed that it is not the result of vitamin K deficiency.

Toxicity Parenteral doses of the water-soluble vitamin K derivative (menadione) have been reported to cause hemolytic anemia and hypobilirubinemia in infants. Toxicity from dietary phylloquinones and menaquinones has not been described. High doses of vitamin K can impair the actions of oral anticoagulants.

TRACE MINERALS (See Table 75-1)

ZINC

Zinc is an integral component of many metalloenzymes in the body; it is involved in the synthesis and stabilization of proteins, DNA, and RNA and plays a structural role in ribosomes and membranes. Zinc is necessary for the binding of steroid hormone receptors and several other transcription factors to DNA and thereby plays an important

role in the regulation of gene transcription. Zinc is absolutely required for normal spermatogenesis, fetal growth, and embryonic development.

Absorption and Physiology Zinc is absorbed in the small intestine by a carrier-mediated mechanism. The absorption of zinc from the diet is inhibited by dietary phytate, fiber, oxalate, iron, and copper, as well as by certain drugs including penicillamine, sodium valproate, and ethambutol. TheRDA for zinc is 15 mg in males and 12 mg in females, with an additional 3 mg in pregnancy and 4 to 7 mg during lactation. Supplemental zinc is recommended for women taking ³60 mg/d of iron during pregnancy.

Meat, shellfish, nuts, and legumes are good sources of bioavailable zinc, whereas zinc in grains is less available for absorption. Zinc is excreted mainly in the feces but also in urine and sweat. The body contains approximately 2 g of zinc, and high concentrations are found in liver, prostate, pancreas, bone, and brain (hippocampus and cerebral cortex), where the metal may function in neural transmission.

Deficiency Mild zinc deficiency has been described in many diseases including diabetes mellitus, AIDS, cirrhosis, alcoholism, inflammatory bowel disease, malabsorption syndromes, and sickle cell anemia (Figs. 75-CD2 and75-CD3). In these diseases, mild chronic zinc deficiency can cause stunted growth in children, decreased taste sensation (hypogusia), impaired immune function, and night blindness due to impaired conversion of retinol to retinaldehyde. Severe chronic zinc deficiency has been described as a cause of hypogonadism and dwarfism in several Middle Eastern countries. In these children, hypopigmented hair is also part of the syndrome. Acrodermatitis enteropathica is a rare autosomal recessive disorder characterized by abnormalities in zinc absorption. Clinical manifestations include diarrhea, alopecia, muscle wasting, depression, irritability, and a rash involving the extremities, face, and perineum. The rash is characterized by vesicular and pustular crusting with scaling and erythema. In addition, hypopigmentation and corneal edema have been described in these patients. Occasional patients with Wilson's disease have developed zinc deficiency as a consequence of penicillamine therapy. Patients on long-term parenteral nutrition have developed deficiency when zinc has been omitted from the total parenteral nutrition (TPN) solution.

The diagnosis of zinc deficiency is usually made by a serum zinc level of <12 umol/L (<70 ug/dL). Pregnancy and birth control pills may cause a slight depression in serum zinc levels, and hypoalbuminemia from any cause can result in hypozincemia. In acute stress situations, zinc may be redistributed from serum into tissues. Zinc deficiency may be treated with 60 mg elemental zinc, given orally twice a day. Zinc gluconate lozenges (13 mg elemental Zn every 2 h while awake) have been reported to reduce the duration and symptoms of the common cold in adults, but these studies are conflicting.

Toxicity Acute zinc toxicity after oral ingestion causes nausea and vomiting, fever, and respiratory distress. Zinc fumes from welding may also be toxic and cause fever, chills, excessive salivation, sweating, and headache. Chronic large doses of zinc may depress immune function and cause hypochromic anemia as a result of copper deficiency.

COPPER

Copper is an integral part of numerous enzyme systems including amine oxidases, ferrooxidase (ceruloplasmin), cytochrome-*c* oxidase, superoxide dismutase, and dopamine hydroxylase. As such, copper plays a role in iron metabolism, melanin synthesis, and central nervous system function; the synthesis and cross-linking of elastin and collagen; and the scavenging of superoxide radicals.

Copper is absorbed in the proximal small intestine, and 90% of circulating copper is bound to ceruloplasmin. The body contains 50 to 120 mg of copper, and high concentrations are found in liver, brain, heart, spleen, kidney, and blood. The U.S.RDA is 1.5 to 3 mg of copper intake per day, although World Health Organization recommendations are somewhat lower. Dietary sources of copper include shellfish, liver, nuts, legumes, bran, and organ meats, whereas milk is a very poor source. Copper is primarily excreted in the feces, and small amounts are also excreted in urine.

Deficiency Dietary copper deficiency is relatively rare, although it has been described in premature infants fed milk diets and in infants with malabsorption. Signs and symptoms of copper deficiency include a hypochromic-normocytic anemia, osteopenia, depigmentation, mental retardation, and psychomotor abnormalities. Copper deficiency anemia has been reported in patients with malabsorptive diseases and nephrotic syndrome and in patients treated for Wilson's disease with chronic high doses of oral zinc, which can interfere with copper absorption. Menkes kinky hair syndrome is an X-linked metabolic disturbance of copper metabolism characterized by mental retardation, hypocupremia, and decreased circulating ceruloplasmin (Chap. 351). It is caused by mutations in a copper-transporting *ATP7A* gene. Children with this disease often die within 5 years due to dissecting aneurysms or cardiac rupture.

The diagnosis of copper deficiency is usually made on the basis of low serum levels of copper (<65 ug/dL) and low ceruloplasmin levels (<18 mg/dL). Serum levels of copper may be elevated in pregnancy or stress conditions since ceruloplasmin is an acute-phase reactant.

Toxicity Toxicity due to copper is usually accidental and may include nausea, vomiting, diarrhea, and hemolytic anemia. In severe cases, kidney failure, liver failure, and coma may ensue. In Wilson's disease, mutations in the copper-transporting *ATP7B* gene lead to accumulation of copper in the liver and brain, with low blood levels due to decreased ceruloplasmin (Chap. 348). Indian childhood cirrhosis is another hereditary disease characterized by extremely high copper levels in the liver. The World Health Organization recommends that adult females should not ingest>10 mg/d and males should not take in>12 mg/d of copper.

SELENIUM

Selenium, in the form of selenocysteine, is a component of the enzyme glutathione peroxidase, which serves to protect proteins, cell membranes, lipids, and nucleic acids from oxidant molecules. Selenocysteine is also found in the deiodinase enzymes, which mediate the deiodination of thyroxine to the more active triiodothyronine (Chap. 330). Rich sources of selenium include seafood, muscle meat, and cereals, although the selenium content of cereal is determined by the soil concentration. Countries with low

soil concentrations include parts of Scandinavia, China, and New Zealand. *Keshan disease* is an endemic cardiomyopathy found in children and young women residing in regions of China where dietary intake of selenium is low (<20 ug/d). Concomitant deficiencies of iodine and selenium may worsen the clinical manifestations of cretinism. The adultRDAs for selenium in the United States are 55 and 70 ug/d for females and males, respectively. Low blood levels of selenium in various populations have been correlated with an increase in coronary artery disease and certain cancers, although the data are not consistent. Selenosis occurs at intakes of[3]400 ug/d and can result in nausea, vomiting, loss of hair, nail changes, peripheral neuropathy, and fatigue.

CHROMIUM

Chromium potentiates the action of insulin in patients with impaired glucose tolerance, presumably by increasing insulin receptor-mediated signaling. In addition, in some patients, improvement in blood lipid profiles has been reported. The usefulness of chromium supplements in muscle building are not substantiated. Rich food sources of chromium include yeast, meat, and grain products. Chromium deficiency has been reported to cause glucose intolerance, peripheral neuropathy, and confusion. The suggested intake of chromium for adults is 50 to 200 ug/d. Chromium in the trivalent state is found in supplements and is largely nontoxic; however, chromium-6 is a product of stainless steel welding and is a known pulmonary carcinogen, as well as causing liver, kidney, and central nervous system.

MAGNESIUM SeeChap. 340

FLUORIDE, MANGANESE, AND ULTRATRACE ELEMENTS

An essential function for *fluoride* in humans has not been described, although it is useful for the maintenance of structure in teeth and bone. An adequate intake for fluoride (on the basis of protection against dental caries) has been set at 3.1 and 3.8 mg/d in adult females and males, respectively. Adult fluorosis can occur at an intake of 10 mg/d for prolonged periods and results in mottled and pitted defects in tooth enamel as well as brittle bone (skeletal fluorosis). Much lower doses of fluoride (0.7 to 2 mg) can cause dental fluorosis or mottled enamel in infants and children.

Manganese and molybdenum deficiencies have been reported in patients with rare genetic abnormalities as well as in a few patients receiving prolongedTPN. Several manganese-specific enzymes have been identified (e.g., manganese superoxide dismutase). The estimated adequate daily dietary *manganese* intake for adults is 2 to 3 mg/d. Deficiencies of manganese have been reported to result in bone demineralization, poor growth, ataxia, and convulsions.

Ultratrace elements are those for which the need is <1 mg/d. Essentiality has not been established for most ultratrace elements, although *iodine* is clearly essential (Chap. 330). *Molybenum* is necessary for the activity of sulfite and xanthine oxidase, and molybdenum deficiency may result in skeletal and brain lesions. The minimum required daily molybdenum intake is estimated to be ~25 ug/d. There is circumstantial evidence to suggest that *arsenic* (impaired growth, infertility), *boron* (impaired energy metabolism, impaired brain function), *nickel* (impaired-growth and reproduction), *silicon* (impaired

growth) and *vanadium* (impaired skeletal formation) might also be essential.

76. ENTERAL AND PARENTERAL NUTRITION THERAPY - *Lyn Howard*

Parenteral and enteral nutrition provide life-sustaining therapy for patients who cannot take adequate food by mouth and who consequently are at risk for malnutrition and its effects, including susceptibility to infection, weakness and immobility; these features predispose the patient to aspiration pneumonia, pulmonary embolism, and pressure sores, all of which delay recovery from illness and increase mortality.

The term *enteral* refers to feeding via the gut and hence includes normal eating, but in the present context implies the infusion of formulas via a tube into the upper gastrointestinal tract. *Parenteral* refers to the infusion of nutrient solutions into the bloodstream. While these are different approaches to nutritional support, their goals are the same. Where feasible, enteral nutrition is the preferred route because it sustains the digestive, absorptive, and immunologic barrier functions of the gastrointestinal tract. The cost of enteral tube feeding is about one-tenth the cost of parenteral feeding.

Several developments have made tube feeding easier and more acceptable to patients. Small-bore pliable tubes have largely replaced large-bore rubber tubes, and double-lumen tubes are now available for simultaneous gastric suction and jejunal feeding when there is concern about gastric retention and aspiration. Enteral tubes can be inserted into the stomach or jejunum through the nose or, for long-term use, directly through the abdominal wall, using endoscopic, radiologic, or surgical techniques. Once the enterocutaneous tract is established, the protruding tube can be replaced by a "button" entry port, flush with the abdominal wall.

Complete nutrition by vein with sufficient calories, amino acids, minerals, and vitamins to permit wound healing, restoration of normal body composition of a cachectic patient, or growth in children became feasible in the 1960s with the development of high-flow central vein catheters. Parental nutrition is now available in all large hospitals and for some patients at home. Adequate calories and other nutrients can be delivered in the form of high-energy, isotonic intravenous fat solutions via a peripheral vein. However, peripheral veins usually cannot sustain such infusions indefinitely, and long-term support requires central venous access.

THE DECISION PROCESS FOR USING PARENTERAL OR ENTERAL NUTRITION

The decision to use specialized nutrition support should be based on the likelihood that averting or redressing malnutrition will improve the quality of life or the ability to recover from a serious illness.

Approximately 15 to 20% of hospitalized patients have evidence of malnutrition. Some malnourished patients benefit from specialized nutrition support; for others, wasting is an inevitable component of a terminal disease. Selecting the appropriate form of nutritional support for the patient requires knowledge of the potential benefits and risks of nutritional support, and the physician must inform the patient and family of these issues. A flow diagram of the steps involved in deciding whether specialized nutrition support should be undertaken and, if so, how, is depicted in Fig. 76-1. Like all life-support measures, these therapies are difficult to withdraw once started.

The first step requires consideration of the nutritional implications of the disease process. Is the condition or its treatment likely to impair appetite or food ingestion and absorption for a prolonged period of time? Because prevention of malnutrition is easier than repleting a cachectic patient, this issue must be considered in the initial evaluation (Chap. 74). The second step is to determine whether the patient is already sufficiently malnourished that lean body mass is decreased and critical functions such as healing and ventilation are impaired. The presence or absence of metabolic stress should be noted, since injury or infection can evoke the secretion of hormonal and cytokine factors that reduce the efficiency of nutrition repletion.

Weight loss without physiologic impairment is probably of no consequence. Physiologic impairment usually develops when more than 20% of body protein is lost and is more likely if key organ systems, such as the gut or liver, are directly affected by disease. Once it is recognized that the patient is malnourished or at major risk, the next question is whether specialized nutritional support will impact positively on the patient's response to the disease, improving the quality of life. While the provision of food and water is part of basic medical care, nutrition support by enteral or parenteral means is associated with risk and discomfort and should be recommended only when potential benefit exceeds risk and undertaken only with the consent of the patient.

If it is decided that preventing or treating malnutrition with specialized nutrition support would improve the prognosis and quality of life, the nutritional requirements must be determined and the route of nutrient delivery must be selected.

RISKS AND BENEFITS OF NUTRITION SUPPORT

The risks are determined primarily by the route required to deliver nutrition support. Providing nutritional requirements by special attention to oral intake of food, or by adding oral liquid supplements and monitoring food intake with frequent calorie counts, is the safest and least costly approach. It is also the most metabolically efficient since normal eating initiates the cephalic phase of digestion. Tube-fed infants grow better if the cephalic phase is stimulated by having the infant suck on a pacifier.

Anorexia, impairment of swallowing, or bowel disease may limit oral intake or the absorption of oral nutrients, in which case tube enteral nutrition is the next consideration. The bowel and its associated digestive organs derive 70% of their required nutrients directly from food in the lumen. In addition, glutamine, short-chain fatty acids, and nucleotides may have particular importance in maintaining gut integrity. Enteral feeding also supports gut function by stimulating splanchnic blood flow, neuronal activity, IgA antibody release, and secretion of gastrointestinal hormones such as epidermal growth factor that stimulate gut trophic activity. All these factors support the gut as an immunologic barrier against enteric pathogens, reducing the likelihood of bacterial overgrowth. For these reasons, some enteral nutrition should always be provided if possible, even when parenteral nutrition is required to provide most of the support. In the past, bowel rest through parenteral nutrition was thought to be the cornerstone of treatment of many severe gastrointestinal disorders, but the value of some enteral nutrition is now widely accepted, and strict bowel rest is rarely appropriate. Parenteral nutrition alone is necessary in severe hemorrhagic pancreatitis, necrotizing enterocolitis, prolonged ileus, and distal bowel obstruction.

Specialized nutrition support is expensive, accounting for >1% of all health care dollars. Consequently, hard clinical endpoints such as mortality rate, incidence of major complications, and duration of hospital stay are required of risk-benefit studies. Better nitrogen balance, increased levels of serum albumin, and improved delayed hypersensitivity are softer endpoints.Table 76-1 summarizes clinical trials that evaluate the use of specialized nutrition support in different disease states.

Perioperative Nutrition There is a clear-cut association between preoperative malnutrition and poor surgical outcome, but it has been difficult to demonstrate the benefit of preoperative parenteral nutrition on the outcome of surgery in malnourished patients. However, a meta-analysis of several small studies and a large cooperative Veterans Administration study indicates that preoperative parenteral nutrition does improve the outcome of severely malnourished surgical patients. In treated patients, noninfectious complications (e.g., pulmonary emboli and delayed wound healing) are reduced in the postoperative period. Effective preoperative restoration of nutrition by the parenteral route requires at least 7 to 14 days. If feasible, a safer and less costly approach is preoperative enteral nutrition, especially if provided at home.

Immediate postoperative nutritional support is appropriate for patients who received preoperative support and for patients unlikely to resume oral feeding within 10 days. The parenteral route is commonly used because of postoperative ileus or concern about disrupting a new bowel anastomosis. However, cautious jejunal feeding is often tolerated. Specialized enteral formulas supplemented with conditionally essential nutrients may be particularly beneficial in debilitated and immunosuppressed postoperative patients (Table 76-2).

Critical Illness Very early nutrition support (within the first 48 h) improves survival and reduces infections and length of hospital stay in patients with severe head injuries, burns, and major abdominal trauma. Enteral therapy, where feasible, is superior to parenteral therapy in several randomized trials. Enteral nutrition equally benefits malnourished and well-nourished injured patients. Animal studies show that enteral feeding reduces translocation of gut bacteria and the systemic catabolic response; however, these phenomena have not been substantiated in humans. Early enteral feeding may prevent bacterial overgrowth and decrease aspiration pneumonia.

The practical issue is obtaining jejunal access in a critically ill patient, who is not easily transferred out of the intensive care unit for endoscopic or radiologic tube placement. Sometimes a nasal or percutaneous combined gastric suction and jejunal feeding tube can be inserted at the bedside. If a surgical laparotomy is indicated, a feeding tube can be placed simultaneously.

Most studies of enteral feeding in critically ill patients used either a general polymeric formula or one with hydrolyzed protein. Formulas supplemented with conditionally essential nutrients reduce infections and length of hospital stay. Parenteral formulas enriched with large amounts of branched-chain amino acids (BCAA) improve nitrogen balance but do not appear to affect clinical outcome.

Cancer Cachexia Early nonrandomized studies suggested that patients with cancer

cachexia benefitted from parenteral nutrition, but randomized trials demonstrated more risk than benefit for patients receiving chemotherapy or radiation. Severely malnourished cancer patients undergoing surgery benefit from preoperative parenteral nutrition, as do other malnourished patients.

In two randomized, prospective trials, patients undergoing bone marrow transplantation had better long-term survival after parenteral or enteral nutrition in the cytoreduction phase; nutrition support did not influence the initial infection rate or the frequency of graft rejection or graft-versus-host disease. Immediate morbidity is reduced if glutamine supplements are added to the parenteral nutrition solution. Parenteral nutrition continued at home delays return to oral feeding. For cancer patients with unresectable upper gastroinstestinal cancer, enteral feeding is usually justified if it is desired by the patient and family. Parenteral feeding should be provided only if clinical improvement can be expected and when quality survival at home for several months is predicted.

Liver Failure Malnutrition is common in advanced liver disease. Patients with acute or chronic liver failure have decreased levels ofBCAA and elevated levels of aromatic amino acids (AAA) in plasma and cerebrospinal fluid. Randomized, prospective trials with parenteral and enteral formulas high in BCAA and low in AAA have demonstrated better nitrogen balance and less risk of encephalopathy. One large multicenter study also reported improved survival. The BCAA-enriched formulas are expensive and should be used only in patients who have encephalopathy or who develop encephalopathy when fed a standard protein formula providing 0.8 g protein/kg per day.

Renal Failure Since renal failure is associated with impaired nitrogen excretion, it is rational to assume that protein restriction might benefit patients with both acute and chronic renal failure. Patients with acute renal failure given parenteral calories and amino acids have fewer infectious complications and a better chance of leaving the hospital than similar patients given only calories. An early randomized study showed benefit when essential amino acids were the sole source of nitrogen, but in other studies, standard solutions supplying both essential and nonessential amino acids provide similar advantage. Thus, the benefit of using expensive formulas containing only essential amino acids or their keto analogues is not established. A large national study failed to show any benefit of a low-protein diet on slowing progression of renal impairment in patients on chronic dialysis. Some 15 to 20% of patients on chronic dialysis have significant nutritional impairment, usually due to profound anorexia. The anorexia may improve with stepped-up dialysis or treatment of gastritis but usually persists. The resulting growth impairment in younger patients has been treated with supplemental tube enteral nutrition. This approach has not been widely used in adult patients. Limited parenteral calories and amino acids can be provided in the last 90 min of hemodialysis treatment (intradialytic parenteral nutrition). This may improve appetite, serum protein levels, and body weight. No randomized studies have documented better survival, so the appropriateness of this regimen is not established. Standard dialysis uses glucose to provide an osmotic load, and some glucose calories are absorbed. During continuous ambulatory peritoneal dialysis, amino acids can be substituted for glucose and are also partly absorbed, offsetting the loss of endogenous amino acids into the dialysate. This approach to nutrition repletion is expensive and also awaits a randomized study.

Pancreatitis Parenteral nutrition does not improve the outcome of patients with mild or moderate pancreatitis. However, in severe pancreatitis, survival decreases as malnutrition becomes more severe. When parenteral nutrition support was delayed beyond 72 h, patients with severe pancreatitis had a threefold higher complication and mortality rate, compared to similar patients treated earlier. In the absence of severe hyperlipidemia or thrombocytopenia, intravenous lipids appear safe and are especially useful if glucose intolerance is present. Several studies report successful enteral jejunal feeding in acute pancreatitis and, compared to parenteral nutrition, the inflammatory response and infectious complications are less.

Inflammatory Bowel Disease Evidence of nutritional deficiencies such as weight loss, growth failure, anemia, and hypoalbuminenia are common in inflammatory bowel disease (IBD), more so in Crohn's disease than in ulcerative colitis (Chap. 287). Nutrition support plays a role in correcting these nutritional deficiencies, particularly prior to elective surgery. Since IBD often improves with diversion of the fecal stream, the question is whether bowel rest and parenteral nutrition have a role as primary treatment. However, randomized, prospective studies have shown no special benefit from bowel rest. Elemental diets are not quite as effective as glucocorticoids for inducing remission in acute Crohn's disease but may be preferable in children to avoid growth impairment. Relapse is common when a regular diet is resumed. In controlled studies, remissions are prolonged if the Crohn's patient does not return to a regular diet but instead eliminates from the diet those foods that induce gastrointestinal symptoms. For the majority of Crohn's patients this leads to avoidance of cereals, yeast, green vegetables, and, early on, dairy products. Because of the possibility that diets high in omega-3 fatty acids have a beneficial effect in immune disorders by altering prostaglandin synthesis, their value in IBD is under investigation. Some studies suggest that high-fiber diets benefit IBD patients, but fiber can also cause obstruction in patients with bowel strictures.

Short Bowel Syndrome Before the advent of parenteral nutrition, patients with acute short bowel syndrome from mesenteric vascular infarction or massive small bowel surgical resection seldom survived. Parenteral nutrition has allowed many patients to survive indefinitely with only a foot or two of small intestine. In some, the remaining bowel eventually adapts and allows the absorption of adequate calories and protein. This is especially true of patients who retain their iliocecal valve and colon. However, fluid and electrolyte imbalance may persist, necessitating some parenteral fluid and electrolyte support. A gradual switch to overnight tube enteral hydration or constant sipping of an electrolyte solution may allow discontinuation of all parenteral support.

Pulmonary Disease Weight loss in patients with advanced pulmonary disease is due to increased work of breathing and poor food intake. Patients with chronic pulmonary disease who are<90% of their ideal weight have a higher 5-year mortality, independent of pulmonary status. The recommended energy intake for these patients is 1.7 times their resting energy expenditure. The use of a low-carbohydrate formula is beneficial in the weaning of patients from ventilators, but the superiority of such formulas in ambulatory patients with chronic lung disease is not established. In cystic fibrosis, malnutrition may hasten pulmonary deterioration, and enteral tube feeding enhances growth and stabilizes or improves pulmonary function, particularly in young children. Tube feeding is safest when delivered into the jejunum. Postpyloric feeding is no safer

than gastric feeding.

HIV Disease Specialized nutrition support can replete body cell mass if the weight loss is due to inadequate oral intake caused by oral or esophageal disease or to inadequate intestinal absorption, which is common in HIV patients with cryptosporidosis or microsporidiosis infections (Chap. 309). The route of nutrition support has usually been parenteral, but patients respond equally well with an isocaloric semi-elemental oral diet. Patients using the oral supplement experience a better quality of life, and their medical costs are significantly lower. Wasting due to systemic infection and increased cytokine secretion is not redressed by specialized nutrition support. Survival, CD4+ counts, and intestinal function also are not improved by specialized nutrition support.

Pregnancy Severe hyperemesis gravidarum can make any oral or tube enteral nutrition impossible, and profound weight loss and ketosis may harm the developing fetus. The underlying mechanism of the disorder is not understood, but it is cured by abortion or delivery. Temporary parenteral nutrition usually results in a successful outcome, but nausea and vomiting tend to persist, despite bowel rest.

Home Parenteral and Enteral Nutrition Some patients require long-term nutrition support, and for many this can be administered at home. Clinical outcomes of patients with severe intestinal disorders that used either parenteral or enteral nutrition are summarized in Table 76-3. Nutrition support is not usually appropriate in terminally ill patients but is an option if the patient is expected to survive for several months. Such therapy must make sense to the patient, and sufficient help must be available so the treatment can be given at home without undue hazard. Both home therapies are relatively safe, with<5% therapy-related mortality.

THE DESIGN OF INDIVIDUAL REGIMENS

Fluid Requirements These can be estimated by adding the normal daily requirement (120 mL/kg of body weight for infants, 35 mL/kg of body weight for adults) to any abnormal loss. If the patient is on parenteral therapy, any enteral intake should be subtracted from the estimate (Table 76-4). Since abnormal loss of enteric fluid implies significant mineral losses, extra amounts of these nutrients, as well as fluid (Table 76-5), must be added to the parenteral formula.

Energy Requirements These can be determined as outlined in Chaps. 73 and74. In the long run, energy expenditure dictates energy requirements, but in the early phase of nutrition repletion, requirements may not reflect expenditure. For example, malnourished patients are hypometabolic and may expend only 85 kJ/kg (20 kcal/kg) per day, but more calories are needed both for tissue repletion and because the metabolic rate increases with refeeding. Conversely, a highly stressed patient (sepsis, trauma) may expend 165 kJ/kg (40 kcal/kg) per day with a significant proportion of the calories coming from protein breakdown and gluconeogenesis and from catecholamine-induced lipolysis. Oxidation of exogenous glucose plateaus at 100 kJ/kg (25 kcal/kg) per day, and administering additional glucose induces hepatic steatosis. Providing such patients with additional calories as exogenous fat does not suppress endogenous lipolysis. Furthermore, lipid solutions are made from vegetable oil and egg phospholipid and lack apoproteins, which they acquire from endogenous lipoproteins.

Initially, the artificial chylomicron may be taken up by the reticuloendothelial system enhancing its blockade. For all these reasons, modest hypocaloric glucose feeding with minimal parenteral fat is safer in the acutely stressed subject.

Parenteral lipid solutions are available as 10 or 20% isotonic solutions and are infused separately from amino acids and glucose or as a combined "three-in-one solution," obviating the need for an extra pump. Three-in-one solutions are less stable than the glucose and amino acid mix, and destabilized fat particles have the potential to coalesce into larger droplets, becoming fat emboli. For this reason, three-in-one solutions have a shorter storage life and must be mixed by a pharmacist knowledgeable about the correct mixing sequence and safe levels of electrolytes and trace elements. Iron, for example, cannot be added to this solution.

Polyunsaturated vegetable oils are used in most enteral formulas because they are absorbed better than animal fat by a diseased gastrointestinal tract. Fat must supply the essential fatty acid requirement (1 to 4% of energy from linoleic and linolenic acid) (Table 76-6). Larger amounts (30% of energy) are safe in relatively stable patients and avoid the problems of providing large amounts of glucose (e.g., hyperglycemia and hepatic steatosis). Substituting omega-3 polyunsaturated fish oils for polyunsaturated vegetable fats may reduce the catabolic response to burn injury, trauma, and radiation by reducing the synthesis of prostaglandins that enhance the inflammatory response (Table 76-2). Such fats are available in enteral formulas and are currently being tested in parenteral formulas.

Protein or Amino Acid Requirements The recommended dietary protein allowance of 0.8 g/kg per day is adequate for nonstressed patients, such as a starved patient with a high-grade esophageal stricture. Catabolic patients, in contrast, may require up to 1.5 g/kg per day of protein to induce positive nitrogen balance and reconstitute normal body mass. Early studies showed that recombinant human growth hormone (rHGH) increases lean body mass. However, subsequent trials have shown that it is associated with increased mortality in critically ill patients, and it should not be used in this setting.

In a stable patient the adequacy of protein support can be assessed by analyzing protein balance:

where protein loss= [(24-h urine urea nitrogen (g) + 4)´ 6.25]. Over a long period, protein balance is assessed by documenting wound healing, restoration of normal body composition, or resumption of longitudinal growth. In states of disturbed protein utilization (e.g., renal and hepatic failure), azotemia and abnormal plasma amino acid patterns develop. The benefit of special enteral and parenteral solutions that correct these aberrations is only established in hepatic encephalopathy (see "Risks and Benefits of Nutrition Support").

Certain nutrients that can normally be synthesized endogenously become essential in severely ill patients when endogenous production or salvage pathways are impaired. This is true of glutamine, nucleotides, and the products of methionine metabolism (Table 76-2). Glutamine, an important fuel for the enterocyte and lymphocyte, is fairly insoluble

and is absent from standard parenteral formulas and present in low concentrations in most enteral formulas. Soluble glutamine-containing dipeptides are under investigation.

Nucleotides and their related metabolic products have beneficial effects on the immune system, growth of the small intestine, lipid metabolism, and hepatic function. Nucleotides can be synthesized de novo in all cells only in small amounts, and the body therefore depends on dietary nucleotides or on salvage pathways that recycle nucleotides from purine and pyrimidine turnover. Nutritionally depleted patients benefit from formulas enriched in nucleotides.

When amino acids are infused systemically, rather than via the more physiologic portal vein, methionine, the only sulfur-containing amino acid in most parenteral solutions, is transaminated in peripheral tissues rather than transulfurated in the liver. As a result, downstream sulfur products such as carnitine, taurine, and glutathione become relatively deficient (Chap. 352). Preliminary studies suggest that the addition of an intermediate compound, *S*-adenosyl methionine, to parenteral solutions results in less cholestasis.

Mineral and Vitamin Requirements Parenteral and enteral mineral and vitamin requirements are summarized in Table 76-6. Electrolyte modifications are necessary if the patient has significant gastrointestinal losses (Table 76-5) or renal failure. Requirements of some minerals and vitamins are higher when administered parenterally for several reasons: (1) many micronutrients delivered into the systemic rather than the portal circulation are not captured by the liver and instead pass directly into the urine; (2) patients with bowel disease may have enteric loss of sodium, potassium, chloride, and bicarbonate and malabsorption of divalent cations, fat-soluble vitamins, and vitamin B_{12}; and (3) nutrients may adhere to the tubing and delivery bags, and exposure to oxygen and light may destroy vitamins (particularly vitamin A).

PARENTERAL NUTRITION

Infusion Technique and Patient Monitoring Partial and short-term total parenteral nutrition can be provided via a peripheral vein if the majority of the energy is supplied by isotonic fat solutions; long-term total parenteral nutrition using glucose as the chief energy source requires administration via a central vein catheter so the hypertonic solution can be rapidly diluted in a high-flow system. The preferred site for central vein infusion is the superior vena cava. Access sites and catheter choices are summarized inTable 76-7. Peripherally inserted central catheters are the most economical option for short-term parenteral nutrition. In one randomized study, the number of catheter-related infections was the same with peripherally and centrally inserted catheters. Tunneled catheters and implanted subcutaneous ports require operating room insertion and are more stable for long-term use. Central catheters should be changed when clinically indicated; routine changes are costly and hazardous. Chlorhexidine solution is a more effective local antiseptic than iodophor or alcohol. Although transparent dressings are helpful in stabilizing catheters and allow easy observation of the skin site, the incidence of catheter-related sepsis is higher than with traditional dry gauze dressings; newer transparent dressings that trap less moisture are under investigation. Catheters made from Silastic material or polyurethane are associated with lower complications than polyvinylchloride catheters. Several types of needleless systems use hub valves, and

contamination rates are higher with these devices when used for long-term parenteral nutrition. Appropriate clinical and laboratory monitoring for patients on parenteral nutrition are summarized inTable 76-8.

Complications (See Table 76-9)

Mechanical The insertion of a central venous catheter should be done only by trained personnel under aseptic techniques. Major mechanical complications include pneumothorax; hemothorax from laceration of the subclavian artery or vein; brachial plexus injury; and malpositioning of the catheter in a cerebral vein, the azygos vein, or the right ventricle. The correct catheter position must be confirmed by x-ray before hypertonic nutrient solution is infused. Catheters can subsequently dislocate, develop leaks, or become detached from the hub and embolize into the heart or pulmonary artery. Catheter thrombosis may occur, especially if the catheter is used for withdrawing blood samples, and extension of the thrombosis to the central vein is frequently coincident with infection. Thrombosed catheters can sometimes be unblocked by urokinase treatment. The addition of low-dose heparin (1000 U/L) to limit thrombosis in parenteral catheters is controversial; no randomized, controlled studies demonstrate benefit, and heparin can contribute to loss of bone mineral, which is already a problem with long-term parenteral nutrition.

Metabolic Fluid overload can cause congestive heart failure, particularly in elderly and debilitated patients. Glucose overload can cause an osmotic diuresis or stimulate insulin secretion, which in turn promotes extracellular to intracellular shifts of potassium and phosphorous. Such shifts are most dangerous in cachectic patients with depletion of potassium and phosphorus stores and can cause arrhythmias, cardiopulmonary dysfunction, and neurologic symptoms. To avoid these problems, parenteral nutrition should be started slowly and monitored carefully. Glucose content is increased gradually as the patient demonstrates tolerance of the high glucose load. Late metabolic complications include cholestatic liver disease with bile sludging and gallstone formation. The exact cause of the liver disease is not understood, but lack of enteral stimulation to bile flow and defective sulfur amino acid metabolism and cholesterol solubilization appear to play a role. Cholestasis is less likely to occur if some enteral feeding is maintained. Parenteral nutrition induces hypercalciuria, which can result in negative calcium balance and osteopenia. Hypercalciuria may have several causes, including the high fixed-acid load of infused amino acids and the bisulfite preservative in parenteral solutions. Earlier, protein hydrolysates were used as an amino acid source and were contaminated with aluminum, which blocked bone mineralization. Aluminum is still a contaminant of some additives such as calcium gluconate. Once patients on long-term parenteral nutrition change from catabolic breakdown to sustained anabolism, deficiencies of micronutrients such as essential fatty acids, trace minerals, and vitamins may develop unless they are supplied in adequate amounts (Table 76-6).

Infectious Infection of the access line rarely occurs in the first 72 h, and fever during this period is usually due to infection elsewhere or some other cause. Infection of the access line is likely if the fever defervesces when the infusion of the parenteral formula is tapered.

Positive central line cultures suggest catheter sepsis, especially if no other infectious

source is identified and if the organism is *Staphylococcus* or *Candida*. Although removal of the central catheter may allow fungemia to clear spontaneously, antibiotic therapy is recommended for bacterial infections and the more invasive fungi. Catheter sepsis rates are similar in single lumen central lines dedicated to parenteral nutrition whether inserted peripherally via the subclavian vein or tunneled; multiple-lumen catheters are associated with a greater incidence of sepsis. While there is no evidence to support the use of prophylactic antibiotics, recurrent catheter sepsis may be avoided if cuffs are used around the catheter exit site or small amounts of an antibiotic solution are left in the line along with a heparin lock.

ENTERAL NUTRITION

Tube Placement and Patient Monitoring The types of enteral feeding tubes, methods of insertion, their clinical uses, and potential complications are outlined inTable 76-10. The different types of enteral formulas are listed in Table 76-11. Patients on enteral feeding are at risk for many of the same metabolic complications as those receiving parenteral nutrition and should be monitored in the same way (Table 76-8). Since small-bore tubes are easily displaced, tube position should be checked at intervals by aspirating and measuring the pH of the gut fluid (<4 in stomach,>6 in jejunum).

Complications

Aspiration The debilitated patient with poor gastric emptying and impairment of swallowing and cough mechanisms is at risk for aspiration; this is particularly so for those on respirators. Tracheal suctioning induces coughing and gastric regurgitation, and cuffs on endotracheal or tracheostomy tubes seldom provide protection against aspiration. Under these circumstances, it may be safer to use a large-bore feeding tube to allow for temporary removal of gastric contents during tracheal suction or to use jejunal feeding. Constant gastric infusion of an enteral formula is better tolerated in sick patients than intermittent bolus feeding. A continuous infusion is best achieved with a pump, especially when using fine-bore tubes that have a greater potential to clog. If long-term feeding is anticipated, endoscopic, radiologic, or surgical placement of a gastric tube is preferred by most patients. For long-term ambulatory patients, a gastrostomy tube can be converted to a gastric "button," an access device that is flush with the skin. A nasojejunal tube reduces the risk of aspiration. However, fluoroscopically guided placement of fine-bore tubes through the pylorus is time-consuming, and such tubes frequently pull back into the stomach. A percutaneous combined gastric-suction and jejunal-feeding tube is more reliable. This can be placed radiologically, endoscopically, or surgically.

Diarrhea Enteral feeding often causes diarrhea, especially if bowel function is compromised by bowel disease or drugs. The diarrhea may be controlled by the use of continuous feeding of fiber-containing formulas or by adding an anticholinergic medication to the formula. Diarrhea associated with enteral feeding does not necessarily imply inadequate absorption of nutrients, other than water and electrolytes. Furthermore, since luminal nutrients exert trophic effects on the gut mucosa and enhance the enteric immunologic barrier, it is often appropriate to persist with tube feeding, despite the diarrhea, even when this necessitates supplemental parenteral fluid support.

THE SCOPE AND COST OF NUTRITION SUPPORT

As many as 25% of patients entering tertiary care hospitals have central catheters placed, and 20 to 30% of these catheters are used for parenteral nutrition. The incidence of catheter-related infection reflects the severity of the underlying medical condition and varies from 2 to 30 per thousand catheter days, depending on the type of patients involved. In critically ill patients, catheter sepsis is associated with a 35% mortality rate and a high cost per survivor. Most catheter-related complications derive from faulty insertion and management of the catheter rather than defects in the device. In large tertiary care hospitals, the insertion and management of these lines by specially trained teams can reduce complications by 80%, impacting significantly on outcome and costs. A growing shift from parenteral to enteral nutrition also promises significant cost savings. Home parenteral nutrition costs approximately half as much as similar treatment in the hospital, and home enteral nutrition costs much less.

77. OBESITY - *Jeffrey S. Flier*

In a world where food supplies are intermittent, the ability to store energy in excess of what is required for immediate use is essential for survival. Fat cells, residing within widely distributed adipose tissue depots, are adapted to store excess energy efficiently as triglyceride and, when needed, to release stored energy as free fatty acids for use at other sites. This physiologic system, orchestrated through endocrine and neural pathways, permits humans to survive starvation for as long as several months. However, in the presence of nutritional abundance and a sedentary lifestyle, and influenced importantly by genetic endowment, this system increases adipose energy stores and produces adverse health consequences.

DEFINITION AND MEASUREMENT

Obesity is a state of excess adipose tissue mass. Although often viewed as equivalent to increased body weight, this need not be the case -- lean but very muscular individuals may be overweight by arbitrary standards without having increased adiposity. Body weights are distributed continuously in populations, so that a medically meaningful distinction between lean and obese is somewhat arbitrary. Obesity is therefore more effectively defined by assessing its linkage to morbidity or mortality.

Although not a direct measure of adiposity, the most widely used method to gauge obesity is the *body mass index* (BMI), which is equal to weight/height$_2$(in kg/m$_2$) (Fig. 77-1). Other approaches to quantifying obesity include anthropometry (skin-fold thickness), densitometry (underwater weighing), computed tomography (CT) or magnetic resonance imaging (MRI), and electrical impedance. Using data from the Metropolitan Life Tables, BMIs for the midpoint of all heights and frames among both men and women range from 19 to 26 kg/m$_2$; at a similar BMI, women have more body fat than men. Based on unequivocal data of substantial morbidity, a BMI of 30 is most commonly used as a threshold for obesity in both men and women. Large-scale epidemiologic studies suggest that all-cause, metabolic, and cardiovascular morbidity begin to rise (albeit at a slow rate) when BMIs are ^{3} 25, suggesting that the cut-off for obesity should be lowered. Some authorities use the term *overweight* (rather than obese) to describe individuals with BMIs between 25 or 27 and 30. A BMI between 25 and 30 should be viewed as medically significant and worthy of therapeutic intervention, especially in the presence of risk factors that are influenced by adiposity, such as hypertension and glucose intolerance.

The distribution of adipose tissue in different anatomic depots also has substantial implications for morbidity. Specifically, intraabdominal and abdominal subcutaneous fat have more significance than subcutaneous fat present in the buttocks and lower extremities. This distinction is most easily made by determining the waist-to-hip ratio, with a ratio >0.9 in women and>1.0 in men being abnormal. Many of the most important complications of obesity, such as insulin resistance, diabetes, hypertension, and hyperlipidemia, and hyperandrogenism in women, are linked more strongly to intraabdominal and/or upper body fat than to overall adiposity. The mechanism underlying this association is unknown but may relate to the fact that intraabdominal adipocytes are more lipolytically active than those from other depots. Release of free fatty acids into the portal circulation has adverse metabolic actions, especially on the

liver.

PREVALENCE

Recent data from the National Health and Nutrition Examination Surveys (NHANES) show that the percent of the American adult population with obesity (BMI> 30) has increased from 14.5% (between 1976 and 1980) to 22.5% (between 1998 and 1994). As many as 50% of U.S. adults³20 years of age were overweight (defined as BMI> 25) between the years of 1998 and 1991. Because substantial health risks exist in many individuals with BMI between 25 and 30, the increasing prevalence of medically significant obesity raises great concern. Obesity is more common among women and in the poor; the prevalence in children is also rising at a worrisome rate.

PHYSIOLOGIC REGULATION OF ENERGY BALANCE

Substantial evidence suggests that body weight is regulated by both endocrine and neural components that ultimately influence the effector arms of energy intake and expenditure. This complex regulatory system is necessary because even small imbalances between energy intake and expenditure will ultimately have large effects on body weight. For example, a 0.3% positive imbalance over 30 years would result in a 9-kg (20-lb) weight gain. Alterations in stable weight by forced overfeeding or food deprivation induce physiologic changes that resist these perturbations: with weight loss, appetite increases and energy expenditure falls; with overfeeding, appetite falls and energy expenditure increases. This latter compensatory mechanism frequently fails, however, permitting obesity to develop when food is abundant and physical activity is limited. A major regulator of these adaptative responses is the adipocyte-derived hormone leptin, which acts through brain circuits (predominantly in the hypothalamus) to influence appetite, energy expenditure, and neuroendocrine function (see below).

Appetite is influenced by many factors that are integrated by the brain, most importantly within the hypothalamus (Fig. 77-2). Signals that impinge on the hypothalamic center include neural afferents, hormones, and metabolites. Vagal inputs are particularly important, bringing information from viscera, such as gut distention. Hormonal signals include leptin, insulin, cortisol, and gut peptides such as cholecystokinin, which signals to the brain through the vagus nerve. Metabolites, including glucose, can influence appetite, as seen by the effect of hypoglycemia to induce hunger; however, glucose is not normally a major regulator of appetite. These diverse hormonal, metabolic, and neural signals act by influencing the expression and release of various hypothalamic peptides [e.g., neuropeptide Y (NPY), Agouti-related peptide (AgRP),a melanocyte-stimulating hormone (MSH), and melanin concentrating hormone (MCH)] that are integrated with serotonergic, catecholaminergic, and opioid signaling pathways (see below). Psychological and cultural factors also appear to play a role in the final expression of appetite. Apart from rare syndromes involving leptin, its receptor, and the melanocortin system (see below), the defects in this complex appetite control network that account for common causes of obesity are not well understood.

Energy expenditure includes the following components: (1) resting or basal metabolic rate; (2) the energy cost of metabolizing and storing food; (3) the thermic effect of exercise; and (4) adaptive thermogenesis, which varies in response to chronic caloric

intake (rising with increased intake). Basal metabolic rate accounts for about 70% of daily energy expenditure, whereas active physical activity contributes 5 to 10%. Thus, a significant component of daily energy consumption is fixed.

Adaptive thermogenesis occurs in *brown adipose tissue* (BAT), which plays an important role in energy metabolism in many mammals. In contrast to white adipose tissue, which is used to store energy in the form of lipids, BAT expends stored energy as heat. A mitochondrial *uncoupling protein* (UCP-1) in BAT dissipates the hydrogen ion gradient in the oxidative respiration chain and releases energy as heat. The metabolic activity of BAT is increased by a central action of leptin, acting through the sympathetic nervous system, which heavily innervates this tissue. In rodents, BAT deficiency causes obesity and diabetes; stimulation of BAT with a specific adrenergic agonist ($\beta_3$agonist) protects against diabetes and obesity. Although BAT exists in humans (especially neonates), its physiologic role is not yet established. Homologues of UCP-1 may mediate uncoupled mitochondrial respiration in other tissues.

THE ADIPOCYTE AND ADIPOSE TISSUE

Adipose tissue is composed of the lipid-storing adipose cell and a stromal/vascular compartment in which preadipocytes reside. Adipose mass increases by enlargement of adipose cells through lipid deposition, as well as by an increase in the number of adipocytes. The process by which adipose cells are derived from a mesenchymal preadipocyte involves an orchestrated series of differentiation steps mediated by a cascade of specific transcription factors. One of the key transcription factors is *peroxisome proliferator-activated receptor* g(PPARg), a nuclear receptor that binds the thiazoladinedione class of insulin-sensitizing drugs used in the treatment of type 2 diabetes (Chap. 333).

Although the adipocyte has generally been regarded as a storage depot for fat, it is also an endocrine cell that releases numerous molecules in a regulated fashion (Fig. 77-3). These include the energy balance-regulating hormone leptin, cytokines such as tumor necrosis factor (TNF)a, complement factors such as factor D (also known as adipsin), prothrombotic agents such as plasminogen activator inhibitor I, and a component of the blood pressure regulating system, angiotensinogen. These factors, and others not yet identified, play a role in the physiology of lipid homeostasis, insulin sensitivity, blood pressure control, and coagulation and are likely to contribute to obesity-related pathologies.

ETIOLOGY OF OBESITY

Though the molecular pathways regulating energy balance are beginning to be illuminated, the causes of obesity remain elusive. In part, this reflects the fact that obesity is a heterogeneous group of disorders. At one level, the pathophysiology of obesity seems simple: a chronic excess of nutrient intake relative to the level of energy expenditure. However, due to the complexity of the neuroendocrine and metabolic systems that regulate energy intake, storage, and expenditure, it has been difficult to quantitate all the relevant parameters (e.g., food intake and energy expenditure) over time in human subjects.

Role of Genes vs. Environment Obesity is commonly seen in families. Inheritance is usually not Mendelian, however, and it is difficult to distinguish the role of genes and environmental factors. Adoptees usually resemble their biologic rather than adoptive parents with respect to obesity, providing strong support for genetic influences. Likewise, identical twins have very similarBMIswhether reared together or apart, and their BMIs are much more strongly correlated than those of dizygotic twins. These genetic effects appear to relate to both energy intake and expenditure.

Whatever the role of genes, it is clear that the environment plays a key role in obesity, as evidenced by the fact that famine prevents obesity in even the most obesity-prone individual. In addition, the recent increase in the prevalence of obesity in the United States is too rapid to be due to changes in the gene pool. Cultural factors are also important -- these relate to both availability and composition of the diet and to changes in the level of physical activity. In industrial societies, obesity is more common among poor women, whereas in underdeveloped countries, wealthier women are more often obese. In children, obesity correlates to some degree with time spent watching television. High-fat diets may promote obesity, as may diets rich in simple (as opposed to complex) carbohydrates.

Specific Genetic Syndromes Obesity in rodents has been known for many years to be caused by a number of distinct mutations distributed through the genome. Most of these single-gene mutations cause both hyperphagia and diminished energy expenditure, suggesting a link between these two parameters of energy homeostasis. Identification of the *ob* gene mutation in genetically obese (ob/ob) mice represents a major breakthrough in the field. The ob/ob mouse develops severe obesity, insulin resistance, and hyperphagia, as well as efficient metabolism (e.g., it gets fat even when given the same number of calories as lean littermates). The product of the *ob* gene is the peptide leptin, a name derived from the Greek root *leptos*, meaning thin. Leptin is secreted by adipose cells and acts through the hypothalamus. Its level of production provides an index of adipose energy stores (Fig. 77-4). High leptin levels decrease food intake and increase energy expenditure. Another mouse mutant, db/db, which is resistant to leptin, has a mutation in the leptin receptor and develops a similar syndrome. The *ob* gene is present in humans and expressed in fat. Several families with morbid, early-onset obesity due to inactivating mutations in either leptin or the leptin receptor have been described, thus demonstrating the biologic relevance of leptin in humans. The obesity in these individuals begins shortly after birth, is severe, and is accompanied by neuroendocrine abnormalities. The most prominent of these is hypogonadotropic hypogonadism, which is reversed by leptin replacement. Central hypothyroidism and growth retardation are seen in the mouse model, but their occurrence in leptin-deficient humans is less clear. To date, there is no evidence to suggest that mutations or polymorphisms in the leptin or leptin receptor genes play a prominent role in common forms of obesity.

Mutations in several other genes cause severe obesity in humans (Table 77-1), each of these syndromes is rare. Mutations in the gene encoding proopiomelanocortin (POMC) cause severe obesity through failure to synthesizea-MSH, a key neuropeptide that inhibits appetite in the hypothalamus. The absence of POMC also causes secondary adrenal insufficiency due to absence of adrenocorticotropic hormone (ACTH), as well as pale skin and red hair due to absence of MSH. Proenzyme convertase 1 (PC-1)

mutations are thought to cause obesity by preventing synthesis of a-MSH from its precursor peptide, POMC. a-MSH binds to the type 4 melanocortin receptor (MC4R), a key hypothalamic receptor that inhibits eating; mutations of this receptor also cause obesity. These three genetic defects, although rare, define a pathway through which leptin (by stimulating POMC and increasing MSH) restricts food intake and limits weight (Fig. 77-5).

In addition to these human obesity genes, studies in rodents reveal several other molecular candidates for hypothalamic mediators of human obesity or leanness. The *tub* gene encodes a hypothalamic peptide of unknown function; mutation of this gene causes late-onset obesity. The *fat* gene encodes carboxypeptidase E, a peptide-processing enzyme; mutation of this gene is thought to cause obesity by disrupting production of one or more neuropeptides.AgRP is coexpressed withNPY in arcuate nucleus neurons. AgRP antagonizesa-MSHaction at MC4 receptors, and its overexpression induces obesity. A putative activating mutation in the gene encoding PPARg, the adipocyte transcription factor required for adipogenesis, has been linked to obesity in a group of German subjects.

A number of complex human syndromes with defined inheritance are associated with obesity (Table 77-2). Although specific genes are undefined at present, their identification will likely enhance our understanding of more common forms of human obesity. In the Prader-Willi syndrome, obesity coexists with short stature, mental retardation, hypogonadotropic hypogonadism, hypotonia, small hands and feet, fish-shaped mouth, and hyperphagia. Most patients have a chromosome 15 deletion (Chap. 66). Laurence-Moon-Biedl syndrome involves obesity, mental retardation, retinitis pigmentosa, polydactyly, and hypogonadotropic hypogonadism.

Other Specific Syndromes Associated with Obesity

Cushing's Syndrome Although obese patients commonly have central obesity, hypertension, and glucose intolerance, they lack other specific stigmata of Cushing's syndrome (Chap. 331). Nonetheless, a potential diagnosis of Cushing's syndrome is often entertained. Cortisol production and urinary metabolites (17OH steroids) may be increased in simple obesity. Unlike in Cushing's syndrome, however, cortisol levels in blood and urine in the basal state and in response to CRH orACTH are normal; the overnight 1-mg dexamethasone suppression test is normal in 90%, with the remainder being normal on a standard 2-day low-dose dexamethasone suppression test.

Hypothyroidism The possibility of hypothyroidism should be considered when evaluating obesity, but it is an uncommon cause of obesity; hypothyroidism is easily ruled out by measuring thyroid stimulating hormone (TSH). Much of the weight gain that occurs in hypothyroidism is due to myxedema (Chap. 330).

Insulinoma Patients with insulinoma often gain weight as a result of overeating to avoid hypoglycemia symptoms (Chap. 334). The increased substrate plus high insulin levels promotes energy storage in fat. This can be marked in some individuals but is modest in most.

Craniopharyngioma and Other Disorders Involving the Hypothalamus Whether through

tumors, trauma, or inflammation, hypothalamic dysfunction of systems controlling satiety, hunger, and energy expenditure can cause varying degrees of obesity (Chap. 328). It is uncommon to identify a discrete anatomic basis for these disorders. Subtle hypothalamic dysfunction is probably a more common cause of obesity than can be documented using currently available techniques. Growth hormone (GH), which exerts lipolytic activity, is diminished in obesity and increases with weight loss. Despite low growth hormone levels, insulin-like growth factor (IGF) I (somatomedin) production is normal, suggesting that GH suppression is a compensatory response to increased nutritional supply.

Pathogenesis of Common Obesity Obesity can result from increased energy intake, decreased energy expenditure, or a combination of the two. Thus, identifying the etiology of obesity should involve measurements of both parameters. However, it is nearly impossible to perform direct and accurate measurements of energy intake in free-living individuals. Obese people, in particular, appear to underreport intake. Measurements of chronic energy expenditure have only recently become available using doubly-labeled water or metabolic chamber/rooms. In subjects at stable weight and body composition, energy intake equals expenditure. Consequently, these techniques allow determination of energy intake in free-living individuals. The level of energy expenditure differs in established obesity, during periods of weight gain or loss, and in the pre- or postobese state. Studies that fail to take note of this phenomenon are not easily interpreted.

There is increased interest in the concept of a body weight "set point." This idea is supported by physiologic mechanisms centered around a sensing system in adipose tissue that reflects fat stores, and a receptor, or "adipostat," that is in the hypothalamic centers. When fat stores are depleted, the adipostat signal is low, and the hypothalamus responds by stimulating hunger and decreasing energy expenditure to conserve energy. Conversely, when fat stores are abundant, the signal is increased, and the hypothalamus responds by decreasing hunger and increasing energy expenditure. The recent discovery of the *ob* gene, and its product leptin, provides a molecular basis for this physiologic concept (see above).

What Is the Status of Food Intake in Obesity (Do the Obese Eat More Than the Lean?) This question has stimulated much debate, due in part to the methodologic difficulties inherent in determining food intake. Many obese individuals believe that they eat small quantities of food, and this claim has often been supported by the results of food intake questionnaires. However, it is now established that average energy expenditure increases as people get more obese, due primarily to the fact that metabolically active lean tissue mass increases with obesity. Given the laws of thermodynamics, the obese person must therefore eat more than the average lean person to maintain their increased weight. It may be the case, however, that a subset of individuals who are predisposed to obesity have the capacity to become obese initially without an absolute increase in caloric consumption.

What Is the State of Energy Expenditure in Obesity? The average total daily energy expenditure is higher in obese than lean individuals when measured at stable weight. However, energy expenditure falls as weight is lost, due in part to loss of lean body mass and to decreased sympathetic nerve activity. When reduced to near-normal

weight and maintained there for a while, (some) obese individuals have lower energy expenditure than (some) lean individuals. There is also a tendency for those who develop obesity as infants or children to have lower resting energy expenditure rates than those who remain lean.

The physiologic basis for variable rates of energy expenditure (at a given body weight and level of energy intake) is essentially unknown. A mutation in the human β_3-adrenergic receptor may be associated with increased risk of obesity and/or insulin resistance in certain (but not all) populations. Homologues of the BAT uncoupling protein, named UCP-2 and UCP-3, have been identified in both rodents and humans. UCP-2 is expressed widely, whereas UCP-3 is primarily expressed in skeletal muscle. These proteins may play a role in disordered energy balance.

One newly described component of thermogenesis, called *nonexercise activity thermogenesis* (NEAT), has been linked to obesity. It is the thermogenesis that accompanies physical activities other than volitional exercise, such as the activities of daily living, fidgeting, spontaneous muscle contraction, and maintaining posture. NEAT accounts for about two-thirds of the increased daily energy expenditure induced by overfeeding. The wide variation in fat storage seen in overfed individuals is predicted by the degree to which NEAT is induced. The molecular basis for NEAT and its regulation are unknown.

Leptin in Typical Obesity The vast majority of obese people have increased leptin levels but do not have mutations of either leptin or its receptor. They appear, therefore, to have a form of functional "leptin resistance." Data suggesting that some individuals produce less leptin per unit fat mass than others or have a form of relative leptin deficiency that predisposes to obesity are at present contradictory and unsettled. The mechanism for leptin resistance, and whether it can be overcome by raising leptin levels, is not yet established. Some data suggest that leptin may not effectively cross the blood-brain barrier as levels rise. It is also possible that leptin signaling inhibitors are involved in the leptin-resistant state.

PATHOLOGIC CONSEQUENCES OF OBESITY

Obesity has major adverse effects on health. Morbidly obese individuals (>200% ideal body weight) have as much as a twelvefold increase in mortality. Morality rates rise as obesity increases, particularly when obesity is associated with increased intraabdominal fat (see above). It is also apparent that the degree to which obesity affects particular organ systems is influenced by susceptibility genes that vary in the population.

Insulin Resistance and Type 2 Diabetes Mellitus Hyperinsulinemia and insulin resistance are pervasive features of obesity, increasing with weight gain and diminishing with weight loss. Insulin resistance is more strongly linked to intraabdominal fat than to fat in other depots. The molecular link between obesity and insulin resistance has been sought for many years, with the major factors under investigation being: (1) insulin itself, by inducing receptor downregulation; (2) free fatty acids, known to be increased and capable of impairing insulin action; and (3) the cytokine TNF-a, which is produced by adipocytes, overexpressed in obese adipocytes, and capable of inhibiting insulin action. Despite insulin resistance, most obese individuals do not develop diabetes, suggesting

that the onset of diabetes requires an interaction between obesity-induced insulin resistance and other factors that predispose to diabetes, such as impaired insulin secretion (Chap. 333). Obesity, however, is a major risk factor for diabetes, and as many as 80% of patients with type 2 diabetes mellitus are obese. Weight loss, even of modest degree, is associated with increased insulin sensitivity and often improves glucose control in diabetes.

Reproductive Disorders Disorders that affect the reproductive axis are associated with obesity in both men and women. Male hypogonadism is associated with increased adipose tissue, often distributed in a pattern more typical of females. In men>160% ideal body weight, plasma testosterone and sex hormone-binding globulin (SHBG) are often reduced, and estrogen levels (derived from conversion of adrenal androgens in adipose tissue) are increased (Chap. 335). Gynecomastia may be seen. However, masculinization, libido, potency, and spermatogenesis are preserved in most of these individuals. Free testosterone may be decreased in morbidly obese men whose weight exceeds 200% ideal body weight.

Obesity has long been associated with menstrual abnormalities in women, particularly in women with upper body obesity (Chaps. 52 and336). Common findings are increased androgen production, decreasedSHBG, and increased peripheral conversion of androgen to estrogen. Most obese women with oligomenorrhea have the polycystic ovarian syndrome (PCOS), with its associated anovulation and ovarian hyperandrogenism; 40% of women with PCOS are obese. Interestingly, most nonobese women with PCOS are also insulin-resistant, suggesting that insulin resistance, hyperinsulinemia, or the combination of the two are causative or contribute to the ovarian pathophysiology in PCOS in both obese and lean individuals. In obese women with PCOS, weight loss or treatment with insulin-sensitizing drugs often restores normal menses, along with a fall in estrone levels and normalized gonadotropin secretion. The increased conversion of androstenedione to estrogen, which occurs to a greater degree in women with lower body obesity, may contribute to the increased incidence of uterine cancer in postmenopausal women with obesity.

Cardiovascular Disease The Framingham Study revealed that obesity was an independent risk factor for the 26-year incidence of cardiovascular disease in men and women [including coronary disease, stroke, and congestive heart failure (CHF)]. The waist/hip ratio may be the best predictor of these risks. When the additional effects of hypertension and glucose intolerance associated with obesity are included, the adverse impact of obesity is even more evident. The effect of obesity on cardiovascular mortality in women may be seen atBMIs as low as 25. Obesity, especially abdominal obesity, is associated with an atherogenic lipid profile, with increased low-density lipoprotein (LDL) cholesterol, very low density lipoprotein and triglyceride, and decreased high-density lipoprotein cholesterol (Chap. 344). Obesity is also associated with hypertension. Measurement of blood pressure in the obese requires use of a larger cuff size to avoid artifactual increases. Obesity-induced hypertension is associated with increased peripheral resistance and cardiac output, increased sympathetic nervous system tone, increased salt sensitivity, and insulin-mediated salt retention; it is often responsive to modest weight loss.

Pulmonary Disease Obesity may be associated with a number of pulmonary

abnormalities. These include reduced chest wall compliance, increased work of breathing, increased minute ventilation due to increased metabolic rate, and decreased total lung capacity and functional residual capacity (Chap. 250). Severe obesity may be associated with obstructive sleep apnea and the "obesity hypoventilation syndrome" (Chap. 263). Sleep apnea can be obstructive (most common), central, or mixed. Weight loss (10 to 20 kg) can bring substantial improvement, as can major weight loss following gastric bypass or restrictive surgery. Continuous positive airway pressure has been used with some success.

Gallstones Obesity is associated with enhanced biliary secretion of cholesterol, supersaturation of bile, and a higher incidence of gallstones, particularly cholesterol gallstones (Chap. 302). A person 50% above ideal body weight has about a sixfold increased incidence of symptomatic gallstones. Paradoxically, fasting increases supersaturation of bile by decreasing the phospholipid component. Fasting-induced cholecystitis is a complication of extreme diets.

Cancer Obesity in males is associated with higher mortality from cancer of the colon, rectum, and prostate; obesity in females is associated with higher mortality from cancer of the gallbladder, bile ducts, breasts, endometrium, cervix, and ovaries. Some of the latter may be due to increased rates of conversion of androstenedione to estrone in adipose tissue of obese individuals.

Bone, Joint, and Cutaneous Disease Obesity is associated with an increased risk of osteoarthritis, no doubt partly due to the trauma of added weight bearing. The prevalence of gout may also be increased (Chap. 322). Among the skin problems associated with obesity is acanthosis nigricans, manifested by darkening and thickening of the skin folds on the neck, elbows, and dorsal interphalangeal spaces. Acanthosis reflects the severity of underlying insulin resistance and diminishes with weight loss. Friability of skin may be increased, especially in skin folds, enhancing the risk of fungal and yeast infections. Finally, venous stasis is increased in the obese.

TREATMENT

Obesity is a chronic medical condition. Successful treatment, defined as the sustained attainment of normal body weight without producing unacceptable treatment-induced morbidity, is rarely achieved in clinical practice. Many approaches produce short-term weight loss, and this has clear benefits for associated morbidities such as hypertension and diabetes. Despite the fact that sustained weight loss is uncommon, enormous resources are expended in pursuit of this goal.

Treatment goals should be guided by the health risks of obesity in any given individual (Fig. 77-6). The clinician should always consider the possibility that an individual has an identified cause of obesity, such as hypothyroidism, hypercortisolism, male hypogonadism, insulinoma, or central nervous system disease that affects hypothalamic function. Although they are infrequent causes of obesity, specific therapy may be available.

Behavior Modification The principles of behavior modification provide the underpinnings for many current programs of weight reduction. Typically, the patient is

requested to monitor and record the circumstances related to eating, and rewards are designed to modify maladaptive behaviors. Patients may benefit from counseling offered in a stable group setting for extended periods of time, including after weight loss.

Diet Reduced caloric intake is the cornerstone of obesity treatment. The fundamental goal is the sustained reduction of energy intake below that of energy expenditure. The difficulty in achieving this goal has led to a wide array of suggested diets that vary in recommended calorie content (from total fasting to mild reductions), as well as specific food content and form (e.g., liquid vs. solid). There is no scientific evidence to validate the utility of specific "fad diets." The main diet regimens in use follow several general facts relevant to food intake and weight loss. First, a deficit of 7500 kcal will produce a weight loss of approximately 1 kg. Therefore, eating 100 kcal/d less for a year should cause a 5-kg weight loss, and a deficit of 1000 kcal/d should cause a loss of approximately 1 kg per week. The rate of weight loss on a given caloric intake is related to the rate of energy expenditure. Because obese individuals have a higher metabolic rate than lean individuals, and because men have a higher metabolic rate than women (due to their greater lean body mass), the rate of weight loss is greater among the more obese and among men (relative to women). With chronic caloric restriction, metabolic rate diminishes, but because of reduced lean body mass (along with much greater loss in fat mass) and possibly because of other adaptations. This fall in metabolic rate with food restriction slows the rate of weight loss on a constant diet. With total starvation or diets restricted to<600 kcal/d, initial weight loss over the first week results predominantly from natriuresis and the loss of fluids.

Very low energy diets (e.g., 400 to 600 kcal/d) are widely used. The liquid protein diets popularized in the 1970s were proved to be unsafe, causing >60 deaths. Life-threatening arrhythmias were documented in the clinical research setting, a consequence of both low-quality protein and deficiencies of vitamins, minerals, and trace elements. These types of diets have now been substantially modified. A very low energy diet consisting of 45 to 70 g high-quality protein, 30 to 50 g carbohydrate, and approximately 2 g fat per day, as well as supplements of vitamins, minerals, and trace elements, appears to be safe in selected patients under medical supervision. Patients should not be started on such diets unless they are >130% of their ideal body weight. Contraindications include pregnancy, cancer, recent myocardial infarction, cerebrovascular disease, hepatic disease, or untreated psychiatric disease. When used in patients with diabetes who are receiving insulin or oral agent therapy, close supervision is required and diabetic treatment may need to be adjusted. Whenever possible, exercise regimens and behavioral modification approaches should be used in conjunction with the diet.

Advantages of very low calorie diets are the greater rate of weight loss compared to less restrictive diets, as well as the possible beneficial effect of hunger suppression brought about by the production of ketones. In patients on such diets, blood pressure, blood glucose, cholesterol, and triglyceride levels fall, and pulmonary function and exercise tolerance improve. Sleep apnea may improve within a few weeks. Complications of these very low energy diets are usually minor and include fatigue, constipation or diarrhea, dry skin, hair loss, menstrual irregularities, orthostatic dizziness, and difficulty concentrating. Cholelithiasis and pancreatitis may occur when such diets are interrupted by binge eating; gallstones have been shown to develop in as many as 25% of patients

while on the diet.

Low-calorie diets,>800 kcal/d, are applicable to most patients and have fewer restrictions than the very low calorie diets. Considerable controversy has attended the question of which diet composition is most appropriate for promoting weight loss. Though commonly recommended, benefits resulting from very low fat diets are modest at best. Nonetheless, the health effects of low-fat diets -- apart from curbing obesity -- may be important. A diet rich in fruits, vegetables, and whole grains may promote weight loss and is preferable to low-fat diets in which large amounts of simple carbohydrates are substituted for fats. The latter may actually promote obesity. Some have advocated diets with protein replacement of simple carbohydrates in an effort to minimize insulin production. The efficacy of this strategy, aside from overall calorie reduction, is unknown.

Exercise Exercise is an important component of the overall approach to treating obesity. Increased energy expenditure is the most obvious mechanism for an effect of exercise. The impact of an exercise regimen as a sole therapy of obesity has been difficult to document. On the other hand, exercise appears to be a valuable means to sustain diet therapy (Fig. 77-7). Even if exercise had no such salutary effect, it would be valuable in the obese individual for its effects on cardiovascular tone and blood pressure. Because many obese individuals have not engaged in exercise on a regular basis and may have cardiovascular risk factors, it should be introduced gradually and under medical supervision, especially in the most obese individuals.

Drugs Unfortunately, drug treatment of obesity is rarely efficacious. Despite short-term benefits, medication-induced weight loss is often associated with rebound weight gain after the cessation of drug use, side effects from the medications, and the potential for drug abuse. Given the need for effective therapies, many possible compounds have been evaluated. On the basis of placebo-controlled trials, the U.S. Food and Drug Administration (FDA) approved several amphetamine-like agents for short-term use. Phentermine is an amphetamine-like drug with low addictive potential that has shown modest efficacy (10 vs. 4.4 kg of weight loss over a 24-week period in well-controlled study). This class of drugs is thought to act centrally by reducing appetite. Effects on energy expenditure are less clear. Over-the-counter drugs, such as phenylpropanolamine HCl, have similar efficacy to prescription appetite suppressants in short-term studies. Drugs that promote serotonin release or inhibit serotonin reuptake, such as fenfluramine, also have modest efficacy. When fenfluramine was administered together with phentermine, as "fen-phen," the combination was widely used based on controlled trials that demonstrated modest but definite efficacy. However, the risk of primary pulmonary hypertension was increased up to 20-fold in association with this treatment. The FDA withdrew approval of the fen-phen combination in 1997 when reports suggested an association with right- and left-sided valvular heart disease. The histopathologic features of the valvular disease are similar to those seen in carcinoid syndrome and are thought to result from fenfluramine. Though the true incidence and long-term effects of these valvular lesions are currently unknown, the occurrence of this complication has been verified in multiple studies.

Sibutramine is a novel central reuptake inhibitor of both norepinephrine and serotonin. Using a once-daily dose over 24 weeks, it produced a 7% weight loss in a double-blind,

placebo-controlled trial. It lowered cholesterol and triglyceride levels and exhibited similar clinical efficacy to fenfluramine. Sibutramine increases pulse and blood pressure in some patients, and long-term safety is not established. Orlistat is an inhibitor of intestinal lipase that causes modest weight loss due to drug-induced fat malabsorption. A randomized, double-blind trial over 2 years revealed modest weight loss (8.7 kg for 120 mg orlistat versus 5.8 kg from diet alone) during the first year and better maintenance of weight loss in a second year compared to the placebo-treated group (3.2 kg regained versus 5.6 kg regained for placebo). LDL cholesterol and insulin levels were also reduced. In patients with obesity and type 2 diabetes mellitus, the antidiabetic medication metformin tends to decrease body weight. The mechanism appears to involve inhibition of appetite. Thyroid hormone has little place in the treatment of obesity, as the vast majority of obese individuals are euthyroid. It promotes loss of lean body mass and raises the risk of complications from the hyperthyroid state.

b_3-Adrenergic receptor agonists may provide a new treatment approach for obesity. Drugs of this class are in clinical trials. In animals, b_3 agonists promote leanness by stimulating thermogenesis in BAT; they also stimulate lipolysis in white adipose tissue. These drugs also reduce insulin resistance and lower blood glucose in animal models by a mechanism that is not yet defined. Recombinant human leptin is also in clinical trials. In the rare cases of leptin deficiency caused by mutations of the leptin gene, the administration of recombinant leptin is highly effective. Preliminary reports suggest that the response to leptin is limited or absent in common causes of obesity (which are associated with hyperleptinemia and leptin resistance). New drugs are also being developed based on insights into central pathways that regulate body weight. These include antagonists for NPY receptors (subtypes Y1, Y5) and agonists for melanocortin 4 receptors.

Surgery Morbid obesity, commonly defined as either 45 kg (100 lb) or 100% above ideal body weight, is estimated to increase mortality by as much as twelvefold in men between 25 and 34 years of age and sixfold between 35 and 45 years of age. Deaths from cardiovascular disease, diabetes, and accidents have been documented. In response to ineffective treatment using diet, exercise, and available drugs, surgical approaches have been tried. The potential benefits of surgery include major weight loss and improvement in hypertension, diabetes, sleep apnea, CHF, angina, hyperlipidemia, and venous disease. Many different approaches have been used, often without adequate assessment of efficacy and complications. Jejunoileal bypass surgery has largely been abandoned because of complications, which have included electrolyte disturbances, nephrolithiasis, gallstones, gastric ulcers, arthritis, and hepatic dysfunction, with cirrhosis occurring in as many as 7% of patients. Two procedures in common use today are the vertical-banded gastroplasty and the Roux-en-Y gastric bypass (Fig. 77-8).

Following the National Institutes of Health Consensus Conference on Gastrointestinal Surgery for Severe Obesity in 1991, it was recommended that suitable patients be selected using the following criteria: (1) the presence of 45 kg (100 lb) or 100% above ideal body weight, or one or more severe medical conditions related to refractory obesity; (2) repeated failures of other therapeutic approaches; (3) at eligible weight for 3 to 5 years; (4) capability of tolerating surgery; (5) absence of alcoholism, other addictions, or major psychopathology; and (6) prior clearance by a psychiatrist. It is

recommended that an appropriately experienced surgeon work together with nutritionists and other support personnel; evaluation and follow-up programs should be monitored closely.

78. EATING DISORDERS - *B. Timothy Walsh*

Anorexia nervosa and bulimia nervosa are characterized by severe disturbances of eating behavior. The salient feature of *anorexia nervosa* is a refusal to maintain a minimally normal body weight. *Bulimia nervosa* is characterized by recurrent episodes of binge eating followed by abnormal compensatory behaviors, such as self-induced vomiting. Anorexia nervosa and bulimia nervosa are closely related. Both occur primarily among previously healthy young women who become overly concerned with body shape and weight. Many patients with bulimia nervosa have past histories of anorexia nervosa, and many patients with anorexia nervosa engage in binge eating and purging behavior. In the current diagnostic system, the critical distinction between anorexia nervosa and bulimia nervosa depends on body weight: patients with anorexia nervosa are, by definition, significantly underweight, whereas the weights of patients with bulimia nervosa are in the normal range or above.

Another syndrome of disturbed eating behavior has been described recently: *Binge eating disorder* is characterized by repeated episodes of binge eating, similar to those of bulimia nervosa, in the absence of inappropriate compensatory behavior. Patients with binge eating disorder are typically middle-aged men or women with significant obesity. They have an increased frequency of anxiety and depression compared to similarly obese patients without binge eating disorder. It is not known whether patients with binge eating disorder are at increased risk for medical complications or what treatments are most useful.

EPIDEMIOLOGY

In women, the full syndrome of anorexia nervosa occurs with a lifetime prevalence of approximately 0.5%; bulimia nervosa occurs with a lifetime prevalence of 1 to 3%. Variants of these eating disorders with only some features of anorexia nervosa or bulimia nervosa are much more common and occur in 5 to 10% of young women. Both anorexia nervosa and bulimia nervosa also occur in males but at frequencies approximately one-tenth of those in females.

Anorexia nervosa and bulimia nervosa are more prevalent in cultures where food is plentiful and in which being thin is associated with attractiveness. These disorders are more frequent among young women who place a premium on thinness, such as ballet dancers and models. The incidence of anorexia nervosa appears to have increased in recent decades. The frequency of bulimia nervosa increased dramatically in the early 1970s and 1980s but may have declined somewhat in recent years.

DIAGNOSIS

The diagnosis of eating disorders is based on the presence of characteristic behavioral, psychological, and physical attributes (Tables 78-1 and78-2). Widely accepted diagnostic criteria are provided by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV).

ANOREXIA NERVOSA

For anorexia nervosa, these criteria include weight <85% of the expected weight for age and height, which is roughly equivalent to a body mass index (BMI) of 18.5 kg/$m_2$for adult women. This weight criterion is somewhat arbitrary, so that a patient who meets all other diagnostic criteria but weighs between 85 and 90% of expected would still merit the diagnosis of anorexia nervosa. Despite being underweight, patients with anorexia nervosa are irrationally afraid of gaining weight, often out of a concern that weight gain will get "out of control." They also exhibit a distortion of body image (criterion 3,Table 78-1), which may express itself in several ways. For example, despite being emaciated, patients with anorexia nervosa may believe that their body as a whole, or some part of their body, is too fat and experience additional weight loss as a highly rewarding achievement. The current diagnostic criteria require that women with anorexia nervosa not have spontaneous menses, but occasional patients with the characteristics and complications of anorexia nervosa describe regular menses. Two mutually exclusive subtypes of anorexia nervosa are specified inDSM-IV. Patients whose weight loss is maintained primarily by caloric restriction, perhaps augmented by excessive exercise, are considered to have the "restricting" subtype of anorexia nervosa. The "binge eating/purging" subtype is characterized by self-induced vomiting or laxative abuse. Patients with the binge/purge subtype are more prone to develop electrolyte imbalances, are more emotionally labile, and are more likely to have other problems with impulse control, such as drug abuse.

The diagnosis of anorexia nervosa can usually be made confidently on the basis of history when significant weight loss is accomplished by restrictive dieting and excessive exercise and is accompanied by a marked reluctance to gain weight. Patients with anorexia nervosa often deny that they have a serious problem and may be brought to medical attention by concerned family or friends. In atypical presentations, other causes of significant weight loss in previously healthy young people should be considered, including inflammatory bowel disease, gastric outlet obstruction, central nervous system (CNS) tumors, and neoplasm (Chap. 43).

BULIMIA NERVOSA

The critical diagnostic features of bulimia nervosa are repeated episodes of binge eating followed by inappropriate and abnormal behaviors aimed at avoiding weight gain. During binges, patients with this disorder tend to consume large amounts of sweet foods with a high fat content, such as dessert items. The most frequent compensatory behaviors are self-induced vomiting and laxative abuse, but a wide variety of techniques have been described, including the omission of insulin injections by diabetics. Typically, patients with bulimia nervosa are ashamed of their behavior and endeavor to keep their disorder hidden from family and friends. Like patients with anorexia nervosa, those with bulimia nervosa place an unusual emphasis on weight and shape as a basis for their self-esteem.

As in anorexia nervosa, there are two mutually exclusive subtypes of bulimia nervosa. Patients with the "purging" subtype utilize compensatory behaviors that directly rid the body of calories or fluids (e.g., self-induced vomiting, laxative or diuretic abuse), whereas those with the "nonpurging" subtype attempt to compensate for binges by fasting or by excessive exercise. Patients with the nonpurging subtype tend to be heavier and are less prone to fluid and electrolyte disturbances.

The diagnosis of bulimia nervosa requires a candid history from the patient detailing recurrent, large eating binges followed by the purposeful use of inappropriate mechanisms to avoid weight gain. Most patients with bulimia nervosa who present for treatment are distressed by their inability to control their eating behavior but are able to provide such details if queried in a supportive and nonjudgmental fashion.

ETIOLOGY

The fundamental etiology of the eating disorders is unknown but is believed to involve a combination of psychological, biologic, and cultural risk factors. Many of these risk factors, such as sexual or physical abuse and a family history of mood disturbance or substance abuse, are best viewed as nonspecific risk factors that increase vulnerability to a range of psychiatric disorders. Other factors appear to be more specific to the development of an eating disorder.

Patients who develop anorexia nervosa are inclined to be more obsessional and perfectionist than their peers. The disorder often begins as a diet not distinguishable at the outset from those undertaken by many adolescents and young women. As weight loss progresses, the fear of gaining weight grows; dieting becomes stricter; and psychological, behavioral, and medical aberrations increase. The fact that most cases are reported from countries where food is plentiful and where thinness, especially among women, is highly valued suggests that cultural factors play a significant role in the development of anorexia nervosa. However, it is notable that the clinical syndrome was well described over a century ago, when the cultural pressures were quite different.

Numerous physiologic disturbances, including abnormalities in a variety of neurotransmitter systems, have been described in anorexia nervosa (see below). It is difficult to distinguish neurochemical, metabolic, and hormonal changes that may have a role in the initiation or perpetuation of the syndrome from those that are secondary to the disorder. The resolution of most of these abnormalities with weight restoration argues against their having a critical etiologic role.

Bulimia nervosa typically begins during or following an episode of dieting, often in association with depressed mood. Patients who develop bulimia nervosa describe a higher-than-expected prevalence of childhood and parental obesity, suggesting that a predisposition towards obesity may increase vulnerability to this eating disorder. The marked increase in the number of cases of bulimia nervosa during the past 25 years and the rarity of bulimia nervosa in underdeveloped countries suggest that cultural factors are important. Several biologic abnormalities in patients with bulimia nervosa may perpetuate this disorder once it has begun. These include abnormalities ofCNSserotonergic function, which is involved in the regulation of eating behavior, and disruption of peripheral satiety mechanisms, including the release of cholecystokinin (CCK) from the small intestine.

Genetic factors probably contribute to the risk of development of eating disorders, as the incidence of these disorders is greater in families with one affected member and the concordance in monozygotic twins is greater than in dizygotic twins. However, specific genes have not been identified, and the range of the estimates of heritability is large.

CLINICAL FEATURES (Table 78-3)

ANOREXIA NERVOSA

Anorexia nervosa typically begins in mid to late adolescence, sometimes in association with a stressful life event such as leaving home for school. The disorder occasionally develops in early puberty, before menarche, but seldom begins after age 40. Despite being underweight, patients with anorexia nervosa rarely complain of hunger or fatigue and often exercise extensively. Further weight loss is viewed by the patient as a fulfilling accomplishment, while weight gain is seen as a personal failure. Patients tend to become socially withdrawn and increasingly committed to work or study, dieting, and exercise. As weight loss progresses, thoughts of food dominate mental life and idiosyncratic rules develop around eating. Patients with anorexia nervosa may obsessively collect cookbooks and recipes and be drawn to food-related occupations. Despite the denial of hunger, one-quarter to one-half of patients with anorexia nervosa engage in eating binges.

Physical Features Patients with anorexia nervosa typically have few physical complaints but may note cold intolerance and constipation. Some women who develop anorexia nervosa after menarche report that their menses ceased before significant weight loss occurred. Weight and height should be measured to allow calculation ofBMI(kg/m_2). Vital signs may reveal bradycardia, hypotension, and hypothermia. Soft, downy hair growth (lanugo) sometimes occurs, especially on the back, and alopecia may be seen. Salivary gland enlargement, which is associated with starvation as well as with binge eating and vomiting, may make the face appear surprisingly full in contrast to the marked general wasting. Acrocyanosis of the digits is common, and peripheral edema can be seen in the absence of hypoalbuminemia, particularly when the patient begins to regain weight. Some patients who consume large amounts of vegetables containing vitamin A develop a yellow tint to the skin (*hypercarotenemia*), which is especially notable on the palms.

Laboratory Abnormalities Mild normochromic, normocytic anemia is frequent, as is mild to moderate leukopenia, with a disproportionate reduction of polymorphonuclear leukocytes. Dehydration may result in slightly increased levels of blood urea nitrogen and creatinine. Serum liver enzyme levels may increase, especially during the early phases of refeeding. The level of serum proteins is usually normal. Blood sugar is often low and serum cholesterol may be moderately elevated. Gastrointestinal motility is diminished, leading to reduced gastric emptying and constipation. A range of electrolyte disturbances may develop, reflecting the degree to which the patient restricts or overconsumes fluids and whether the patient engages in purging behavior. Hypokalemic alkalosis suggests self-induced vomiting or the use of diuretics. Hyponatremia is common and may result from excess fluid intake and disturbances in the secretion of antidiuretic hormone.

Endocrine Abnormalities The regulation of virtually every endocrine system is altered in anorexia nervosa, but the most striking changes occur in the reproductive system. Amenorrhea is hypothalamic in origin and reflects diminished production of gonadotropin-releasing hormone (GnRH). When exogenous GnRH is administered in a

physiologic pulsatile manner, pituitary responses of luteinizing hormone (LH) and follicle stimulating hormone (FSH) are normalized, indicating the absence of a primary pituitary abnormality. The resulting gonadotropin deficiency causes low plasma estrogen in women and reduced testosterone in men. The hypothalamic GnRH pulse generator is exquisitely sensitive, particularly in women, to body weight, stress, and exercise, each of which may contribute to *hypothalamic amenorrhea* in anorexia nervosa (Chap. 336). Although the mechanisms underlying these effects are unknown, the decreased adipose tissue associated with weight loss leads to a marked reduction in leptin, a hormone that plays a permissive role in GnRH production (Chap. 77). In many patients, weight gain to a specific threshold triggers restoration of the GnRH pulse generator, initially recapitulating the pubertal pattern of nocturnal gonadotropin secretion before returning to the normal adult pattern.

Serum cortisol and 24-h urine free cortisol levels are generally elevated but without characteristic clinical signs of cortisol excess. Thyroid function tests resemble the pattern seen in euthyroid sick syndrome (Chap. 330). Thyroxine (T_4) and free T_4levels are usually in the low-normal range, triiodothyronine (T_3) levels are reduced, and reverse T_3(rT_3) is elevated. The level of thyroid stimulating hormone (TSH) is normally or partially suppressed. Growth hormone is increased, but insulin-like growth factor 1 (IGF-1), which is produced mainly by the liver, is reduced, as it is in other conditions of starvation. Diminished bone density is routinely observed in anorexia nervosa and reflects the effects of multiple nutritional deficiencies, reduced gonadal steroids, and increased cortisol. The degree of bone density reduction is proportional to the length of the illness, and patients are at risk for the development of symptomatic fractures. The occurrence of anorexia nervosa during adolescence may lead to the premature cessation of linear bone growth and a failure to achieve expected adult height.

Cardiac Abnormalities Cardiac output is reduced, and congestive heart failure occasionally occurs during rapid refeeding. The electrocardiogram usually shows sinus bradycardia, reduced QRS voltage, and nonspecific ST-T-wave abnormalities. Some patients develop a prolonged QT_cinterval, which may predispose to serious arrhythmias.

BULIMIA NERVOSA

The typical patient presenting for treatment of bulimia nervosa is a woman of normal weight in her mid-twenties who reports binge eating and purging 5 to 10 times a week for 5 to 10 years. The disorder usually begins in late adolescence or early adulthood during or following a diet. The self-imposed caloric restriction leads to increased hunger and to overeating. In an attempt to avoid weight gain, the patient induces vomiting, takes laxatives or diuretics, or engages in some other form of compensatory behavior. Initially, patients may experience a sense of satisfaction that appealing food can be eaten without weight gain. However, as the disorder progresses, patients perceive diminished control over eating. Binges increase in size and frequency and are provoked by a variety of stimuli, such as transient depression, anxiety, or a sense that too much food has been consumed in a normal meal. Between binges, patients attempt to restrict caloric intake, which increases hunger and sets the stage for the next binge.

Although vomiting may be triggered initially by manual stimulation of the gag reflex, most patients with bulimia nervosa develop the ability to induce vomiting at will. Rarely,

patients resort to the regular use of syrup of ipecac. Laxatives and diuretics are frequently taken in impressive quantities, such as 30 or 60 laxative pills on a single occasion. The resulting fluid loss produces dehydration and a feeling of emptiness but has little impact on caloric balance.

The physical abnormalities associated with bulimia nervosa primarily result from the purging behavior. Painless bilateral salivary gland hypertrophy (sialadenosis) may be noted. A scar or callus on the dorsum of the hand may develop due to repeated trauma from the teeth among patients who manually stimulate the gag reflex. Recurrent vomiting and the exposure of the lingual surfaces of the teeth to stomach acid leads to loss of dental enamel and eventually to chipping and erosion of the front teeth. Laboratory abnormalities are surprisingly infrequent, but hypokalemia, hypochloremia, and hyponatremia are observed occasionally. Repeated vomiting may lead to alkalosis, whereas repeated laxative abuse may produce a mild metabolic acidosis. Serum amylase may be mildly elevated due to an increase in the salivary isoenzyme.

Serious physical complications resulting from bulimia nervosa are rare. Oligomenorrhea and amenorrhea are more frequent than in women without eating disorders. Arrhythmias occasionally occur secondary to electrolyte disturbances. Tearing of the esophagus and rupture of the stomach, which constitute life-threatening events, have been reported. Some patients who have chronically abused laxatives or diuretics develop transient peripheral edema when this behavior ceases, presumably due to high levels of aldosterone resulting from persistent fluid and electrolyte depletion.

PROGNOSIS

The course and outcome of anorexia nervosa are highly variable. One-quarter to one-half of patients eventually recover fully, with few psychological or physical sequelae. However, many patients have persistent difficulties with weight maintenance, depression, and eating disturbances, including bulimia nervosa. The development of obesity following anorexia nervosa is rare. The long-term mortality of anorexia nervosa is among the highest associated with any psychiatric disorder. Approximately 5% of patients die per decade of follow-up, primarily due to the physical effects of chronic starvation or by suicide.

Virtually all of the physiologic abnormalities associated with anorexia nervosa are observed in other forms of starvation and markedly improve or disappear with weight gain. A worrisome exception is the reduction in bone mass, which may not recover fully, particularly when anorexia nervosa occurs during adolescence when peak bone mass is normally achieved.

The prognosis of bulimia nervosa is much more favorable. Mortality is low, and full recovery occurs in approximately 50% of patients within 10 years. Approximately 25% of patients have persistent symptoms of bulimia nervosa over many years. Few patients progress from bulimia nervosa to anorexia nervosa.

TREATMENT

Anorexia Nervosa Because of the profound physiological and psychological effects of

starvation, there is a broad consensus that weight restoration to 90% of predicted weight is the primary goal in the treatment of anorexia nervosa. Unfortunately, because most patients resist this goal, its accomplishment is often accompanied by frustration for the patient, the family, and the physician. In attempting to engage the patient in treatment, it may be useful for the physician to elicit the patient's physical concerns (e.g., about osteoporosis, weakness, or fertility) and, if possible, educate the patient regarding the importance of normalizing nutritional status in order to address those concerns. The physician should attempt to reassure the patient that weight gain will not be permitted to get "out of control" but simultaneously emphasize that weight restoration is medically and psychologically imperative.

The intensity of the initial treatment, including the need for hospitalization, is determined by the patient's current weight, the rapidity of recent weight loss, and the severity of medical and psychological complications (Fig. 78-1). Hospitalization should be strongly considered for patients weighing <75% of expected, even if the results of routine blood studies are within normal limits. Acute medical problems, such as severe electrolyte imbalances, should be identified and addressed. Nutritional restoration can almost always be successfully accomplished by oral feeding, and parenteral methods are rarely required. For severely underweight patients, sufficient calories (approximately 1500 to 1800 kcal/d) should be provided initially in divided meals as food or liquid supplements to maintain weight and to permit stabilization of fluid and electrolyte balance. Calories can then be gradually increased to achieve a weight gain of 1 to 2 kg (2 to 4 lb) per week, typically requiring an intake of 3000 to 4000 kcal/d. Meals must be supervised, ideally by personnel who are firm regarding the necessity of food consumption, empathic regarding the challenges entailed, and reassuring regarding the patient's eventual recovery. Patients have great psychological difficulty complying with the need for increased caloric consumption, and the assistance of psychiatrists or psychologists experienced in the treatment of anorexia nervosa is usually necessary.

Psychiatric treatment focuses primarily on two issues. First, patients require much emotional support during the period of weight gain. Second, patients must learn to base their self-esteem, not on the achievement of an inappropriately low weight, but on the development of satisfying personal relationships and the attainment of reasonable academic and occupational goals. For younger patients, the active involvement of the family in treatment is crucial.

Less severely affected patients may be treated in a partial hospitalization program where medical and psychiatric supervision is available and several meals can be monitored each day. Outpatient treatment may suffice for mildly ill patients. Weight must be monitored at frequent intervals, and explicit goals agreed on for weight gain, with the understanding that more intensive treatment will be required if the level of care initially employed is not successful.

Medical complications occasionally occur during refeeding. Most patients transiently retain excess fluid, occasionally resulting in peripheral edema. Fluid retention occurs during recovery from other forms of malnutrition and generally does not require specific treatment in the absence of cardiac, renal, or hepatic dysfunction. Congestive heart failure and acute gastric dilatation have been described when refeeding has been rapid. Transient modest elevations in serum levels of liver enzymes occasionally occur. Low

levels of magnesium and phosphate should be repleted. Multivitamins should be given, and it is important to ensure adequate intake of vitamin D (400 IU/d) and calcium (1500 mg/d) to minimize bone loss.

No psychotropic medications are of established value in the treatment of anorexia nervosa; tricyclic antidepressants are contraindicated when there is prolongation of the QT_c interval. The alterations of cortisol and thyroid hormone metabolism do not require specific treatment and are corrected by weight gain. Estrogen treatment appears to have minimal impact on bone density in underweight patients but may be helpful to relieve symptoms of estrogen deficiency.

Bulimia Nervosa Bulimia nervosa can usually be treated on an outpatient basis. Cognitive behavioral therapy (CBT) is a short-term (4 to 6 months) psychological treatment that focuses on the intense concern with shape and weight, the persistent dieting, and the binge eating and purging that characterize this disorder. Patients are directed to monitor the circumstances, thoughts, and emotions associated with binge/purge episodes, to eat regularly, and to challenge their assumptions linking weight to self-esteem. CBT produces symptomatic remission in 25 to 50% of patients.

Numerous double-bind, placebo-controlled trials have documented that antidepressant medications are useful in the treatment of bulimia nervosa but are probably somewhat less effective thanCBT. Although efficacy has been established for virtually all chemical classes of antidepressants, only the selective serotonin reuptake inhibitor fluoxetine (Prozac) has been approved for use in bulimia nervosa by the U.S. Food and Drug Administration. Antidepressant medications are helpful even for patients with bulimia nervosa who are not depressed, and the dose of fluoxetine recommended for bulimia nervosa (60 mg/d) is higher than that typically used to treat depression. These observations suggest that different mechanisms may underlie the utility of these medications in bulimia nervosa and in depression.

A substantial minority of patients with bulimia nervosa do not respond adequately toCBT, antidepressant medication, or their combination. More intensive forms of treatment, including hospitalization, may be required for such patients.

PART SIX -ONCOLOGY AND HEMATOLOGY

SECTION 1 -NEOPLASTIC DISORDERS

79. APPROACH TO THE PATIENT WITH CANCER - *Dan L. Longo*

The application of current treatment techniques (surgery, radiation therapy, chemotherapy, and biological therapy) results in the cure of>50% of patients diagnosed with cancer. Nevertheless, patients experience the diagnosis of cancer as one of the most traumatic and revolutionary events that has ever happened to them. Independent of prognosis, the diagnosis brings with it a change in a person's self-image and in his or her role in the home and workplace. The prognosis of a person who has just been found to have pancreatic cancer is the same as the prognosis of the person with aortic stenosis who develops the first symptoms of congestive heart failure (median survival, about 8 months). However, the patient with heart disease may remain functional and maintain a view of him- or herself as a fully intact person with just a malfunctioning part, a diseased organ ("a bum ticker"). By contrast, the patient with pancreatic cancer has a completely altered self-image and is viewed differently by family and anyone who knows the diagnosis. He or she is being attacked and invaded by a disease that could be anywhere in the body. Every ache or pain takes on desperate significance. Cancer is an exception to the coordinated interaction among cells and organs. In general, the cells of a multicellular organism are programmed for collaboration. Many diseases occur because the specialized cells fail to perform their assigned task. Cancer takes this malfunction one step further. Not only is there a failure of the cancer cell to maintain its specialized function, but it also strikes out on its own; the cancer cell competes to survive using natural mutability and natural selection to seek advantage over normal cells in a recapitulation of evolution. One consequence of the traitorous behavior of cancer cells is that the patient feels betrayed by his or her body. The cancer patient feels that he or she, and not just a body part, is diseased.

THE MAGNITUDE OF THE PROBLEM

There is no nationwide cancer registry; therefore, the incidence of cancer is estimated on the basis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database, which tabulates cancer incidence and death figures from nine sites, accounting for about 10% of the U.S. population, and from population data from the Bureau of the Census. In 2000, 1.22 million new cases of invasive cancer (619,700 men, 600,400 women) were diagnosed and 552,200 people (284,100 men, 268,100 women) died from cancer. The percent distribution of new cancer cases and cancer deaths by site for men and women are shown inTable 79-1. Cancer incidence has been declining by about 2% each year since 1992.

The most significant risk factor for cancer overall is age; two-thirds of all cases were in people over age 65. Cancer incidence increases as the third, fourth, or fifth power of age in different sites. For the interval between birth and age 39, 1 in 62 men and 1 in 52 women will develop cancer; for the interval between ages 40 and 59, 1 in 12 men and 1 in 11 women will develop cancer; and for the interval between ages 60 and 79, 1 in 3 men and 1 in 4 women will develop cancer.

Cancer is the second leading cause of death behind heart disease. Deaths from heart disease have declined 45% in the United States since 1950 and continue to decline. After a 70-year period of increases, cancer deaths began to decline in 1997 (Fig. 79-1). The five leading causes of cancer deaths are shown for various populations inTable 79-2. Along with the decrease in incidence has come an increase in survival for cancer patients. The 5-year survival for white patients was 39% in 1960-1963 and 61% in 1989-1995. Cancers are more often deadly in blacks; the 5-year survival was 48% for the 1989-1995 interval. Incidence and mortality vary among racial and ethnic groups (Table 79-3). The basis for these differences is unclear.

PATIENT MANAGEMENT

Important information is obtained from every portion of the routine history and physical examination. The duration of symptoms may reveal the chronicity of disease. The past medical history may alert the physician to the presence of underlying diseases that may affect the choice of therapy or the side effects of treatment. The social history may reveal occupational exposure to carcinogens or habits, such as smoking or alcohol consumption, that may influence the course of disease and its treatment. The family history may suggest an underlying familial cancer predisposition and point out the need to begin surveillance or other preventive therapy for unaffected siblings of the patient. The review of systems may suggest early symptoms of metastatic disease or a paraneoplastic syndrome.

DIAGNOSIS

The diagnosis of cancer relies most heavily on invasive tissue biopsy and should never be made without obtaining tissue; no noninvasive diagnostic test is sufficient to define a disease process as cancer. Although in rare clinical settings (e.g., thyroid nodules) fine-needle aspiration is an acceptable diagnostic procedure, the diagnosis generally depends on obtaining adequate tissue to permit careful evaluation of the histology of the tumor, its grade, and its invasiveness and to yield further molecular diagnostic information, such as the expression of cell-surface markers or intracellular proteins that typify a particular cancer, or the presence of a molecular marker, such as the t(8;14) translocation of Burkitt's lymphoma. Increasing evidence links the expression of certain genes with the prognosis and response to therapy (Chaps. 81 and82).

Occasionally a patient will present with a metastatic disease process that is defined as cancer on biopsy but has no apparent primary site of disease. Efforts should be made to define the primary site based on age, sex, sites of involvement, histology and tumor markers, and personal and family history. Particular attention should be focused on ruling out the most treatable causes (Chap. 99).

Once the diagnosis of cancer is made, the management of the patient is best undertaken as a multidisciplinary collaboration among the primary care physician, medical oncologists, surgical oncologists, radiation oncologists, oncology nurse specialists, pharmacists, social workers, rehabilitation medicine specialists, and a number of other consulting professionals working closely with each other and with the patient and family.

DEFINING THE EXTENT OF DISEASE AND THE PROGNOSIS

The first priority in patient management after the diagnosis of cancer is established and shared with the patient is to determine the extent of disease. The curability of a tumor usually is inversely proportional to the tumor burden. Ideally, the tumor will be diagnosed before symptoms develop or as a consequence of screening efforts (Chap. 80). A very high proportion of such patients can be cured. However, most patients with cancer present with symptoms related to the cancer, caused either by mass effects of the tumor or by alterations associated with the production of cytokines or hormones by the tumor.

For most cancers, the extent of disease is evaluated by a variety of noninvasive and invasive diagnostic tests and procedures. This process is called *staging*. There are two types. *Clinical staging* is based on physical examination, radiographs, isotopic scans, computed tomography, and other imaging procedures; *pathologic staging* takes into account information obtained during a surgical procedure, which might include intraoperative palpation, resection of regional lymph nodes and/or tissue adjacent to the tumor, and inspection and biopsy of organs commonly involved in disease spread. Pathologic staging includes histologic examination of all tissues removed during the surgical procedure. Surgical procedures performed may include a simple lymph node biopsy or more extensive procedures such as thoracotomy, mediastinoscopy, or laparotomy. Surgical staging may occur in a separate procedure or may be done at the time of definitive surgical resection of the primary tumor.

Knowledge of the predilection of particular tumors for spread to adjacent or distant organs helps direct the staging evaluation.

Information obtained from staging is used to define the extent of disease either as localized, as exhibiting spread outside of the organ of origin to regional but not distant sites, or as metastatic to distant sites. The most widely used system of staging is the TNM (tumor, node, metastasis) system codified by the International Union Against Cancer and the American Joint Committee on Cancer (AJCC).

[1]The AJCC *Manual for Staging Cancer*, 5th edition, can be obtained from the AJCC at 55 East Erie Street, Chicago, Il, 60611.

The TNM classification is an anatomically based system that categorizes the tumor on the basis of the size of the primary tumor lesion (T1-4, where a higher number indicates a tumor of larger size), the presence of nodal involvement (usually N0 and N1 for the absence and presence, respectively, of involved nodes, although some tumors have more elaborate systems of nodal grading), and the presence of metastatic disease (M0 and M1 for the absence and presence, respectively, of metastases). The various permutations of T, N, and M scores are then broken into stages, usually designated by the roman numerals I through IV. Tumor burden increases and curability decreases with increasing stage. Other anatomic staging systems are used for some tumors, e.g., the Dukes classification for colorectal cancers, the International Federation of Gynecologists and Obstetricians (FIGO) classification for gynecologic cancers, and the Ann Arbor classification for Hodgkin's disease.

Certain tumors cannot be grouped appropriately on the basis of anatomic considerations. For example, hematopoietic tumors such as leukemia, myeloma, and lymphoma are often disseminated at presentation and do not spread in the fashion typical of solid tumors. For these tumors, other prognostic factors have been identified (Chaps. 111,112, and113).

In addition to tumor burden, a second major determinant of treatment outcome is the physiologic reserve of the patient. Patients who are bedridden before developing cancer are likely to fare worse, stage for stage, than fully active patients. Physiologic reserve is a determinant of how a patient is likely to cope with the physiologic stresses imposed by the cancer and its treatment. This factor is difficult to assess directly. Instead, surrogate markers for physiologic reserve are used, such as the patient's age or Karnofsky performance status (Table 79-4). Older patients and those with a Karnofsky performance status <70 have a poor prognosis unless the poor performance is a reversible consequence of the tumor.

Increasingly, biologic features of the tumor are being related to prognosis. The expression of particular oncogenes, drug-resistance genes, apoptosis-related genes, and genes involved in metastasis are being found to influence response to therapy and prognosis. The presence of selected cytogenetic abnormalities may influence survival. Tumors with higher growth fractions, as assessed by expression of proliferation-related markers such as proliferating cell nuclear antigen (PCNA), behave more aggressively than tumors with lower growth fractions. Information obtained from studying the tumor itself will increasingly be used to influence treatment decisions.

MAKING A TREATMENT PLAN

From information on the extent of disease and the prognosis and in conjunction with the patient's wishes, it is determined whether the treatment approach should be curative or palliative in intent. Cooperation among the various professionals involved in cancer treatment is of the utmost importance in treatment planning. For some cancers, chemotherapy or chemotherapy plus radiation therapy delivered before the use of definitive surgical treatment (so-called neoadjuvant therapy) may improve the outcome, as seems to be the case for locally advanced breast cancer and head and neck cancers. In certain settings in which combined modality therapy is intended, coordination among the medical oncologist, radiation oncologist, and surgeon is crucial to achieving optimal results. Sometimes the chemotherapy and radiation therapy need to be delivered sequentially, and other times concurrently. Surgical procedures may precede or follow other treatment approaches. It is best for the treatment plan either to follow a standard protocol precisely or else to be part of an ongoing clinical research protocol evaluating new treatments. Ad hoc modifications of standard protocols are likely to compromise treatment results.

The choice of treatment approaches was formerly dominated by the local culture in both the university and the practice settings. However, it is now possible to gain access electronically to standard treatment protocols and to every approved clinical research study in North America through a personal computer interface with the Internet.

[2]The National Cancer Institute maintains a database called PDQ (Physician Data Query)

that is accessible on the Internet under the name CancerNet at wwwicic.nci.nih.gov/health.htm. Information can be obtained through a facsimile machine using CancerFax by dialing 301-402-5874. Patient information is also provided by the National Cancer Institute in at least three formats: on the Internet via CancerNet at wwwicic.nci.nih.gov/patient.htm, through the CancerFax number listed above, or by calling 1-800-4-CANCER. The quality control for the information provided through these services is rigorous.

The skilled physician also has much to offer the patient for whom curative therapy is no longer an option. Often a combination of guilt and frustration over the inability to cure the patient and the pressure of a busy schedule greatly limit the time a physician spends with a patient who is receiving only palliative care. Resist these forces. In addition to the medicines administered to alleviate symptoms (see below), it is important to remember the comfort that is provided by holding the patient's hand, continuing regular examinations, and taking time to talk.

MANAGEMENT OF DISEASE AND TREATMENT COMPLICATIONS

Because cancer therapies are toxic (Chap. 84), patient management involves addressing complications of both the disease and its treatment as well as the complex psychosocial problems associated with cancer. In the short term during a course of curative therapy, the patient's functional status may decline. Treatment-induced toxicity is less acceptable if the goal of therapy is palliation. The most common side effects of treatment are nausea and vomiting (see below), febrile neutropenia (Chap. 85), and myelosuppression (Chap. 104). Therapeutic tools are now available to minimize the acute toxicity of cancer treatment.

New symptoms developing in the course of cancer treatment should always be assumed to be reversible until proven otherwise. The fatalistic attribution of anorexia, weight loss, and jaundice to recurrent or progressive tumor could result in a patient dying from a reversible intercurrent cholecystitis. Intestinal obstruction may be due to reversible adhesions rather than progressive tumor. Systemic infections, sometimes with unusual pathogens, may be a consequence of the immunosuppression associated with cancer therapy. Some drugs used to treat cancer or its complications (e.g., nausea) may produce central nervous system symptoms that look like metastatic disease or may mimic paraneoplastic syndromes such as the syndrome of inappropriate antidiuretic hormone. A definitive diagnosis should be pursued and may even require a repeat biopsy.

A critical component of cancer management is assessing the response to treatment. In addition to a careful physical examination in which all sites of disease are physically measured and recorded in a flow chart by date, response assessment usually requires periodic repeating of imaging tests that were abnormal at the time of staging. If imaging tests have become normal, repeat biopsy of previously involved tissue is performed to document complete response by pathologic criteria. Biopsies are not usually required if there is macroscopic residual disease. A *complete response* is defined as disappearance of all evidence of disease, and a *partial response* as>50% reduction in the sum of the products of the perpendicular diameters of all measureable lesions. *Progressive disease* is defined as the appearance of any new lesion or an increase of

>25% in the sum of the products of the perpendicular diameters of all measurable lesions. Tumor shrinkage or growth that does not meet any of these criteria is considered *stable disease*. Some sites of involvement (e.g., bone) or patterns of involvement (e.g., lymphangitic lung or diffuse pulmonary infiltrates) are considered unmeasurable. No response is complete without biopsy documentation of their resolution but partial responses may exclude their assessment unless clear objective (though unmeasurable) progression has occurred.

Tumor markers may be useful in patient management in certain tumors. Response to therapy may be difficult to gauge with certainty. However, some tumors produce or elicit the production of markers that can be measured in the serum or urine and, in a particular patient, rising and falling levels of the marker are usually associated with increasing or decreasing tumor burden, respectively. Some clinically useful tumor markers are shown in Table 79-5. Tumor markers are not in themselves specific enough to permit a diagnosis of malignancy to be made, but once a malignancy has been diagnosed and shown to be associated with elevated levels of a tumor marker, the marker can be used to assess response to treatment.

The recognition and treatment of depression are important components of management. The incidence of depression in cancer patients is ~25% overall and may be greater in patients with greater debility. This diagnosis is likely in a patient with a depressed mood (dysphoria) and/or a loss of interest in pleasure (anhedonia) for at least 2 weeks. In addition, three or more of the following symptoms are usually present: appetite change, sleep problems, psychomotor retardation or agitation, fatigue, feelings of guilt or worthlessness, inability to concentrate, and suicidal ideation. Patients with these symptoms should receive therapy. Medical therapy with a serotonin reuptake inhibitor such as fluoxetine (10 to 20 mg/d), sertraline (50 to 150 mg/d), or paroxetine (10 to 20 mg/d) or a tricyclic antidepressant such as amitriptyline (50 to 100 mg/d) or desipramine (75 to 150 mg/d) should be tried, allowing 4 to 6 weeks for response. Effective therapy should be continued at least 6 months after resolution of symptoms. If therapy is unsuccessful, other classes of antidepressants may be used. In addition to medication, psychosocial interventions such as support groups, psychotherapy, and guided imagery may be of benefit.

Many patients opt for unproven or unsound approaches to treatment when it appears that conventional medicine is unlikely to be curative. Those seeking such alternatives are often well educated and may be early in the course of their disease. Unsound approaches are usually hawked on the basis of unsubstantiated anecdotes and not only cannot help the patient but may be harmful. Physicians should strive to keep communications open and nonjudgmental, so that patients are more likely to discuss with the physician what they are actually doing. The appearance of unexpected toxicity may be an indication that a supplemental therapy is being taken.

[3]Information about unsound methods may be obtained from the National Council Against Health Fraud, Box 1276, Loma Linda, CA 92354, or from the Center for Medical Consumers and Health Care Information, 237 Thompson Street, New York, NY 10012.

LONG-TERM FOLLOW-UP/LATE COMPLICATIONS

At the completion of treatment, sites originally involved with tumor are reassessed, usually by radiography or imaging techniques, and any persistent abnormality is biopsied. If disease persists, the multidisciplinary team discusses a new salvage treatment plan. If the patient has been rendered disease-free by the original treatment, the patient is followed regularly for disease recurrence. The optimal guidelines for follow-up care are not known. For many years, a routine practice has been to follow the patient monthly for 6 to 12 months, then every other month for a year, every 3 months for a year, every 4 months for a year, every 6 months for a year, and then annually. At each visit, a battery of laboratory and radiographic and imaging tests were obtained on the assumption that it is best to detect recurrent disease before it becomes symptomatic. However, where follow-up procedures have been examined, this assumption has been found to be untrue. Studies of breast cancer, melanoma, lung cancer, colon cancer, and lymphoma have all failed to support the notion that asymptomatic relapses are more readily cured by salvage therapy than symptomatic relapses. In view of the enormous cost of a full battery of diagnostic tests and their manifest lack of impact on survival, new guidelines are emerging for less frequent follow-up visits during which the history and physical examination are the major investigations performed.

As time passes, the likelihood of recurrence of the primary cancer diminishes. For many types of cancer, survival for 5 years without recurrence is tantamount to cure. However, important medical problems can occur in patients treated for cancer and must be examined (Chap 103). Some problems emerge as a consequence of the disease and some as a consequence of the treatment. An understanding of these disease- and treatment-related problems may help in their detection and management.

Despite these concerns, most patients who are cured of cancer return to normal lives.

SUPPORTIVE CARE

In many ways, the success of cancer therapy depends on the success of the supportive care. Failure to control the symptoms of cancer and its treatment may lead patients to abandon curative therapy. Of equal importance, supportive care is a major determinant of quality of life. Even when life cannot be prolonged, the physician must strive to preserve its quality. Quality-of-life measurements have become common end-points of clinical research studies. Furthermore, palliative care has been shown to be cost-effective when approached in an organized fashion. A credo for oncology could be to cure sometimes, to extend life often, and to comfort always.

Pain Pain occurs with variable frequency in the cancer patient: 25 to 50% of patients present with pain at diagnosis, 33% have pain associated with treatment, and 75% have pain with progressive disease. The pain may have several causes. In about 70% of cases, pain is caused by the tumor itself -- by invasion of bone, nerves, blood vessels, or mucous membranes or obstruction of a hollow viscus or duct. In about 20% of cases, pain is related to a surgical or invasive medical procedure, to radiation injury (mucositis, enteritis, or plexus or spinal cord injury), or to chemotherapy injury (mucositis, peripheral neuropathy, phlebitis, steroid-induced aseptic necrosis of the femoral head). In 10% of cases, pain is unrelated to cancer or its treatment.

Assessment of pain requires the methodical investigation of the history of the pain, its location, character, temporal features, provocative and palliative factors, and intensity (Chap. 12); a review of the oncologic history and past medical history as well as personal and social history; and a thorough physical examination. The patient should be given a 10-division visual analogue scale on which to indicate the severity of the pain. The clinical condition is often dynamic, making it necessary to reassess the patient frequently. Pain therapy should not be withheld while the cause of pain is being sought.

A variety of tools are available with which to address cancer pain. About 85% of patients will have pain relief from pharmacologic intervention. However, other modalities, including antitumor therapy (such as surgical relief of obstruction, radiation therapy, and strontium-89 or samarium-153 treatment for bone pain), neurostimulatory techniques, regional analgesia, or neuroablative procedures are effective in an additional 12% or so. Thus, very few patients will have inadequate pain relief if appropriate measures are taken.

The World Health Organization (WHO) has devised a simple and effective method for the rational titration of oral analgesia, called the *WHO ladder*. The ladder has the following three steps. (1) For mild to moderate pain, one begins with acetaminophen (650 mg every 4 h or 975 mg every 6 h), aspirin (650 mg every 4 h or 975 mg every 6 h), or a nonsteroidal anti-inflammatory agent (NSAID; e.g., ketoprofen, 25 to 60 mg every 6 h) with or without an adjuvant such as a glucocorticoid (dexamethasone) or an antidepressant (amitriptyline). (2) When pain persists or increases, an opioid such as codeine or hydrocodone (30 mg every 3 to 4 h is roughly equivalent to 10 mg of intravenous morphine) should be added (not substituted); fixed combinations such as oxycodone/acetaminophen (Percocet) or oxycodone/aspirin (Percodan) are worth testing. (3) Pain that is persistent or that is moderate to severe at the outset should be treated by increasing the potency of the opioid or using higher dosages (e.g., morphine, 15 to 30 mg every 3 to 4 h, or controlled-release morphine, 90 to 120 mg bid), and fixed opioid/NSAID combinations should be abandoned. Adjuvants may be used at all steps. The critical features of this approach are that the treatment is oral, should be given around the clock with supplemental doses as needed to control pain, and is tailored to the individual patient. Transmucosal fentanyl (in lollipop form) may aid in control of breakthrough pain. Records of pain control should be a prominent component of the medical record. When opioids are used, the patient should be placed on a prophylactic regimen to prevent constipation.

Nausea Emesis in the cancer patient is usually caused by chemotherapy (Chap. 84). Its severity can be predicted from the drugs used to treat the cancer. Three forms of emesis are recognized on the basis of their timing with regard to the noxious insult. *Acute emesis*, the most common variety, occurs within 24 h of treatment. *Delayed emesis* occurs 1 to 7 days after treatment; it is rare, but, when present, usually follows cisplatin administration. *Anticipatory emesis* occurs before administration of chemotherapy and represents a conditioned response to visual and olfactory stimuli previously associated with chemotherapy delivery.

Acute emesis is the best understood form. Stimuli that activate signals in the chemoreceptor trigger zone in the medulla, the cerebral cortex, and peripherally in the intestinal tract lead to stimulation of the vomiting center in the medulla, the motor center

responsible for coordinating the secretory and muscle contraction activity that leads to emesis. Diverse receptor types participate in the process, including dopamine, serotonin, histamine, opioid, and acetylcholine receptors. The serotonin receptor antagonists ondansetron and granisetron are the most effective drugs against highly emetogenic agents, but they are expensive.

As with the analgesia ladder, emesis therapy should be tailored to the situation. For mildly and moderately emetogenic agents, prochlorperazine, 5 to 10 mg orally or 25 mg rectally, is effective. Its efficacy may be enhanced by administering the drug before the chemotherapy is delivered. Dexamethasone, 10 to 20 mg intravenously, is also effective and may enhance the efficacy of prochlorperazine. For highly emetogenic agents such as cisplatin, mechlorethamine, dacarbazine, and streptozocin, combinations of agents work best and administration should begin 6 to 24 h before treatment. Ondansetron, 8 mg orally every 6 h the day before therapy and intravenously on the day of therapy, plus dexamethasone, 20 mg intravenously before treatment, is an effective regimen. Like pain, emesis is easier to prevent than to alleviate.

Delayed emesis may be related to bowel inflammation from the therapy and can be controlled with oral dexamethasone and oral metoclopramide, a dopamine receptor antagonist that also blocks serotonin receptors at high dosages. The best strategy for preventing anticipatory emesis is to control emesis in the early cycles of therapy to prevent the conditioning from taking place. If this is unsuccessful, prophylactic antiemetics the day before treatment may help. Experimental studies are evaluating behavior modification.

Effusions Fluid may accumulate abnormally in the pleural cavity, pericardium, or peritoneum. Asymptomatic malignant effusions may not require treatment. Symptomatic effusions occurring in tumors responsive to systemic therapy usually do not require local treatment but respond to the treatment for the underlying tumor. Symptomatic effusions occurring in tumors unresponsive to systemic therapy may require local treatment in patients with a life expectancy of at least 6 months.

Pleural effusions due to tumors may or may not contain malignant cells. Lung cancer, breast cancer, and lymphomas account for about 75% of malignant pleural effusions. Their exudative nature is usually gauged by an effusion/serum protein ratio of 0.5 or an effusion/serum lactate dehydrogenase ratio of 0.6. When the condition is symptomatic, thoracentesis is usually performed first. In most cases, symptomatic improvement occurs for <1 month. Chest tube drainage is required if symptoms recur within 2 weeks. Fluid is aspirated until the flow rate is <100 mL in 24 h. Then either 60 units of bleomycin or 1 g of doxycycline is infused into the chest tube in 50 mL of 5% dextrose in water; the tube is clamped; the patient is rotated on four sides, spending 15 min in each position; and, after 1 to 2 h, the tube is again attached to suction for another 24 h. The tube is then disconnected from suction and allowed to drain by gravity. If<100 mL drains over the next 24 h, the chest tube is pulled, and a radiograph taken 24 h later. If the chest tube continues to drain fluid at an unacceptably high rate, sclerosis can be repeated. Bleomycin may be somewhat more effective than doxycycline but is very expensive. Doxycycline is usually the drug of first choice. If neither doxycycline nor bleomycin is effective, talc can be used.

Symptomatic pericardial effusions are usually treated by creating a pericardial window or by stripping the pericardium. If the patient's condition does not permit a surgical procedure, sclerosis can be attempted with doxycycline and/or bleomycin.

Malignant ascites is usually treated with repeated paracentesis of small volumes of fluid. If the underlying malignancy is unresponsive to systemic therapy, peritoneovenous shunts may be inserted. Despite the fear of disseminating tumor cells into the circulation, widespread metastases are an unusual complication. The major complications are occlusion, leakage, and fluid overload. Patients with severe liver disease may develop disseminated intravascular coagulation.

Nutrition Cancer and its treatment may lead to a decrease in nutrient intake of sufficient magnitude to cause weight loss and alteration of intermediary metabolism. The prevalence of this problem is difficult to estimate because of variations in the definition of cancer cachexia, but most patients with advanced cancer experience weight loss and decreased appetite. A variety of both tumor-derived factors (e.g., bombesin, adrenocorticotropic hormone) and host-derived factors (e.g., tumor necrosis factor, interleukins 1 and 6, growth hormone) contribute to the altered metabolism, and a vicious cycle is established in which protein catabolism, glucose intolerance, and lipolysis cannot be reversed by the provision of calories.

It remains controversial how to assess nutritional status and when and how to intervene. Efforts to make the assessment objective have included the use of a prognostic nutritional index based on albumin levels, triceps skin fold thickness, transferrin levels, and delayed-type hypersensitivity skin testing. However, a simpler approach has been to define the threshold for nutritional intervention as>10% unexplained body weight loss, serum transferrin level <1500 mg/L (150 mg/dL), and serum albumin <34 g/L (3.4 g/dL).

The decision is important, because it appears that cancer therapy is substantially more toxic and less effective in the face of malnutrition. Nevertheless, it remains unclear whether nutritional intervention can alter the natural history. Unless some pathology is affecting the absorptive function of the gastrointestinal tract, enteral nutrition provided orally or by tube feeding is preferred over parenteral supplementation. However, the risks associated with the tube may outweigh the benefits. Megestrol acetate, a progestational agent, has been advocated as a pharmacologic intervention to improve nutritional status. Research in this area may provide more tools in the future as cytokine-mediated mechanisms are further elucidated.

Psychosocial Support The psychosocial needs of patients vary with their situation. Patients undergoing treatment experience fear, anxiety, and depression. Self-image is often seriously compromised by deforming surgery and loss of hair. Women who receive cosmetic advice that enables them to look better also feel better. Loss of control over how one spends time can contribute to the sense of vulnerability. Juggling the demands of work and family with the demands of treatment may create enormous stresses. Sexual dysfunction is highly prevalent and needs to be discussed openly with the patient. An empathetic health care team is sensitive to the individual patient's needs and permits negotiation where such flexibility will not adversely affect the course of treatment.

Cancer survivors have other sets of difficulties. Patients may have fears associated with the termination of a treatment they associate with their continued survival. Adjustments are required to physical losses and handicaps, real and perceived. Patients may be preoccupied with minor physical problems. They perceive a decline in their job mobility and view themselves as less desirable workers. They may be victims of job and/or insurance discrimination. Patients may experience difficulty reentering their normal past life. They may feel guilty for having survived and may carry a sense of vulnerability to colds and other illnesses. Perhaps the most pervasive and threatening concern is the ever-present fear of relapse (the Damocles syndrome).

Patients in whom therapy has been unsuccessful have other problems related to the end of life.

Death and Dying The most common causes of death in patients with cancer are infection (leading to circulatory failure), respiratory failure, hepatic failure, and renal failure. Intestinal blockage may lead to inanition and starvation. Central nervous system disease may lead to seizures, coma, and central hypoventilation. About 70% of patients develop dyspnea preterminally. However, many months usually pass between the diagnosis of cancer and the occurrence of these complications, and during this period the patient is severely affected by the possibility of death. The path of unsuccessful cancer treatment usually occurs in three phases. First, there is optimism at the hope of cure; when the tumor recurs, there is the acknowledgment of an incurable disease, and the goal of palliative therapy is embraced in the hope of being able to live with disease; finally, at the disclosure of imminent death, another adjustment in outlook takes place. The patient imagines the worst in preparation for the end of life and may go through stages of adjustment to the diagnosis. These stages include denial, isolation, anger, bargaining, depression, acceptance, and hope. Of course, patients do not all progress through all the stages or proceed through them in the same order or at the same rate. Nevertheless, developing an understanding of how the patient has been affected by the diagnosis and is coping with it is an important goal of patient management.

It is best to speak frankly with the patient and the family regarding the likely course of disease. These discussions can be difficult for the physician as well as for the patient and family. The critical features of the interaction are to reassure the patient and family that everything that can be done to provide comfort will be done. They will not be abandoned. Many patients prefer to be cared for in their homes or in a hospice setting rather than a hospital. The American College of Physicians has published a book called *Home Care Guide for Cancer: How to Care for Family and Friends at Home* that teaches an approach to successful problem-solving in home care. With appropriate planning, it should be possible to provide the patient with the necessary medical care as well as the psychological and spiritual support that will prevent the isolation and depersonalization that can attend in-hospital death.

The care of dying patients may take a toll on the physician. A "burnout" syndrome has been described that is characterized by fatigue, disengagement from patients and colleagues, and a loss of self-fulfillment. Efforts at stress reduction, maintenance of a balanced life, and setting realistic goals may combat this disorder.

End-of-Life Decisions Unfortunately, a smooth transition in treatment goals from

curative to palliative may not be possible in all cases because of the occurrence of serious treatment-related complications or rapid disease progression. Vigorous and invasive medical support for a reversible disease or treatment complication is assumed to be justified. However, if the reversibility of the condition is in doubt, the patient's wishes determine the level of medical care. These wishes should be elicited before the terminal phase of illness and reviewed periodically. This information can guide the physician should the patient be unable to speak for him- or herself. The family cannot be expected to make such decisions without guidance from the patient and support from the physician when surrogate decisions are required. Advance directives such as a living will or a durable power of attorney for health care provide guidance for the health care team and the family regarding the patient's wishes and may protect the patient's assets from depletion on expensive but unwanted care.

Only about 15%of the population has implemented an advance directive. Physicians should take the initiative to speak with patients and family members about advance directives.

80. PREVENTION AND EARLY DETECTION OF CANCER - *Otis W. Brawley*, *Barnett S. Kramer*

The prevention and control of cancer is a burgeoning field because of advances in understanding the biology of carcinogenesis. The field has expanded beyond the identification and avoidance of carcinogens to include studies of specific interventions to lower cancer risk, as well as screening for early detection of cancer.

Central to the prevention and control of cancer is the concept that carcinogenesis is not an event but a process, a series of discrete cellular changes that result in progressively more autonomous cellular processes. *Primary prevention* concerns the identification and manipulation of the genetic, biologic, and environmental factors in the causal pathway. Smoking cessation, diet modification, and chemoprevention are primary prevention activities. *Secondary prevention* concerns the identification of asymptomatic neoplastic lesions combined with effective therapy. Screening is a form of secondary prevention. Screening may also be a form of primary prevention of invasive cancer; screening Pap smears are used to identify and treat preinvasive lesions of the cervix.

EDUCATION AND HEALTHFUL HABITS

Public education on the avoidance of identified risk factors for cancer and encouraging healthy habits were among early efforts in cancer prevention and control. Many educational messages have come to the public through commercials in the print and electronic media and through school health courses. The physician is a potentially powerful messenger in this education campaign about the hazards of smoking, the benefits of a healthful diet, and sun avoidance.

Smoking Cessation Tobacco use through cigarettes and other means is the most avoidable risk factor for cardiovascular disease and cancer. Lung cancer mortality rates correlate with the number of cigarettes smoked per day as well as the degree of inhalation of cigarette smoke. Those who stop smoking have a lower lung cancer mortality rate than those who continue smoking, despite the persistence for years of some carcinogen-induced genetic mutations. In addition to lung cancer, cigarette smoking is a causative agent in cancers of the larynx, oropharynx, esophagus, bladder, and pancreas. Smoking cessation and avoidance have the potential to save and extend more lives than any other public health activity. About 400,000 Americans die prematurely every year because of cigarette smoking. A smoker has a one in three lifetime risk of dying prematurely of a cancer or cardiovascular or pulmonary disease caused by cigarette smoking. Indeed, more human lives are lost due to cardiovascular disease caused by smoking than from smoking-related cancer. The risk of tobacco smoke is not necessarily limited to the smoker. Epidemiologic studies suggest that environmental tobacco smoke may cause lung cancer and other pulmonary diseases in nonsmokers.

Nonsmoking persons should be encouraged not to start smoking, and persons who smoke should be encouraged to stop. Tobacco prevention is a pediatric issue. Over 80% of American smokers begin smoking before the age of 18. Nearly 20% of Americans aged 12 to 18 have smoked a cigarette in the past month. Counseling of adolescents and young adults is critical to prevent smoking. A physician's simple advice

to not start smoking or to quit smoking can be of benefit. The U.S. Agency for Health Care Research and Quality recommends that physicians query patients on tobacco use on every office visit, record the answer with the vital signs, and ask smokers if they would like assistance in quitting.

Current approaches to smoking cessation recognize that smoking is an addiction (Chap. 390). The smoker who is quitting goes through a process with identifiable stages that include contemplation of quitting, an action phase in which the smoker quits, and a maintenance phase. Smokers who quit completely are more likely to be successful than those who gradually reduce the number of cigarettes smoked or change to cigarettes lower in tar or nicotine. More than 90% of the Americans who have successfully quit smoking did so on their own without participation in an organized cessation program, but cessation programs are helpful for some smokers. The Community Intervention Trial for Smoking Cessation (COMMIT) was a community-based 4-year program. One community of each of 11 matched community pairs was randomly assigned to intervention. The intervention included public education through the media and community-wide events, health care providers, worksites and other organizations, and cessation resources. COMMIT demonstrated that light smokers can benefit from simple cessation messages and cessation programs. The quit rate (fraction of the subjects followed who achieved and maintained cessation at the end of the trial) was 30.6% in the intervention communities and 27.5% in the control communities. This finding is statistically significant, but modest. The control communities enjoyed a substantial decrease in smoking through study participation. The COMMIT interventions were not successful for heavy smokers (>25 cigarettes per day). Heavy smokers need an intensive, broad-based cessation program that includes counseling, behavioral strategies, and pharmacologic adjuncts such as nicotine gum and nicotine patches.

Cigar and pipe smoking carry the same risks as tobacco smoke including lung cancer. Smokeless tobacco is the fastest growing part of the tobacco industry and represents a significant health risk. Chewing tobacco is a carcinogen linked to dental caries, gingivitis, oral leukoplakia, and oral cancer. The systemic effects of smokeless tobacco may increase risks for other cancers. Nitrosamines found in smokeless tobacco cause lung cancer in laboratory animals.

Diet Modification Dietary modification may have significant potential for lowering cancer risk in western culture. Studies of international dietary patterns and animal studies suggest that diets high in fat increase the risk for cancers of the breast, colon, prostate, and endometrium. These cancers have their highest incidence and mortalities in western countries, where fat comprises an average of 40 to 45% of the total calories consumed. In populations at low risk for these cancers, fat accounts for<20% of dietary calories.

Nonetheless, dietary fat has not been accepted by all as important in the etiology of cancers. Case-control and cohort epidemiologic studies give conflicting results. In addition, diet is a highly complex exposure to many nutrients and chemicals. Low-fat diets may render some protection through anticarcinogens found in vegetables, fruits, legumes, nuts, and grains. Substances found in these foods that may be protective include phenols, sulfur-containing compounds, flavones, and fiber.

In observational studies, dietary fiber appears protective against colonic polyps and invasive cancer of the colon. The mechanisms involved are complex and speculative. They involve binding of oxidized bile acids, a decrease in bowel transit time, and generation of soluble fiber products, such as butyrate, that may have differentiating properties. High-fiber diets may also protect against breast and prostate cancer by absorbing and inactivating dietary estrogenic and androgenic cancer promoters. Protective effects of fiber have not been proved in a prospective clinical trial.

The U.S. National Institutes of Health (NIH) Women's Health Initiative, launched in 1994, is a long-term clinical trial enrolling more than 100,000 women aged 45 to 69. It studies the potential cancer-preventing effects of a low-fat diet and vitamin supplementation. It must be stressed that the scientific evidence does not currently establish the anticarcinogenic value of vitamin, mineral, or nutritional supplements in amounts greater than that provided by a good diet.

The Polyp Prevention Trial studied 2000 elderly persons randomly assigned to a low-fat, high-fiber diet or a routine diet followed for 4 years. No significant differences in polyp formation were noted.

A simple way to decrease dietary fat and increase fiber is to consume at least 5 to 9 servings of fruits and vegetables a day. Such a diet may lower the risk of cardiac disease as well as cancer.

Sun Avoidance Nonmelanoma skin cancers (basal cell and squamous cell) are induced by cumulative exposure to ultraviolet radiation. Intermittent acute sun exposure and sun damage have been linked to melanoma. Sunburns, especially in childhood and adolescence, are associated with an increased risk of melanoma in adulthood. Reduction of sun exposure through use of protective clothing and changes in the pattern of outdoor activities can reduce skin cancer risk. Sunscreens decrease the risk of actinic keratoses, the precursor to squamous cell skin cancer, but melanoma risk may be increased. Sunscreens prevent burning and may encourage more prolonged exposure to the sun; yet they may not filter out wavelengths of energy that cause melanoma.

Educational interventions to help people assess their risk of developing skin cancer accurately have some impact. Self-examination for skin pigment characteristics associated with melanoma, such as freckling, may be useful in identifying people at high risk. People who recognize themselves as being at risk tend to be more compliant with sun-avoidance recommendations. Possible risk factors for melanoma include a propensity to sunburn, a large number of benign melanocytic nevi, and atypical nevi.

CANCER CHEMOPREVENTION

Chemoprevention of cancer is a relatively new concept. It involves the use of specific natural or synthetic chemical agents to reverse, suppress, or prevent carcinogenesis before the development of invasive malignancy. While the concept that pharmacologic agents can prevent a cancer is relatively new, the idea that a compound can prevent chronic disease is not. Clinicians routinely prevent heart disease, kidney disease, and stroke by treating hypertension with pharmacologic agents. Lipid-lowering drugs are used to prevent coronary artery disease.

Improved understanding of the biology of cancer makes chemoprevention a real possibility. Cancer develops through an accumulation of genetic changes that are potential points of intervention to prevent cancer. The initial genetic changes are termed *initiation*. The alteration can be inherited or acquired through the action of physical, infectious, or chemical carcinogens. Like most human diseases, cancer arises through an interaction between genetics and environmental exposures (Table 80-1). Influences that cause the initiated cell to progress through the carcinogenic process and to change phenotypically are termed *promoters*. Promoters include hormones such as androgens, linked to prostate cancer, and estrogen, linked to breast and endometrial cancer. The distinction between an initiator and a promoter is sometimes arbitrary; some components of cigarette smoke are "complete carcinogens," acting as both initiators and promoters. Cancer can be prevented or controlled through interference with the factors that cause initiation, promotion, or progression. Compounds of interest in chemoprevention often have antimutagenic, antioxidant, or antiproliferative activity.

Before a chemoprevention strategy can become standard practice, evidence of benefit must be gathered from clinical trials. These trials are usually large, long-term, randomized, placebo-controlled, and double-blinded. They often allow for the study of drugs for prevention of multiple cancers and the study of end-points beyond cancer, such as other chronic diseases. Several large clinical trials have been completed, and a number are continuing in the twenty-first century. Only tamoxifen has been approved by the U.S. Food and Drug Administration for prevention; it lowers risk of breast cancer in high-risk women.

Multiple Cancer Site Prevention Trials The Physicians' Health Trial involves 22,071 American male physicians. Participants were randomly assigned to receiveb-carotene, aspirin, and/or placebo in a 2´ 2 factorial design. All major medical events were recorded. In 1988, the aspirin arm was unblinded after the trial demonstrated that aspirin therapy causes a significant reduction in cardiovascular mortality. The b-carotene arm of the study stopped in 1998, and data analysis is proceeding.

The Women's Health Study, launched in 1992, is a 10-year trial involving 44,000 female nurses. Subjects are randomly assigned to b-carotene,a-tocopherol, aspirin, and/or placebo in a factorial design yielding eight different treatment groups. The end-points are total epithelial cancers, breast cancer, lung cancer, colon cancer, and vascular disease.

The Women's Health Initiative uses a partial factorial design that places women in 22 intervention groups. Participants can receive calcium and vitamin D supplementation, hormone replacement therapy, and counseling to increase exercise and cease smoking. Prevention of a number of cancers, cardiovascular disease, osteoporosis, and other diseases will be assessed.

Prevention of Hormonally Driven Cancers Hormonal manipulation is being tested in the primary prevention of breast and prostate cancer. Tamoxifen is an antiestrogen with partial estrogen agonistic activity in some tissues, such as endometrium and bone. One of its actions is to upregulate transforming growth factorb, which decreases breast cell proliferation. In randomized placebo-controlled trials to assess tamoxifen as an adjuvant

in breast cancer treatment, this drug reduced the number of new breast cancers in the uninvolved breast by more than a third. In a randomized placebo-controlled trial involving >13,000 women at high risk, tamoxifen decreased the risk of developing cancer by 49% compared to placebo. Tamoxifen also reduced the risk of bone fractures; a small increase in risk of endometrial cancer, stroke, pulmonary emboli, and deep vein thrombosis was noted. A trial to compare tamoxifen with another selective estrogen receptor modulator, raloxifene, is ongoing.

Finasteride is a 5a-reductase inhibitor. It inhibits the conversion of testosterone to dihydrotestosterone, a more potent stimulator of prostate cell proliferation than testosterone. In an F344 rat model of carcinogen-induced prostate cancer, finasteride decreased the incidence of cancers. Finasteride is being tested as a preventive agent for prostate cancer in a 10-year study involving 18,000 men age 55 and older.

Chemoprevention of Cancers of the Upper Aerodigestive Tract Smoking causes diffuse epithelial injury in the head, neck, esophagus, and lung. Patients cured of squamous cell cancers of the lung, esophagus, head, and neck are at risk (as high as 5% per year) of developing a second cancer of the upper aerodigestive tract. Cessation of cigarette smoking does not markedly decrease the cured cancer patient's risk of second malignancy, even though it does lower the cancer risk in those who have never developed a malignancy. Smoking cessation may halt the early stages of the carcinogenic process (such as metaplasia), but it may have no effect on late stages of carcinogenesis. This "field carcinogenesis" hypothesis for cancer of the upper aerodigestive tract has made "cured" patients an important population for chemoprevention of second malignancies. A randomized, placebo-controlled clinical trial has demonstrated that adjuvant isoretinoin (13-*cis*-retinoic acid) can reduce the incidence of second primary tumors in patients treated with local therapy for head and neck cancer. However, overall survival was not improved due to mortality from recurrences of the primary tumor.

Oral leukoplakia, a premalignant lesion commonly found in smokers, has been used as an intermediate marker allowing the demonstration of chemopreventive activity in smaller, shorter-duration, randomized, placebo-controlled trials. Response was associated with upregulation of retinoic acid receptor b. Therapy with isoretinoin causes regression of oral leukoplakia. However, the lesions recur when the agent is withdrawn, suggesting the need for chronic administration of retinoids. Premalignant lesions in the oropharyngeal area have also responded to b-carotene, retinol,a-tocopherol (vitamin E), and selenium. Further study to improve the definition of the activity of these drugs is ongoing. The ability of isoretinoin to prevent second malignancies in patients cured of early-stage non-small cell lung cancer is also being assessed.

Several large-scale trials have assessed agents in the chemoprevention of lung cancer in patients at high risk. In the Alpha-Tocopherol/Beta-Carotene (ATBC) Lung Cancer Prevention Trial, participants were male smokers, aged 50 to 69 at entry. At entry, participants had smoked an average of one pack of cigarettes per day for 35.9 years. Participants received a-tocopherol,b-carotene, and/or placebo in a randomized, 2´ 2 factorial design. After a median follow-up of 6.1 years, lung cancer incidence and mortality were statistically significantly *increased* in those receiving b-carotene.a-Tocopherol had no significant impact on lung cancer mortality, and no

evidence suggested interaction between the two drugs. Patients receiving a-tocopherol had a higher incidence of hemorrhagic stroke.

The Beta-Carotene and Retinol Efficacy Trial (CARET) involved 17,000 American smokers and workers with asbestos exposure. Entrants were randomly assigned to one of four arms and received b-carotene, retinol, and/or placebo in a 2´2 factorial design. This trial demonstrated harm from b-carotene: a lung cancer rate of 5 per 1000 subjects per year for those taking placebo and of 6 per 1000 subjects per year for those taking b-carotene. The difference was statistically significant.

TheseATBC andCARETresults demonstrate the importance of testing chemoprevention hypotheses before implementing them widely, because the results stand in contrast to a number of observational epidemiologic studies. In the ATBC trial, participants takinga-tocopherol had a one-third reduction in the incidence of prostate cancer, compared to those not takinga-tocopherol. Assessment of these findings continues. The Physicians' Health Trial showed neither an increased nor a decreased risk of lung cancer in those using b-carotene; fewer of its participants were smokers than those in the ATBC and CARET studies.

Chemoprevention of Colon Cancer Many of the current colon cancer prevention trials are based on the premise that most colorectal cancers develop from adenomatous polyps. These trials use adenoma recurrence or disappearance as a surrogate end-point to assess colon cancer prevention. Early clinical trial results suggest that nonsteroidal anti-inflammatory drugs (NSAIDs), such as piroxicam, sulindac, and aspirin, may prevent adenoma formation or cause regression of adenomatous polyps. The mechanism of action of NSAIDs is unknown, but they are presumed to work through the cyclooxygenase pathway. In the Physicians' Health Trial, aspirin had no effect on colon cancer incidence, although the 6-year assessment period may not have been long enough to evaluate definitively this end-point.

Epidemiologic studies suggest that diets high in calcium lower colon cancer risk. Calcium binds bile and fatty acids, which cause hyperproliferation of colonic epithelium. It is hypothesized that this effect reduces intraluminal exposure to these compounds. Early data from randomized studies suggest that calcium supplementation decreases the risk of adenomatous polyp recurrence by about 20%, even though it does not decrease the proliferative rate of the colonic epithelium. Epithelial proliferative rate may not be an adequate surrogate marker in colon cancer prevention trials.

Cyclooxygenase II inhibitors may be even more effective at colon cancer prevention.

Vaccines and Cancer Prevention A number of infectious agents have been linked to the development of cancer, leading to interest in developing vaccines to protect against these agents. The hepatitis B vaccine is quite effective in preventing hepatitis and hepatomas due to chronic hepatitis B infection. Public health officials are encouraging widespread administration of this vaccine, especially in Asia, where the disease is epidemic. In the future, human papilloma virus (HPV) vaccines could be developed to prevent cervical cancer, and *Helicobacter pylori* vaccines may be developed to prevent gastric cancer.

CANCER SCREENING

Screening is a means of detecting disease early in asymptomatic individuals with the goal of decreasing morbidity and mortality. Screening for cancer is intuitively appealing and has attracted great public interest as technology has generated a number of diagnostic tests and procedures that are safe, quick, and inexpensive. While screening can potentially save lives, and has been shown clearly to do so in the case of breast, cervical, and colon cancer, it is also subject to a number of biases, which can suggest a benefit when actually there is none. Bias can even mask net harm. Early detection does not in itself confer benefit. To be of value, screening must detect disease earlier, and treatment of earlier disease must yield a better outcome than treatment at the onset of symptoms. Cause-specific mortality, rather than survival after diagnosis, is the preferred end point (see below).

Because screening is done on asymptomatic, healthy persons, it should offer substantial likelihood of benefit. A critical approach to screening is necessary to ensure that benefit results. Screening tests and their appropriate use should be carefully evaluated before their use is widely encouraged in screening programs as a matter of public policy.

Screening examinations, tests, or procedures are usually not diagnostic of cancer but instead indicate that a cancer may be present. The diagnosis is then made following a workup that includes a biopsy and pathologic confirmation.

A number of genes have been identified that predispose for a disease, and many more will be identified in the near future. Testing for these genes can define a high-risk population. The ability to predict the development of a particular cancer may some day present therapeutic options as well as ethical dilemmas. It may eventually allow for early intervention to prevent a cancer or limit its severity. People at high risk will be ideal candidates for chemoprevention and screening; however, the efficacy of these interventions in the high-risk population should be investigated. Currently, persons at high risk for a particular cancer can engage in intensive screening. While this course is clinically prudent, it is not known if it saves lives in these populations.

The Accuracy of Screening A screening test's accuracy or ability to discriminate disease is described by four indices: sensitivity, specificity, positive predictive value, and negative predictive value (Table 80-2). *Sensitivity* is the proportion of persons with the disease who test positive in the screen (i.e., the ability of the test to detect disease when it is present). *Specificity* is the proportion of persons who do not have the disease and test negative in the screening test (i.e., the ability of a test to tell that the disease is not present). The *positive predictive value* is the proportion of persons who test positive who actually have the disease. Similarly, *negative predictive value* is the proportion of who test negative and do not have the disease. The sensitivity and specificity of a test are relatively independent of the underlying prevalence (or risk) of the disease in the population screened, but the predictive values depend strongly on the prevalence of the disease (Table 80-3).

Screening is most beneficial, efficient, and economical when the target disease is common in the population being screened. To be valuable, the screening test should

have a high specificity; sensitivity need not be very high, as demonstrated in Table 80-3.

Potential Biases of Screening Tests The common biases of screening are lead time, length, and selection. These biases can make a screening test seem beneficial when actually it is not (or even causes net harm). Whether beneficial or not, screening can create the false impression of an epidemic by increasing the number of cancers diagnosed. It can also give the appearance of a shift in stage, thus improving survival statistics without reducing mortality (i.e., the number of deaths from a given cancer relative to the number of people at risk for the cancer). In such a case, the *apparent* duration of survival increases without lives being saved or life expectancy changed.

Lead-time bias occurs when a test does not influence the natural history of the disease; the patient is merely diagnosed at an earlier date. When lead-time bias occurs, survival *appears* increased, but life is not really prolonged. The screening test only prolongs the time the subject is aware of the disease and spends as a patient.

Length bias occurs when slow-growing, less aggressive cancers are detected during screening. Cancers diagnosed owing to the onset of symptoms between scheduled screenings are on average more aggressive, and treatment outcomes are not as favorable. An extreme form of length bias is termed *overdiagnosis*, the detection of "pseudodisease." The reservoir of some undetected slow-growing tumors is large. Many of these tumors fulfill the histologic criteria of cancer but will never become clinically significant or cause death. This problem is compounded by the fact that the most common cancers appear most frequently at ages when competing causes of death are more frequent.

Selection bias must be considered in assessing the results of any screening effort. The population most likely to seek screening may differ from the general population to which the screening test might be applied. The individuals screened may have volunteered because of a particular risk factor not found in the general population, such as a strong family history. In general, volunteers for studies may be more health conscious and thus likely to have a better prognosis or lower mortality rate, irrespective of the screening result. This is termed the *healthy volunteer effect*.

Potential Drawbacks of Screening Risks associated with screening include harm caused by the screening intervention itself, harm due to the further investigation of persons with positive test results (both true and false positives), and harm from the treatment of persons with a true-positive result, even if life is extended by treatment. The diagnosis and treatment of cancers that would never have caused medical problems can lead to the harm of unnecessary treatment and give patients the anxiety of a cancer diagnosis. The psychosocial impact of cancer screening, whether the result is positive or negative, can also be substantial when applied to the entire population.

Assessment of Screening Tests Good clinical trial design can offset some biases of screening and demonstrate the relative risks and benefits of a screening test. A randomized, controlled screening trial with cause-specific mortality as the end-point provides the strongest support for a screening intervention. In a randomized trial, two like populations are randomly established. One is given the medical standard of care (which may be no screening at all), and the other receives the screening intervention

being assessed. The two populations are compared over time. Efficacy for the population studied is established when the group receiving the screening test has a better cause-specific mortality rate than the control group. Studies showing a reduction in the incidence of advanced-stage disease, an improved survival, or a stage shift are weaker evidence of benefit. These latter criteria are necessary but not sufficient to establish the value of a screening test.

Although a randomized, controlled screening trial provides the strongest evidence to support the usefulness of a screening test, it is not perfect. Unless the trial is population-based, it does not remove the issue of generalizability to the target population. Screening trials generally involve thousands of persons and last for years. Less definitive study designs are therefore often used to estimate the effectiveness of screening practices. After a randomized controlled clinical trial, in descending order of strength, evidence may be derived from:

· The findings of internally controlled trials using intervention allocation methods other than randomization (e.g., allocation determined by birth date, date of clinic visit);

· The findings of cohort or case-control analytic observational studies;

· The results of multiple time series studies with or without the intervention;

· The opinions of respected authorities based on clinical experience, descriptive studies, or consensus reports of experts (the weakest evidence because even experts can be misled by the biases described above).

Screening for Specific Cancers Widespread screening for breast, cervical, and colon cancer is beneficial for certain age groups. Special surveillance of those at high risk for a specific cancer because of a family history or a genetic risk factor may be prudent, but few studies have been carried out to assess the impact of this practice on mortality in specific high-risk populations. A number of organizations have considered whether or not to endorse routine use of certain screening tests. Because these groups have not used the same criteria to judge whether a screening test should be endorsed, they have arrived at different recommendations. The screening guidelines of the U.S. Preventive Services Task Force, the Canadian Task Force on Preventive Health Care, and the American Cancer Society are often quoted and show a range of recommendations (Table 80-4).

Breast Cancer Breast self-examination, clinical breast examination by a care giver, and mammography have been advocated as useful screening tools. Only screening mammography alone and screening mammography with clinical examination have been evaluated in randomized controlled trials. A number of well-designed trials have demonstrated that annual or biennial screening with mammography or mammography plus clinical breast examination in women over the age of 50 saves lives. In these trials, the breast cancer mortality rate is decreased by about a third. Experts disagree on whether average-risk women aged 40 to 49 should receive regular screening (Table 80-4). The statistical significance of the screening effect in women aged 40 to 49 depends on the statistical test used. An analysis of eight large randomized trials showed no benefit from mammographic screening for women aged 40 to 49 when assessed 5 to

7 years after trial entry. However, a small benefit emerged 10 to 12 years after study entry. What proportion of this possible benefit is due to screening after these women turned 50 is not known. In randomized screening studies of women aged 50 to 69, the decline in mortality begins about 5 years after initiation of screening. Nearly half of women aged 40 to 49 years screened annually will have false-positive mammograms necessitating further evaluation, often including biopsy. The risk of false-positive testing should be discussed with the patient.

While no study has shown breast self-examination to decrease mortality, it is recommended as prudent by many organizations. A substantial fraction of breast cancers are first detected by the patient, even with widespread mammographic screening.

Cervical Cancer Screening with Papanicolaou smears decreases cervical cancer mortality. The cervical cancer mortality rate has fallen significantly since the widespread use of the Pap smear, although this trend actually began earlier. Most screening guidelines recommend regular Pap testing for all women who are or have been sexually active or have reached the age of 18. With the onset of sexual activity comes the risk of sexual transmission ofHPV, the most common etiologic factor for cervical cancer. The recommended interval for Pap screening varies from 1 to 3 years. An upper age limit at which screening ceases to be effective is not known.

Colorectal Cancer Fecal occult blood testing, digital rectal examination, rigid and flexible sigmoidoscopy, radiographic barium contrast studies, and colonoscopy have been considered for colorectal cancer screening. Annual fecal occult blood testing using hydrated specimens could reduce colorectal cancer mortality by a third. The sensitivity for fecal occult blood is increased if specimens are rehydrated before testing, but at the cost of lower specificity. The false-positive rate for rehydrated fecal occult blood testing is high; 1 to 5% of persons tested have a positive result. About 2 to 10% of those with occult blood in the stool have cancer, and 20 to 30% have adenomas. The high false-positive rate of fecal occult blood testing dramatically increases the number of colonoscopies performed.

Two case-control studies suggest that regular screening of people over 50 with sigmoidoscopy decreases mortality. These types of studies are prone to selection biases. A quarter to a third of polyps can be discovered with the rigid sigmoidoscope; half are found with a 35-cm flexible scope, and two-thirds to three-quarters are found with a 60-cm scope. Diagnosis of polyposis by sigmoidoscopy should lead to evaluation of the entire colon with colonoscopy and/or barium enema. The most efficient interval for screening sigmoidoscopy is unknown. Case-control studies suggest that testing at intervals of up to 9 years may confer benefit. Most authorities feel that full colonoscopy is too cumbersome and invasive for widespread use as a screening tool in standard-risk populations. It may be suitable for subjects at extremely high risk, such as members of families with a genetic predisposition to colorectal cancer. Colonoscopy is accepted in screening persons with inflammatory bowel disease. Data are not available on digital rectal examination or barium enema as colon cancer screening tools, but both are insensitive.

Lung Cancer Screening chest radiographs and sputum cytology have been evaluated

as methods for lung cancer screening. No reduction in lung cancer mortality has been found in these studies, although all the controlled trials performed have had low statistical power. Even screening of high-risk subjects (smokers) has not been proved to be beneficial. Spiral computed tomography (CT) can diagnose lung cancers at early stages; however, false-positive rates are high. Ongoing studies are evaluating spiral CT screening.

Ovarian Cancer Adnexal palpation, transvaginal ultrasound, and serum CA-125 determination have been considered for ovarian cancer screening. Adnexal palpation is too insensitive to detect ovarian cancer at an early enough stage to affect mortality substantially. Neither transvaginal ultrasound nor CA-125 screening has been tested in a completed randomized prospective trial. Ovarian cancer screening can lead to an invasive diagnostic workup, which may include laparotomy. In a clinical study, 0.6% of 900 adult women had a serum CA-125 level >35 U/mL. Thus, if 100,000 adult women were screened, 600 would be identified as having a high CA-125. The prevalence of ovarian cancer in the female adult population is approximately 20 per 100,000. Thus, the screening test would identify 600 women who would undergo further evaluation to identify 20 cases of ovarian cancer. Some of these 600 would only be inconvenienced by an ultrasound examination. Others would undergo an exploratory laparotomy. A large proportion of the 20 women identified as having ovarian cancer would have advanced, incurable disease and thus not benefit from screening. AnNIHconsensus conference in 1994 concluded that routine screening for ovarian cancer was not indicated for standard-risk women or those with a single affected family member, but that it might be worthwhile in families with genetic ovarian cancer syndromes.

Prostate Cancer The most common prostate cancer screening modalities are digital rectal examination and assays for serum prostate-specific antigen (PSA). Newer serum tests, such as measurement of the ratio of bound to free serum PSA, have yet to be fully evaluated. An emphasis on PSA screening has caused prostate cancer to become the most common non-skin cancer diagnosed in American males. Screening for this disease is very prone to lead-time bias, length bias, and overdiagnosis, and substantial debate rages among experts on whether it is effective. Some experts are concerned that prostate cancer screening, more than screening for other cancers, may cause net harm. Prostate cancer screening clearly detects many asymptomatic cancers, but the ability to distinguish tumors that are lethal but still curable from those that pose little or no threat to health is limited. Men over age 50 have a very high prevalence of indolent, clinically insignificant prostate cancers. No well-designed trial has demonstrated the true benefit of prostate cancer screening and treatment, but trials are in progress.

The effectiveness of radical prostatectomy, radiation therapy, and other treatments for low-stage prostate cancer is also under study in randomized trials. Definitive treatment of cancers detected by screening may cause morbidity for some men, such as impotence and urinary incontinence, and carries a low but finite risk of death. Pending the completion of ongoing randomized trials comparing usual care to prostate screening and comparing definitive therapy to "watchful waiting," organizations have provided conflicting recommendations on prostate cancer screening (Table 80-4). After a thorough review of the literature, the American Cancer Society and the American Urologic Association changed their guidelines from a recommendation for screening to a recommendation that men be offered screening after being informed of the potential

risks and benefits. A man should have a life expectancy of at least 10 years to be eligible for screening.

Endometrial Cancer Transvaginal ultrasound and endometrial sampling have been advocated as screening tests for endometrial cancer. Benefit from routine screening has not been shown. Transvaginal ultrasound and endometrial sampling are indicated for workup of vaginal bleeding in postmenopausal women but are not considered as screening tests in symptomatic women.

Skin Cancer Visual examination of all skin surfaces by the patient or by a health care provider is used in screening for basal and squamous cell cancers and melanoma. No prospective randomized study has been performed to look for a mortality decrease. Observational epidemiologic evidence from Scotland and Australia suggests that screening programs have caused a stage shift in melanomas diagnosed. Screening may reinforce sun avoidance and other skin cancer prevention behaviors.

81. CANCER GENETICS - *Francis S. Collins*, *Jeffrey M. Trent*

THE CLONAL NATURE OF CANCER

Nearly all cancers originate from a single cell. While multiple cumulative events are invariably required to move a cell from normal to the transformed phenotype (see below andChap. 82), the origin of tumors from a single clone of cells is a critical discriminating feature between neoplasia and hyperplasia.

CANCER IS A GENETIC DISEASE

Cancer arises because of alterations in DNA that result in unrestrained cellular proliferation. Most of these alterations involve actual sequence changes in the DNA (i.e., mutation). They may arise as a consequence of random replication errors, exposure to carcinogens (e.g., radiation), or faulty DNA repair processes.

While virtually all cancer is genetic, most cancer is not inherited. Certain individuals with cancer have inherited a germline mutation that predisposes them to the cancer, but even in that situation additional somatic mutations are required for a tumor to develop. In a truly sporadic cancer, *all* of the mutations responsible for the malignant phenotype arise somatically. Such a cancer is caused by genetic alterations but has no hereditary implications.

RNA AND RNA TUMOR VIRUSES

Many malignancies in animals are transmissible, and the etiologic agent is frequently a retrovirus, which possesses a single-stranded RNA genome. During the life cycle of the virus, the single-stranded RNA is converted to double-stranded DNA and is inserted at random into the host chromosome. On rare occasions the virus can be remobilized, carrying along with it an adjacent segment of host DNA. Should this host DNA contain a growth-promoting gene, then the retrovirus is potentially transforming. Although efforts to identify retroviruses in human malignancies have mostly been fruitless, retroviruses are implicated in at least one human malignancy. Human T cell lymphotropic virus (HTLV) type I causes adult T cell lymphoma/leukemia, particularly in Japan and the Caribbean (Chap. 191). Unlike animal retroviruses that induce neoplasia, HTLV-I does not contain a growth-promoting transforming oncogene. The tax protein, a 40-kDa molecule encoded in the pX region of the viral genome, induces the activation of a number of genes (including some promoting growth) through interactions with *rel* family and CREB (cyclic AMP response element binding protein) family transcription factors.

DNA tumor viruses are more commonly involved in human malignancy. Human papilloma viruses (especially types 16 and 18) cause cervical cancer (Chap. 188), and both hepatitis B and hepatitis C viruses have been implicated in hepatocellular carcinoma (Chap. 297) . In addition, the Epstein-Barr virus, a herpesvirus that causes a mild illness in children but infectious mononucleosis in nonimmune adolescents and adults, causes Burkitt's lymphoma in Africa, nasopharyngeal carcinoma in Asia, and lymphomas in the setting of immune deficiency (Chap. 184).

GENERAL CLASSES OF CANCER GENES

In 1914 Boveri hypothesized that cells become malignant either because of overactivation of a gene that promotes cell division or because of loss of function of a gene that normally restrains growth. This hypothesis is largely correct, although defects in DNA repair genes are also involved. Genes that promote normal cell growth are referred to as *protooncogenes*, and activation of such genes by point mutation, amplification, or dysregulation converts them to *oncogenes*.

Genes that normally restrain growth are called *tumor suppressors* (use of the alternative designation of anti-oncogenes is to be discouraged), and unregulated cell growth arises if their function is lost. The diploid nature of mammalian cells allows certain predictions about the consequences of somatic mutations of tumor suppressor genes. Loss of one allele is unlikely to have significant consequences in most instances, as the remaining normal allele is usually sufficient for normal function. Thus, most cells of an individual with an inherited loss of function of one tumor suppressor allele are functionally normal. Only the rare cell that loses or develops a mutation in the remaining normal copy will exhibit uncontrolled growth. This model correctly predicts that the inheritance pattern of cancer in a family with a tumor suppressor gene mutation will be expressed as an autosomal dominant trait, though the cellular mechanism is recessive.

The third category of genes that contribute to malignancy is the DNA repair genes. Every cell division involves the copying of 6 billion base pairs (bp) of DNA. DNA polymerase has a finite error rate, and many environmental influences can damage DNA. As a consequence, repair systems are essential to protect the integrity of the genome. When the repair systems themselves are faulty, either on the basis of inherited or acquired mutation, the rate of accumulation of mutations throughout the genome rises as cell divisions occur. To the extent that these mutations involve oncogenes and tumor suppressor genes, the likelihood of developing malignancy increases.

MENDELIAN CANCER SYNDROMES

Roughly 100 syndromes of familial cancer have been reported, though many are rare. The majority are inherited as autosomal dominant traits, although some of those associated with DNA repair abnormalities (xeroderma pigmentosum, Fanconi anemia, ataxia telangiectasia) are autosomal recessives. Most of the genes responsible for the dominantly inherited cancer syndromes are tumor suppressor genes (Table 81-1). The hallmarks of a tumor suppressor gene are as follows: (1) the germline mutation that affects one allele generally causes a loss of function; (2) tumors also show loss of the second normal allele as a result of a somatic mutation; and (3) often the *normal* function of the gene is to suppress unrestrained cellular growth or to promote differentiation.

The retinoblastoma gene (*RB*) is a paradigm of such a tumor suppressor gene. In a pedigree showing dominant inheritance of susceptibility to retinoblastoma, a loss-of-function germline mutation occurs in one allele of the *RB* gene on chromosome 13. Analysis of the DNA from the tumors invariably shows that the wild-type allele has also been lost by one of several possible mechanisms (Fig. 81-1). However, not all retinoblastoma tumors arise in the context of a strong family history. Sporadic retinoblastoma, which is usually unilateral and on average occurs at a slightly older age than familial retinoblastoma, is usually a consequence of somatic mutation in both

alleles of the *RB* gene without any germline predisposition.

Another tumor suppressor gene is the p53 gene on chromosome 17p, which is frequently altered in solid tumors. p53 is somewhat unusual for a tumor suppressor gene in that missense mutations that produce a dominant negative protein product may also be growth-promoting, so that not all alterations obliterate function. Mutations in p53 are found in nearly half of human tumors. Germline mutations in p53 have dramatic consequences, resulting in a phenotype known as the *Li-Fraumeni syndrome*, where affected individuals may develop a variety of sarcomas, brain tumors, and leukemia. Figure 81-2 illustrates a typical pedigree of this devastating disorder.

In many instances the discovery of genes responsible for familial cancer syndromes has provided insight into the normal control of cell growth. For instance, in type I neurofibromatosis -- one of the more common dominant disorders of humans -- positional cloning efforts uncovered a previously unknown gene on chromosome 17q that, when mutated, produces a clinical phenotype of cafe au lait spots, neurofibromas, Lisch nodules of the iris, and a predisposition to neurofibrosarcoma and glioma. The responsible gene, which (like many of the genes inTable 81-1) has a close homologue in yeast, is neurofibromin (*NF1*), a critical participant in the regulation of the protooncogene *ras*. As shown inFig. 81-3, the NF1 protein is a GTPase-activating protein (GAP) that normally acts to convert *ras* from its active, growth-promoting, GTP-bound form to its inactive, GDP-bound form. Loss of both copies of *NF1* (one copy by inheritance, one by somatic mutation) thus renders a cell vulnerable to overgrowth, since *ras* is left in the "on" position.

While most autosomal dominant inherited cancer syndromes are due to mutations in tumor suppressor genes, there are a few interesting exceptions. Multiple endocrine neoplasia type II -- a dominant disorder characterized by pituitary adenomas, medullary carcinoma of the thyroid, and (in some pedigrees) pheochromocytoma -- is due to gain-of-function mutations in the protooncogene *ret* on chromosome 10. Interestingly, loss-of-function mutations in *ret* cause a totally different phenotype, Hirschsprung's disease (aganglionic megacolon) (Chaps. 339 and289).

Dominantly inherited colon cancer is sometimes associated with familial polyposis, which is usually due to mutations in the adenomatous polyposis coli (*APC*) tumor suppressor gene on chromosome 5 (Table 81-1). However, in most colon cancer families affected individuals do not have familial polyposis, but instead the cancer arises from normal-appearing epithelium. Hereditary nonpolyposis colon cancer (HNPCC, or Lynch's syndrome) is commonly defined as the occurrence of colon cancer in at least three individuals over at least two generations and with at least one individual diagnosed under the age of 50. As many as 1 in 200 individuals in the general population may have HNPCC, although this number is somewhat controversial. Most HNPCC is due to mutations in one of four DNA mismatch repair genes (Table 81-2). All four of these genes are components of a repair system that is normally responsible for correcting errors in freshly copied DNA. Tumors in patients with HNPCC are characterized by profound genomic instability, especially for short repeated sequences called *microsatellites*. Figure 81-4 shows an example of the instability in allele sizes for dinucleotide repeats in the cancers in HNPCC. The unstable phenotype [sometimes referred to as the "mutator" phenotype, or the "RER+" (replication error) phenotype]

probably requires loss of both copies of the particular mismatch repair gene (one inherited, one somatic), so that the mechanism is similar to that typical of a tumor suppressor gene.

MORE COMPLEX INHERITED FORMS OF CANCER

While the Mendelian forms of cancer described above have taught us much about mechanisms of cellular growth control, most forms of cancer do not follow such simple patterns of inheritance. In many instances (e.g., lung cancer), a strong environmental contribution is at work, but even in such circumstances some individuals may be genetically more susceptible to developing cancer given the appropriate exposure.

In the case of breast and ovarian cancer, circumstantial evidence indicates that a subset of affected individuals (5 to 10%) might be accounted for by dominantly inherited high-penetrance susceptibility genes; two of these genes have been identified by positional cloning. *BRCA1*, located on chromosome 17, is capable when mutated of producing a high risk (up to 85% lifelong) of breast cancer and also of ovarian cancer (50% lifelong risk). Roughly 1 in 500 women carries a germline *BRCA1* mutation, often giving rise to a strong family history. Men with *BRCA1* mutations may have a modestly increased risk of prostate cancer. An array of mutational heterogeneity has been described for *BRCA1* (Fig. 81-5), as is often the case for genetic disorders. An exception is the Ashkenazi Jewish population, where 1 in 100 individuals carries a particular 2-bp deletion (denoted 185delAG) of *BRCA1*, apparently as a consequence of descent from a common ancestor.

Mutations in another gene on chromosome 13, *BRCA2*, also confer a high risk of breast cancer (and a somewhat lower risk of ovarian cancer); men with *BRCA2* mutations are prone to develop breast cancer. The frequency of *BRCA2* mutations is estimated to be about half that of *BRCA1*. About 1% of Ashkenazi Jews again have a common mutation: 6174delT.

What then of the 90 to 95% of breast cancers that arise in individuals without germline alterations in *BRCA1* or *BRCA2*? Hereditary factors may still contribute to a significant fraction of these, but those factors must be weaker and therefore more difficult to discern.

GENETIC TESTING AND COUNSELING FOR CANCER SUSCEPTIBILITY

The discovery of genes like *RB*, p53, *NF1*, *ret*, theHNPCCmismatch repair genes, *BRCA1*, and *BRCA2* raises the possibility of DNA analysis to predict risk of cancer. There are many complexities associated with such testing. First, one must know the sensitivity and specificity of the test; the mutational heterogeneity for each of these genes constitutes a considerable technical challenge, as it is often necessary to sample every nucleotide of the coding region, the splice junctions, and the promoter to identify most mutations. False-positive results -- i.e., sequence alterations that turn out to be benign polymorphic variants (allelic variations) rather than disease-causing mutations -- can present a thorny problem. Unless proven interventions are available and the test is sensitive, specific, and relatively inexpensive, it will be inappropriate to offer such tests to the general population; the number of false-positive tests will exceed the number of

true positives and a great deal of anxiety and expense will be incurred evaluating persons who are not at an increased risk. Generally, therefore, such testing is not considered except for individuals of higher-than-normal risk, usually on the basis of their family history. In deciding whether to offer such testing, it is critical to determine whether evidence exists for effective interventions to reduce the risk of cancer in those found to be at high risk. If such interventions do not exist (as is the case for Li-Fraumeni syndrome), then the value of the information is limited, and the major negative psychological consequences of this information must be seriously considered.

For conditions such as colon and breast cancer, prophylactic measures exist (total colectomy and bilateral mastectomy, respectively), but these prophylactic measures are more radical and potentially disfiguring than the surgical procedures that would be used to treat the patient if the malignancies actually occurred (segmental bowel resection and lumpectomy, respectively). Other potential negative consequences of a positive genetic test include insurance and employment discrimination. One can still argue, of course, that a close relative of an individual known to carry a mutation in a cancer-causing gene is already sensitized to his or her personal risk of cancer, and that a test establishing that an individual at risk does *not* harbor the mutation can be quite useful. Testing should never be undertaken, however, without a full consideration of how the individual will handle a positive as well as a negative result.

Despite these caveats, genetic testing for some cancer syndromes already appears to have greater benefits than risks, and in those situations it is reasonable to offer testing to individuals at high risk. This would include conditions such as multiple endocrine neoplasia type 2 (Chap. 339) and von Hippel-Lindau disease (Chap. 370). More in the gray zone, although potentially applicable to much larger numbers of individuals, are tests for *BRCA1*, *BRCA2*, and theHNPCCgenes. More research is urgently needed in those situations to determine the effectiveness of various interventions (life-style, diet, surveillance, or surgery). Until those answers are available, such testing should be offered only as part of a research protocol. As more susceptibility genes are identified, better answers become available about the effectiveness of interventions, and health insurance discrimination is legislatively prohibited, genetic testing will move into the mainstream of medicine. Every physician of the future will need to have the skills of a genetic counselor.

ACQUIRED MUTATIONS IN CANCER

The identification of mutations in the germline of patients with heritable cancers means that the alteration is present in every cell of the body. However, in most cancers a normal cell becomes a malignant cell by a series of mutations that arise not in the germline but in somatic cells. Usually mutations must occur in several genes to give rise to neoplasia. The underlying questions are "how many mutations cause a cancer?" and "what specific genes are affected?" rather than whether or not mutational events cause cancer.

While answers to these questions are not available for every human malignancy, advances in molecular and cellular biology and epidemiologic analyses of human and experimental cancers are providing insights in cancer causation.Table 81-3 summarizes evidence from several lines of investigation pointing to a mutational basis for cancer

causation. One particularly striking feature is the fact that the overall incidence of cancer increases as the fourth to sixth power of age for most malignancies (Fig. 81-6*A*). For some tumors, the shape of the age-incidence curve suggests heterogeneity in molecular mechanisms. For example, Hodgkin's disease has a bimodal age distribution, suggesting that two etiologically (and therefore mutationally) distinct forms of this disease may exist (Fig. 81-6*B*).

MULTISTEP BASIS OF CANCER

From 5 to 10 accumulated mutations are thought to be necessary for a cell to move from the normal to the fully malignant phenotype. At each step the mutated cell may gain a slight growth advantage, so that it is increased in its representation relative to its neighbors. Figure 81-7, a representation of a lineage diagram hypothesized by Peter Nowell, illustrates how a single cell, afflicted with progressive alterations in tumor suppressor genes and protooncogenes, can develop into a clonal malignancy.

We are beginning to understand the precise nature of the genetic alterations responsible for some malignancies and to get a sense of the order in which they occur. Perhaps the best studied example is colon cancer, where an analysis of DNA from tissues extending from normal epithelium through adenoma to carcinoma have identified some of the genes mutated along the way (Fig. 81-8). However, the order of mutational events is far from uniform, and the diagram inFig. 81-8 should be considered a generalization and not a defined pathway. Similar data are being accumulated for other malignancies.

MECHANISMS OF SOMATIC MUTATION OF ONCOGENES IN MALIGNANCY

Cellular protooncogenes, their necessity and importance in normal cell growth, and their responsibility for transformation-associated change after removal of normal growth controls are discussed in Chap. 82. Mechanisms that upregulate (or activate) cellular protooncogenes can be grouped into three broad areas: point mutations, DNA amplification, and chromosome rearrangements.

Point Mutation One protooncogene that is commonly activated in solid tumors by point mutation is a member of the *ras* family of oncogenes; these were initially cloned from human bladder carcinoma cells and are critical regulators of normal and aberrant cell growth (Fig. 81-3). Mutations in one of the *ras* genes (H-*ras*, K-*ras*, or N-*ras*) are present in up to 85% of pancreatic cancers and 15% of all human cancers. In studies of K-*ras* (particularly in lung and colon cancer), the mutational spectrum of this gene has been identified. Remarkably, and in contrast to the diversity of mutations observed in the *BRCA1* gene (Fig. 81-5), most of these activated genes contain point mutations in codons 12 or 61 (which convey resistance to the inactivating action of GAP). The specificity of this pattern of mutation means that it has potential value in diagnostic or prognostic studies of cancer. For K-*ras*, mutations may be a useful prognostic marker in lung cancer, but for most other cancers (including pancreas and colon cancer) no prognostic utility has been demonstrated. This is in part because *ras* mutations occur early in colon cancer (Fig. 81-8), being common in precancerous lesions of the bowel.

DNA Amplification The second mechanism for activation of oncogene overexpression

is DNA sequence amplification. This increase in DNA sequence copy number may cause cytologically recognizable chromosome alterations referred to as *homogeneous staining regions* (HSRs), if integrated within chromosomes, or *double minutes* (dmins), if extrachromosomal in nature (Fig. 81-9).

The recognition of DNA amplification was greatly facilitated by the development of a procedure based on dual-color fluorescence in situ hybridization (FISH) called *comparative genomic hybridization* (CGH). DNA from tumor and normal cells is labeled with different fluorescent reporter molecules and then hybridized to normal metaphase chromosomes. Regions of duplications and deletions within tumor DNA are then demonstrated as quantifiable alterations in signal intensity at particular sites. With this technique the entire genome can be surveyed for gains and losses of DNA sequences, thus pinpointing chromosomal regions likely to contain genes important in the development or progression of cancer.

Numerous genes are known to be amplified in human malignancies. Several genes, including N-*myc* were identified because they were present within the amplified DNA sequences of a tumor and had homology to known oncogenes. Because the region amplified often extends to hundreds of thousands of base pairs, more than one oncogene may be amplified in some cancers (particularly sarcomas). Genes simultaneously amplified in many cases include *MDM2*, *GLI*, *CDK4*, *SAS*, and others implicated in cellular growth control. The clinical implications of gene amplification have been explored for some cancers [most notably *ERBB2 (HER-2/neu)* in breast cancer and N-*myc* in neuroblastoma]; demonstration of amplification of a cellular gene is usually a predictor of poor prognosis. Once a patient has been exposed to the selective effects of chemotherapy, gene amplification may lead to drug resistance. Amplification of the dihydrofolate reductase gene may follow clinical exposure to methotrexate, a drug that inhibits the activity of the enzyme.

Chromosomal Alterations in Human Cancer Chromosomal alterations provide important clues to the genetic changes in cancers. To date, most chromosome analyses have been performed on hematopoietic cancers, although solid tumors may also have translocations. The breakpoints of several recurring chromosome abnormalities often occur at the sites of cellular protooncogenes. Translocations are particularly common in lymphoid tumors, probably because these cell types normally rearrange DNA to generate antigen receptors. Indeed, antigen receptor genes are commonly involved in the translocations, implying that an imperfect regulation of receptor gene rearrangement may be involved in the pathogenesis. An example is Burkitt's lymphoma, a B-cell tumor characterized by a reciprocal translocation between chromosomes 8 and 14. Molecular analysis of Burkitt's lymphomas demonstrated that the breakpoints occurred within or near the *myc* locus on chromosome 8 and within the immunoglobulin heavy chain locus on chromosome 14, resulting in the transcriptional activation of *myc*. Enhancer activation by translocation, although not universal, appears to play an important role in malignant progression.

Chromosome rearrangements can lead to the abnormal overexpression of a transcription factor that performs its normal function and turns on growth-related genes. The translocation may create a chimeric transcription factor that has altered function. For example, the t(15;17) of acute promyelocytic leukemia produces a retinoic acid

receptor with an abnormal cell distribution that inhibits differentiation. Gene rearrangements most commonly involve transcription factors, but other components of signaling pathways may also be involved.

The first reproducible chromosome abnormality detected in human malignancy was the Philadelphia chromosome in chronic myelogenous leukemia (CML). This cytogenetic abnormality is generated by reciprocal translocation involving the *ABL* oncogene, a tyrosine kinase on chromosome 9 being placed in proximity to the *BCR* (breakpoint cluster region) on chromosome 22. Figure 81-10 illustrates the generation of the translocation and its protein product. The consequence of expression of the *BCR-ABL* gene product is the activation of signal transduction pathways, leading to cell growth independent of normal external growth factor signals.

In addition to transcription factors and signal transduction molecules, translocations may involve the overexpression of cell cycle regulatory proteins, such as cyclins, and of proteins that regulate cell death, such as bcl2. Altering control of expression of cell cycle regulatory proteins can lead to aberrant cell cycle control. The overexpression of bcl-2 can prevent the death of a cell that has endured enough genetic damage to cause its death. If such a cell survives to receive additional genetic damage, a tumor can develop. Table 81-4 lists representative examples of recurring chromosome alterations in malignancy and the associated gene(s) rearranged or dysregulated by the chromosomal change.

Technical obstacles have slowed the identification of recurring chromosome abnormalities in human solid tumors (particularly carcinomas) because of the complexity of chromosome alterations in such tumors, in contrast to the solitary, often reciprocal, nature of chromosome rearrangements in hematopoietic malignancies.

EPIGENETIC REGULATION OF GENE EXPRESSION AND CANCER

The term *epigenetic* refers to mechanisms of gene regulation independent of DNA sequence. The inactivation of the second X chromosome in female cells is an example of an epigenetic mechanism that prevents gene expression from the inactivated chromosome. During embryologic development, entire regions of chromosomes from one parent are silenced and gene expression proceeds from the chromosome of the other parent. For most genes, expression occurs from both parental alleles or randomly from one parent or the other. The preferential expression of a particular gene exclusively from the allele contributed by one parent is called *parental imprinting* and is thought to be regulated by the methylation of the silenced allele.

The role of epigenetic control mechanisms in the development of human cancer is unclear. However, a general decrease in the level of DNA methylation has been noted as a common change in cancers. In addition, the loss of imprinting of the normally silent maternal allele of the insulin-like growth factor II gene at chromosome 11p15.5 has been implicated in some cases of the rare pediatric malignancy Wilms' tumor. The loss of imprinting may result in the overexpression of the growth factor and a predisposition to malignant transformation.

THE FUTURE

The real challenge in oncology is to convert the growing molecular understanding of cancer into clinical advances, particularly the development of new therapies. One can anticipate that in the coming years the molecular analysis of mutations in tumors will allow stratification of malignancies into more precise subgroups than is currently possible by histologic classification, including subgroups with particularly good or bad prognoses or that have a lower or higher likelihood of responding to a particular therapy. Some of this information is already accumulating, but usually only one or two genes are assessed; the promise of the future is to obtain a detailed molecular "fingerprint" of every tumor in order to provide the maximum information about its biology and response to therapy. The application of techniques for assessing global gene expression (cDNA microarrays, serial analysis of gene expression, or SAGE, and others) is leading to novel ways of looking at cancer that are considerably more discriminating than light microscopy, the gold standard of medical practice. The National Cancer Institute in conjunction with the National Center for Biotechnology Information have undertaken the Cancer Genome Anatomy Project (CGAP) (http://www.ncbi.nlm.nih.gov/ncicgap/) to collect data on the differences in gene expression between normal and malignant tissues and make it available on the Internet.

Genetics will also influence cancer prevention and early detection. The ability to identify cancer susceptibility genes presages a new era of cancer prevention, if the potential risks of such testing can be surmounted. Currently, most cancer early detection strategies (such as mammography, stool occult blood testing, or digital rectal examination) are applied to population groups. The ability to identify the individuals at highest risk and to focus preventive medicine efforts accordingly may be both better received by patients and more cost effective. Early detection strategies will be even more effective if we can develop the ability to identify very small numbers of malignant or premalignant cells at a time when the risk of metastasis is still very low.

More importantly, detailed molecular information about the regulation of the cell cycle and the interplay of tumor suppressor genes and proto-oncogenes that control it may lead to new effective therapies, based on pathophysiology rather than empiricism. Whether such strategies will rely on drugs of the traditional types or will be based on more novel strategies such as gene therapy or immunotherapy is hard to predict.

82. CELL BIOLOGY OF CANCER - *Robert G. Fenton*, *Dan L. Longo*

Two characteristic features define a cancer: cell growth not regulated by external signals (i.e., autonomous) and the capacity to invade tissues and metastasize to and colonize distant sites (Chap. 83). The first of these features, the uncontrolled growth of abnormal cells, is a property of all neoplasms, or new growths. A neoplasm may be benign or malignant. If invasion, the second cardinal feature of cancer, is present, the neoplasm is malignant. Cancer is a synonym for *malignant neoplasm*. Cancers of epithelial tissues are called *carcinomas*; cancers of nonepithelial (mesenchymal) tissues are called *sarcomas*.

Cancer is a genetic disease, but the level of its expression is the single cell. Although some forms of cancer are heritable, most mutations occur in somatic cells and are caused by intrinsic errors in DNA replication or are induced by carcinogen exposure. A single genetic lesion is usually not sufficient to induce neoplastic transformation of a cell. The malignant phenotype is acquired only after several (5 to 10) mutations lead to derangements in a variety of gene products. Each genetic alteration may cause phenotypic changes typified by the progression in epithelial tissues from hyperplasia to adenoma to dysplasia to carcinoma in situ to invasive carcinoma. Cells have evolved mechanisms to resist neoplastic transformation (see below).

The>200 discrete cell types in the body are not equally susceptible to developing cancer. Some cells, such as cardiac myocytes, sensory receptor cells for light and sound, and lens fibers, persist throughout life without dividing or being replaced. Neoplasia in such tissues is exceedingly rare. Most differentiated tissues undergo constant renewal characterized by cell death and replacement.

In tissues with rapid turnover, such as skin, bone marrow, and gut, an individual cell is on one of two largely mutually exclusive paths: division or differentiation. Cells capable of dividing are undifferentiated (stem cells), whereas terminally differentiated cells are unable to divide. Stem cells produce daughter cells that can either become new stem cells (thus replenishing the stem cell compartment) or undergo terminal differentiation, depending on the circumstances and the environmental signals. Stem cells are distinguished from differentiating cells by different patterns of gene expression. Gene expression is the product of the tissue-specific programming interacting with environmental factors such as cell-to-cell contact; interactions with extracellular matrix; endocrine hormones; paracrine growth and differentiation factors; and stresses such as heat, oxidation, irradiation, and physical distortion or traction.

Cancer is most common in tissues with rapid turnover, especially those exposed to environmental carcinogens and whose proliferation is regulated by hormones. The most common genetic changes involve the activation of proto-oncogenes or the inactivation of tumor suppressor genes (Chap. 81). Although genetic damage is nearly universal in human cancer, cells with neoplastic features can be generated in vitro without genetic damage. Removal and in vitro culture of cells from the epiblast of a murine embryo lead to the uncontrolled proliferation of the cells and the generation of a teratocarcinoma cell line capable of producing tumors when inoculated into animals. The removal of these normal embryonic cells from their normal environment leads to uncontrolled growth. However, if the teratocarcinoma cells are reinjected into an early embryo, under the

inductive influence of their normal neighbors they can differentiate into normal organs and tissues appropriate for the location where they are injected.

Thus, environmental factors exert potent effects on the gene expression of target cells. The panoply of signals received by a particular cell leads to the activation of particular sets of transcription factors. The pattern of gene expression determines whether a cell will divide, differentiate, or die.

PRINCIPLES OF CELL CYCLE REGULATION

The mechanism of cell division is substantially the same in all dividing cells and has been conserved throughout evolution. The process assures that the cell accurately duplicates its contents, especially its chromosomes. The cell cycle is divided into four phases. During M phase, the replicated chromosomes are separated and packaged into two new nuclei by mitosis and the cytoplasm is divided between the two daughter cells by cytokinesis. The other three phases of the cell cycle are called *interphase*: G1 (gap 1), a period of growth during which the cell determines its readiness to commit to DNA synthesis; S (DNA synthesis), during which the genetic material is replicated and no re-replication is permitted; and G2 (gap 2), during which the fidelity of DNA replication is determined and errors are corrected.

During S phase, DNA synthesis begins with the unfolding of chromatin and nucleosome complexes rendering DNA accessible for the addition of DNA helicase and single-strand binding proteins that help open the double helix. Replication origins are spaced roughly 100,000 nucleotide pairs apart throughout the genome. DNA polymerase and DNA primase attach to these sites and catalyze the polymerization of the DNA at a rate of about 50 nucleotides per second. DNA polymerased catalyzes leading-strand synthesis, while DNA polymerase a uses DNA primase-generated Okazaki fragments for lagging-strand synthesis. Topoisomerase I nicks DNA, relieving torsional tension of the replicating helix; topoisomerase II introduces double strand breaks to avoid DNA tangles. Topoisomerases are targets of many chemotherapeutic drugs. Once a DNA segment is replicated, chromatin is reassembled, and replication origins are relicensed by binding of specific proteins that prevent re-replication until the next S phase. Although this system for replication is efficient and accurate, occasional mistakes are made, and these are repaired by a variety of mechanisms. In some cancers, the mismatch repair mechanisms are defective and errors increase by 3 to 4 logs, greatly increasing the likelihood of mutations in growth regulatory genes in daughter cells.

DNA polymerase is unable to replicate the end of a DNA chain completely, resulting in loss of DNA with each replication. This problem has been solved by a mechanism that replicates tandem repeats of a six-nucleotide sequence (GGGTTA) to the ends of each chromosome. These repeated sequences are called *telomeres* and are replicated through an RNA-dependent DNA polymerase called *telomerase*. Normal somatic cells do not express telomerase, and the replicative lifetime of such cells is limited to approximately 30 cell divisions due to the progressive loss of telomere repeats; the limit imposed on somatic cell division is called the *Hayflick limit*, at which time replicative senescence occurs. Germ cells do express telomerase and have a long (possibly unlimited) replicative lifetime. The aberrant expression of telomerase in cancer cells is thought to be a component of the neoplastic process, assuring that the cell will be able

to undergo many divisions without inducing senescence or genetic catastophe. Inhibition of telomerase activity in cancer cells could have antitumor effects.

The cell cycle transitions between G1 and S and between G2 and M are tightly regulated to ensure that cells are prepared to divide and to minimize errors in the replication process. Checkpoints in G1 and G2 determine whether a cell will enter S or M phase, respectively; these checkpoints are regulated by serine/threonine protein kinases (cyclin-dependent kinases, or cdk) and kinase-associated proteins called *cyclins*. The enzymatic activity of each cdk is determined by its association with a cyclin and its phosphorylation state. There are at least seven cdk family members, and a like number of cyclins, which generate a group of cdk/cyclin complexes with differing substrate specificities and times of action during the cell cycle. Cyclin expression varies with the cell cycle, and the synthesis of these proteins is transcriptionally regulated and their degradation is mediated by ubiquitin conjugation and destruction in proteasomes.

The cyclin B/cdc2 complex (also called *mitosis promoting factor*, or MPF) is the primary regulator of transition from G2 to M phase. It is activated by acdk-activating kinase (CAK) and a phosphatase (cdc25c) that removes inhibitory phosphates. The cdc25C is the target of a DNA damage-induced kinase that inhibits its activity. DNA damage leads to phosphorylation of cdc25C and its transport out of the nucleus, away from cyclin B/cdc2. This prevents entry into M phase until DNA damage is repaired. The regulated movement of molecules into and out of the nucleus is a common control mechanism in signal transduction. Some of the substrates of cyclin B/cdc2 are defined; its phosphorylation of histone H1, nuclear lamins, and microtubule-associated proteins facilitates chromosome condensation, nuclear membrane breakdown, and spindle formation, respectively.

The checkpoint regulating transition from G1 to S is frequently disrupted in cancer. The product of the retinoblastoma tumor suppressor gene, the nuclear phosphoprotein Rb, governs the key transition referred to as the *reaction point*. A second pathway regulated by the p53 tumor suppressor interacts with the Rb pathway to ensure that cell proliferation can safely take place. Rb and p53 are inactivated by products encoded by DNA tumor viruses, including SV40 large T antigen, adenovirus E1A and E1B, and human papillomavirus E6 and E7. The Rb and p53 pathways each include other oncogenes and tumor suppressors that are frequently disrupted in cancer (Table 82-1).

Regulation of passage through the restriction point is complex. In early G1, Rb is hypophosphorylated and in a complex with the E2F transcription factor. This nuclear complex binds to the promoters of genes required for cell cycle progression and inhibits their expression. However, in mid and late G1, Rb becomes phosphorylated (at ~10 sites) by the sequential activity of the cyclin D/cdk4 and cyclin E/cdk2 complexes. Hyperphosphorylated Rb releases E2F, thus relieving transcriptional repression, and heterodimers of E2F and DP1 transcription factor family members activate several genes required for S phase progression, including dihydrofolate reluctase, thymidine kinase, DNA polymerase, and cdc2 (Fig. 82-1). In addition to its role in growth regulation, Rb is required for the in vitro differentiation of muscle cells and adipocytes. Cell cycle control and induction of differentiation are functions of Rb that contribute to tumor suppression.

The activity ofcdk is also regulated by cdk inhibitors (cdki). These low-molecular-weight proteins are divided into two families: the Cip/Kip family encoding $p21^{Cip1/Waf1}$, $p27^{Kip1}$, $p57^{Kip2}$, which inhibit cdk activity broadly, and the Ink4 family encoding $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$, which block cyclin D/cdk4 activity and inhibit Rb phosphorylation and G1/S transition. p21 is induced by p53 in response to DNA damage, causing G1 arrest to permit DNA repair. If DNA damage is too great, a cell suicide pathway is induced to eliminate cells that may be dysfunctional (see below).

Thecdki can be induced by growth inhibitors such as transforming growth factor (TGF)b and can be inhibited by growth factors such as interleukin (IL) 2. Genetic alterations in cdki, especially p16 and p15, occur with high frequency in certain tumors. Alterations at the p16 locus on chromosome 9p21 have been detected in 75% of pancreatic cancers; 40 to 70% of glioblastomas; 50% of esophageal cancers; and about 20% of non-small cell lung cancers, soft tissue sarcomas, and bladder cancers. Mutations in p16 account for half of familial melanomas. Some tumors fail to express cdki because the genes are methylated, an epigenetic mechanism for blocking transcription. Rb pathway regulation is also circumvented by overexpression of cyclin D1 [breast cancer and the t(11;14) in mantle cell lymphoma] and by mutations in cdk4 that abrogate p16 binding.

Whereas Rb, cyclin D,cdk4, and p16 are commonly altered in cancer, E2F overexpression or p21 mutations have not yet been seen. Additional study may reveal why some components of the system are susceptible to alterations and other components are not.

p53, the "guardian of the genome," is a transcription factor that is not usually called upon to act in the course of normal replication. Levels of p53 are normally kept low by its association with mdm2, which binds p53 and shuttles it out of the nucleus for degradation. However, with DNA damage, p53 is phosphorylated by the ataxia telangiectasia gene product ATM, it dissociates from mouse double minute 2 (mdm2), and its destruction is slowed, leading to increased levels. Also, p53 influences transcription to either halt cell cycle progression (e.g., through induction of p21 expression to inhibitcdkactivity) to permit repair of the DNA or, if the damage is too great, to initiate cell suicide (*apoptosis*). p53-induced genes involved in apoptosis include death receptors (DR5) and death-inducing members of the Bcl-2 family. p53 also induces expression of mdm2, thus down-regulating its own activity.

Inducers of p53 include hypoxia, DNA damage, ribonucleotide depletion, and telomere shortening. Dysregulated activity of oncogenes such as *myc*, which promote aberrant G1/S transition, induces p53-mediated apoptosis. A second product of the Ink4a locus is $p14^{ARF}$, encoded by an alternative reading frame (ARF) from p16. Levels of ARF are upregulated by *myc* and E2F. ARF binds to mdm2/p53 complexes and rescues p53 from the inhibitory effects of mdm2 with subsequent activation of p53-induced genes. This oncogene checkpoint leads to the death of renegade cells that attempt to traverse the restriction point without the right signals.

Mutation in p53 is the most common genetic alteration found in human cancer (>50%) and is the causative lesion in Li-Fraumeni familial cancer sydrome. In tumors, usually one p53 allele on chromosome 17p is deleted and the other is mutated. The mutations often involve the region between codons 120 and 290, the portion of the gene specifying

the site of p53 involved in transcription. Some environmental agents cause mutations at specific sites. In 81% of hepatomas in persons from developing countries, codon 249 is mutated due to exposure to the carcinogen, aflatoxin. Codon 249 mutations occur in only 11% of hepatomas in persons from industrialized countries where aflatoxin exposure is low. Inactivation of the p53 pathway compromises cell cycle arrest, inhibits apoptosis induced by DNA damage or oncogene activation, and predisposes cells to chromosome instability.

Regardless of the pathogenesis of the tumor, most have some mechanism(s) to bypass the G1 checkpoint, avoid activation of cell suicide pathways, and propagate cells with damaged DNA. Table 82-1 summarizes some of the changes in cell cycle regulators detected in human cancers.

SIGNALING FROM OUTSIDE THE CELL TO THE NUCLEUS

The behavior of cells in the body is tightly regulated by environmental signals. The ability of a cell to respond to a specific set of signals determines whether the cell will live or die, differentiate, proliferate, or remain quiescent. In normal cells and tissues, coordinated action such as wound healing or the inflammatory response is regulated by signaling pathways that convert extracellular signals into the performance of specialized action in the responding cells. In cancer cells, the process of invading and metastasizing is influenced by signal transduction pathways activated by paracrine and autocrine factors.

The coupling of extracellular signals to cell response varies for different receptor and signaling systems. The binding of a growth factor [e.g., epidermal growth factor (EGF)] to its receptor on the cell surface produces measurable changes in the cell within seconds and elicits a sequence of events that may last for days. Rapid responses are elicited by changes in ion flux, phosphorylation events, lipid metabolism, and production of second messengers. Long-term responses are mediated by the transfer of signaling information from the receptor to the nucleus, where alterations in the pattern of gene expression result in phenotypic change. Signal transduction comprises the mechanisms by which information received at the plasma membrane is imparted to the nuclear transcriptional machinery and other cell functions. Many signal transduction pathways are perturbed in cancer cells. There are three families of cell surface receptors: ion channel-linked receptors. G protein-linked receptors, and enzyme-linked receptors. Although ion channel-linked receptors are a component of growth-related activation in many cell types, they are primarily involved in neurotransmitter signal transduction and are somewhat less important in the pathogenesis of neoplasia than the other two types and will not be discussed further.

G PROTEIN-LINKED RECEPTORS

The G protein-linked receptors traverse the plasma membrane seven times (serpentine receptors). They do not induce covalent modification of their substrates, as do enzyme-linked receptors, but generate second messenger molecules such as cyclic AMP, cyclic GMP, and calcium to activate downstream processes. Upon ligand binding, these receptors activate trimeric G proteins inducing the release of Ga and Gbg subunits, each of which elicits downstream signals. The process is terminated by GTP

hydrolysis by Ga subunits. The roles of G protein signaling pathways in human cancer include certain endocrine tumors whose cells of origin depend on cyclic AMP for growth. About half of growth hormone-secreting pituitary tumors encode mutant Ga subunits that are defective in GTPase activity and are constitutively activated even in the absence of ligand. These Ga subunits bind to and stimulate the activity of adenyl cyclase, leading to unregulated synthesis of cyclic AMP. Cyclic AMP binds to the repressor subunit of protein kinase A thus activating the kinase, which enters the nucleus and phosphorylates CREB (cyclic AMP response element binding protein), a transcription factor that activates genes required for proliferation of the cancer cells. Growth stimulatory Ga mutations have also been described in adrenal cortical tumors and endocrine tumors of the ovary. Factors involved in normal cell and tumor cell migration also stimulate cells through G protein-coupled receptors.

ENZYME-LINKED RECEPTORS

There are at least five classes of enzyme-linked receptors: receptor guanylyl cyclases, receptor tyrosine kinases, tyrosine kinase-associated receptors, receptor tyrosine phosphatases, and receptor serine/threonine kinases. The atrial natriuretic peptide receptor is a receptor guanylyl cyclase. Some disease manifestations in cancer may be related to atrial natriuretic peptide activity (such as hyponatremia), but little is known about this receptor class. Receptor phosphatases are not known to be involved in cancer. The other classes of enzyme-linked receptors are better defined and play a more important role in cancer.

Receptor Tyrosine Kinases The receptors for most growth factors are transmembrane tyrosine kinase receptors, including platelet-derived growth factor (PDGF), fibroblast growth factors (FGFs),EGF, heregulin, insulin, insulin-like growth factors (IGF) I and II, nerve growth factor (NGF), stem cell factor, vascular endothelial growth factor, macrophage colony stimulating factors (CSF), and others. Much of what we know about receptor tyrosine kinases and the events that follow their ligation emerged from the study of the proliferation-inducing altered forms of the normal cellular genes (proto-oncogenes) that are the cancer-causing genes (oncogenes) in animal retroviruses. Although downstream events vary with the receptor/ligand combinations, the activation of the receptor follows a typical pattern. Ligand binding induces dimerization or oligomerization of receptor subunits, which activates tyrosine kinase activity and causes autophosphorylation of specific tyrosine residues in the cytoplasmic domain of the receptor. Phosphorylated tyrosine residues on the receptors or on associated adaptor proteins form docking sights for other signal transduction molecules that contain one or more *src-homology region 2*, or SH2, domains, named because the sequence was first identified in the *src* nonreceptor tyrosine kinase. Phosphorylation of tyrosine residues provides a unique amplification signal because of the rapid and specific binding of SH2 domains to p-Tyr, although p-Tyr comprises only 0.05% of total cell phosphoamino acid. These associations via SH2 domains trigger subsequent events (Fig. 82-2). Signaling is terminated by the action of p-Tyr-specific phosphatases.

Protein domain interactions between evolutionarily conserved motifs play critical roles in all forms of signal transduction, ranging from tyrosine kinase pathways, death-inducing molecules, and the association of transcription complexes on gene regulatory regions. The most common docking mechanisms are based on recognition of particular protein

sequences; the SH2 domains recognize p-Tyr-containing sequences with specificity conferred by surrounding amino acid residues, the SH3 domains dock with proline-rich sequences, and the pleckstrin homology domains [pleckstrin is a major protein kinase C (PKC) substrate in platelets] lead to associations with phosphatidylinositol lipids phosphorylated in the 3 position by phosphatidylinositol 3-kinase (PI3K; see below). Some molecules that do not have docking domains are brought into association with the receptors through the activity of adaptor proteins that are composed of docking domains only. Thus, the nucleotide exchange factor son of sevenless (SOS; named for its role in *Drosophila* eye development) is brought close to the membrane to activate Ras through its association with the adaptor protein grb2 (identified because it "grabbed" p-Tyr-containing proteins).

Receptor tyrosine kinases activate many signaling pathways including phospholipase C-g, which hydrolyzes phosphoinoside 4,5-bisphosphate (PIP2) into diacylglycerol (DAG) and inositol triphosphate (IP3). DAG together with calcium ion activatesPKC, a family of serine/threonine kinases with different activation requirements, subcellular locations, and substrates in different cell types. PKC is the target of tumor-promoting phorbol esters, and its activation can influence cell proliferation, differentiation, and tumorigenesis. IP3 induces the release of intracellular calcium, which binds to calmodulin, a protein that regulates the activity of many enzymes, including phosphatases. Calcium fluxes within cells can be short or prolonged, and the duration has profound physiologic effects. PI3K is a lipid kinase that generates PI(3,4)P2 and PI(3,4,5)P3, membrane lipids that act as binding sites for proteins containing PH motifs. Such proteins include Akt serine/threonine kinase, which is implicated in activating survival pathways in many cells. Src family tyrosine kinases bind to p-Tyr on activated receptors and amplify signaling information by phosphorylation of distinct protein substrates within the cell. Src activity is required for G1 progression in some cells through its induction of the transcription factor c-myc. Another consequence of receptor tyrosine kinase activation is stimulation of the Ras/MAP (mitogen-activated protein) kinase pathway that leads to activation of a number of transcription factors that regulate proliferation, differentiation, and cell survival. This pathway is frequently abnormal in cancer cells.

Ras is a 21-kDa member of a large family of proteins, including rho, rac, rab, and others, that regulate cytoskeletal changes, vesicular and nuclear transport, and proliferation and that share sequence homology with the Ga subunit of G protein-linked receptors. Ras is attached to the inner cell membrane through an isoprenyl lipid group added after translation by the enzyme farnesyl transferase. If the lipid group is not added, Ras does not localize to the membrane and cannot function normally. In unstimulated cells, Ras is bound to GDP and is inactive. Following receptor tyrosine kinase activation, the guanine nucleotide exchange factorSOS is brought to the membrane by its association with grb2. SOS removes GDP from Ras and adds GTP. GTP-bound Ras then activates a cascade ending withMAPkinase, which migrates to the nucleus and phosphorylates (activates) a number of transcription factors (Fig. 82-3). The kinetics of MAP kinase activity are critical: in PC12 rat pheochromocytoma cells, stimulation withEGFresults in transient stimulation of MAP kinase activity, retention of MAP kinase in the cytoplasm, and cell proliferation; stimulation of PC12 cells with NGF induces sustained activation of MAP kinase, nuclear translocation of MAP kinase, and neuronal differentiation.

Genetic defects leading to increased signaling from receptor tyrosine kinase-linked pathways are important in the etiology and progression of human cancer. About 30% of human cancers (especially pancreatic, lung, and colon adenocarcinomas) have mutated *Ras*. The mutations usually involve codons 12, 13, or 61 and result in a Ras protein that fails to hydrolyze its bound GTP and is thus constitutively active. In the hereditary disorder, neurofibromatosis, a mutation in the gene that encodes neurofibromin, a GTPase activating protein (GAP), inhibits its ability to inactivate Ras by converting the GTP to GDP. Constitutively activated Ras results in the unregulated activity of the signaling pathways downstream of Ras, including the MAP kinase pathway and activation of PI3K. Some epithelial cancers overexpress one or more members of the receptor tyrosine kinase family.EGFreceptors,IGF-I receptors, and HER-2/*neu* are overexpressed in lung, bladder, breast, head and neck, and ovarian cancers. Mutations within the Ret tyrosine kinase receptor lead to constitutive receptor dimerization and kinase activation and are responsible for the dominant inherited cancer syndromes multiple endocrine neoplasia (MEN) type 2A and type 2B and familial medullary thyroid carcinoma. Autocrine and paracrine sources of the relevant growth factors have been noted in some cases.

Tyrosine Kinase-Associated Receptors The receptors for growth hormone, prolactin, erythropoietin, thrombopoietin, most interleukins, granulocyteCSF, granulocyte-macrophage CSF, interferon-a, interferon-g, and many other cytokines are members of the tyrosine kinase-associated receptor family. These single-transmembrane receptors contain ligand-specific subunits and shared signaling subunits. Ligand binding induces the activation of receptor-associated tyrosine kinases. Three families of kinases are known to be associated with this class of receptors: *src* family (*src*, *yes*, *fgr*, *fyn*, *lck*, *lyn*, *hck*, *blk*, and counting), *syk* family (*syk*, ZAP-70), and Janus family (JAK1, JAK2, JAK3, Tyk2). The Janus family kinases have receptor sites that act as docking sites for SH2-containing transcription factors called STATs (signal transducers and activators of transcription). Tyrosine phosphorylation of STATs induces their dimerization by SH2-p-Tyr association followed by translocation to target genes in the nucleus. A unique feature of JAK/STAT signaling is that the pathway from cell membrane to nucleus is traversed by a single dimeric molecule, as opposed to the cascade of kinase and adaptor molecules associated with membrane tyrosine kinases. The *src* family kinases can associate with receptor tyrosine kinases as well as tyrosine kinase-associated receptors, and, not surprisingly, signal transduction through either receptor class leads to the activation of similar signaling cascades. As a consequence of *src* family activation, *myc* is one of the transcription factors activated. The *syk* family usually activates the *src* family member in the receptor complex.

These receptors are often overexpressed on tumors of hematopoietic origin, and, similar to receptor tyrosine kinases, autocrine or paracrine stimulation may contribute to the neoplastic state of the tumor cell.

Serine/Threonine Kinase Receptors These receptors recognizeTGF-b, bone morphogenetic factors, and other activins as ligands. Ligand binding leads to activation of the receptor kinase activity, but downstream events are not well defined. Bone morphogenetic factors are important in bone formation and in determining ventral vs. dorsal orientation in the developing embryo. TGF-b induces transformation of

mesenchymal cells but inhibits the proliferation of most cell types through the induction ofcdki, which block G1 progression in an Rb-dependent manner. Activation of TGF-b receptors leads to the phosphorylation of transcription factors Smad2 and Smad3, which then associate with their obligate partner Smad4. This complex, probably a heterotrimer, translocates into the nucleus where specific genes are activated. The direct path to the nucleus is analogous to the JAK/STATsignaling pathway. Smads bind to specific DNA sequences adjacent to other transcription factor sites in the promoters of target genes, leading to cooperative interaction for gene induction. TGF-binduced genes include plasminogen activator inhibitor-1 (PAI-1), collagenase I, and $p15^{INK4b}$.

Many cancers are resistant to growth inhibition byTGF-b, including leukemias, lymphomas, melanomas, and breast and colon cancers. Colon cancers harboring defects in DNA mismatch repair develop inactivating mutations in the extracellular domain of the TGF-b receptor. In pancreatic and colon cancers, missense mutations and loss of heterozygosity at the DPC4 locus on chromosome 18q21 are frequent. This locus has been found to encode Smad4, and its inactivation blocks TGF-bsignaling. Loss of expression or loss of function of TGF-b receptors occurs in several tumor types including colon cancer and lymphomas.

Nuclear Hormone Receptors Steroids, retinoids, thyroid hormone, vitamin D, and other lipid-soluble hormones diffuse through the plasma membrane and bind to members of the nuclear hormone receptor family. Receptors for these ligands are transcription factors that reside in the nucleus. The hydrophobic nature of the ligands obviates the need for machinery to transduce signals from the cell surface to the cell interior. Steroid hormone receptors are bound as heterodimers to promoter/enhancer elements of genes; in the absence of ligand, these complexes act as transcriptional repressors. Upon ligand binding, conformational changes are induced and the active transcription factor binds to coactivating factors and transcription is induced. Coactivators tend to open chromatin structure by adding acetyl groups to histones. Histone acetylation in nucleosomal complexes permits access of promoter regions to RNA polymerase II. Transcriptional repressor complexes associate with histone deacetylases (HDAC; co-repressor complexes), and chromatin remains condensed. Nuclear hormone-induced pathways affect virtually all biologic processes. Retinoic acid receptors (RAR) provide a clear link to cancer. Retinoids bind receptors composed of an RAR subunit (a, b,g) dimerized with a retinoid-X receptor (RXR) and activate genes that influence differentiation in many cell types.

Acute promyelocytic leukemia (APL) is associated with the t(15;17) translocation, which fuses sequences from a novel gene PML (promyelocytic leukemia) to theRARagene, resulting in expression of a PML-RARa fusion protein. PML-RARa binds to and represses RARa-inducible genes required for myeloid differentiation. Repression is mediated byHDACbinding to PML-RARa. The developmental arrest at the promyelocyte stage of differentiation is associated with unregulated proliferation in these cells. Patients with APL can achieve complete remission with pharmacologic doses of all-trans retinoic acid (tretinoin), the ligand for RARa. Tretinoin induces the release of HDAC, permitting coactivator binding. Drugs that inhibit HDAC activity may provide a therapeutic benefit by activating genes required for the differentiation of cancer cells.

Cell-Cell and Cell-Extracellular Matrix (ECM) Communication In addition to

information conveyed by soluble mediators, cell surface receptors relay important signals between cells, such as contact inhibition, and cell-ECM signals, such as anchorage-dependent growth. In cancer, these highly organized mechanisms of intercellular interaction often become disrupted or are subsumed for the purpose of metastasizing (Chap. 83). Individual cells no longer respond to signals from their neighbors, actin filaments are highly disorganized, and adherens junctions are lost. Normal patterns of growth and differentiation are disrupted, and the potential for metastasis increases.

E-cadherins are integral membrane glycoproteins that mediate calcium-dependent homophilic adhesion as the major component of adherens junctions between epithelial cells. E-cadherin cytoplasmic domains bind complexes containing a- andb-catenins, which are structurally linked to the cytoskeleton (actin cables and intermediate filaments).b-Catenin that is not sequestered in E-cadherin complexes is rapidly phosphorylated by glycogen synthesis kinase (GSK) 3b in a complex with the APC (adenomatous polyposis coli) gene product (maps to chromosome 5, mutated in familial polyposis) and is degraded by the ubiquitin/proteosome pathway. Degradation ofb-catenin can be blocked by several mechanisms, including mutations that inactivate APC and mutations in serine phosphorylation sites within b-catenin that target it for degradation. Such mutations result in increased free b-catenin, which translocates into the nucleus and binds to members of the T cell factor (TCF) family of transcription factors, influencing the expression of genes such as c-*myc* and cyclin D1 that promote progression through G1. Excess freeb-catenin has been implicated in hereditary and sporadic forms of colon cancer and melanoma. Decreased expression of E-cadherin has been noted in breast, colon, prostate, gastric, and other cancers and is a marker of poor prognosis.

Epithelial cell growth and survival require attachment of cells to components of theECM that compose basement membranes, including collagen, fibronectin, vitronectin, and laminin. The integrin family of transmembrane receptors is composed ofa and b subunits that adhere to the ECM and convey information to cytoplasmic membrane-associated structures called *focal adhesions*. The complexes, whose assembly is mediated by the Rho and Rac GTPases, are sites of attachment of actin cables but are also active in cell signaling through their association with focal adhesion kinase (FAK) and Src tyrosine kinases. Integrin-ECM interactions lead to activation of the Ras/MAPkinase, PI3K, and phospholipase C-g pathways. Detachment of epithelial and endothelial cells from ECM induces their death by a form of programmed cell death called *anoikis* (Greek, "homeless"). This molecular safeguard prevents abnormal spread of cells. Invasive cancers often avoid anoikis by activating Ras or Src, which allow anchorage-independent growth of cells by activation of Akt kinase.

REGULATION OF GENE TRANSCRIPTION

One consequence of signal transduction is the activation of sequence-specific transcription factors that regulate gene expression. Whether a cell proliferates, differentiates, or undergoes apoptosis is regulated by gene products made in response to physiologic stimuli. For some transcription factors, the ligand goes directly to the nucleus where they reside (nuclear hormone receptors). For others, activated kinases enter the nucleus and phosphorylate factors already bound to DNA (MAPkinase and

AP-1 transcription factor). Some transcription factors are activated in the cytoplasm and translocate to the nucleus (STATs). NF-kB is held in the cytoplasm by the negative regulator IkB, which is phosphorylated and degraded as a consequence of signal transduction. NF-kB is then released from IkB, and NF-kB translocates to the nucleus.

Transcription factors recognize short stretches of DNA of a defined nucleotide sequence 6 to 12 base pairs in length. These recognition sites may be upstream or downstream of the transcription start site [the TATA box where the first subunit of the transcription machinery, transcription factor IID (TFIID), binds]. Transcription factors may affect transcription at sites remote from the start site by looping out large intervening DNA sequences.

Transcription factors contain specific amino acid sequences capable of recognizing the DNA sequence and usually form one of several structural motifs: helix-turn-helix, homeodomain, zinc finger, leucine zipper, and helix-loop-helix are all used as DNA-binding motifs or mediate dimerization of factors required for DNA binding. Transcription factors function in one or more of several ways. They can physically bend the DNA to permit the ordered addition of the components of the transcription machinery. Activated transcription factors bind to coactivator proteins in complexes that encode enzymatic activity leading to the acetylation of histones. This alters nucleosomal conformation and increases accessibility of DNA to transcription proteins. Transcription factors can inhibit transcription by blocking binding of a positive transcription factor or preventing the assembly of a transcription complex. They can form complexes with co-repressors and deacetylate histones. Promoters can also be made inaccessible by methylation of cytosine- and guanosine-rich sequences near promoters. The complex interaction between positive and negative transcription factors dictates the level of gene transcription. Individual genes may have^{3}20 sites for transcription factor binding. The pattern of gene expression is determined by which factors are expressed in a given cell type.

Most genes are regulated at multiple levels, though transcription initiation is the dominant control point. The von Hippel-Lindau gene on chromosome 3p (a tumor suppressor gene involved in the pathogenesis of renal cell cancer) appears to act by inhibiting the elongation of an RNA chain after transcription initiation. A message may be spliced alternatively and encode different proteins in different cells. Transport of the message from the nucleus to the cytoplasm may be altered. Messenger RNA turnover may be accelerated. Some proteins, such as apoferritin and thymidylate synthase, regulate the translation of their own messages (and perhaps other messages) by binding to mRNA and preventing initiation of protein synthesis. Thus, there are many levels at which gene expression may be influenced.

Some transcription factors were identified because of their transforming effects when their genes, usually in mutated form, were incorporated into animal retroviral genomes; *myc*, *rel*, *fos*, *jun*, and others are examples of proto-oncogene transcription factors that are overexpressed in certain cancers and that contribute to the malignant phenotype of tumor cells. The mutated oncogenes are often more resistant to protein degradation and have a longer half-life than the normal cellular counterpart. Transcription factors with unusual properties may be generated by chromosome translocation that produces a chimeric protein. Novel genes may be activated that promote proliferation and inhibit

apoptosis. Usually the genetic changes lead to inhibition of normal lineage-specific differentiation, resistance to apoptosis, and proliferation.

REGULATION OF CELL DEATH

The homeostasis of adult organisms requires a balance between the generation of new cells and the death of old cells. Some cells die when their telomeres no longer protect the integrity of DNA replication. Some cells die when they have sustained sufficient hypoxic, heat, oxidative, or ultraviolet irradiation damage that cannot be repaired. A cell can be killed if it becomes infected with a virus or other intracellular pathogen that destroys the cell or is recognized by the host's lymphocytes, which kill the infected cell. Multicellular organisms are models of cellular cooperation; some cells die to preserve the rest of the organism.

Genetic damage to growth-regulating genes of stem cells could be catastrophic; however, single genetic events such as activation of *myc* expression or loss of the Rb checkpoint often lead to the death of the cell by apoptosis. Apoptosis is a form of cell death initiated by extracellular or intracellular signals in which enzymes are activated to degrade nuclear DNA by making intranucleosomal cuts, causing the cell to shrink and finally break up. The core apoptosis machinery consists of a family of specialized proteases called *caspases* (they contain a *c*ysteine at their active site and cleave substrates after *asp*artic acid residues). Like coagulation and complement systems, caspases exist as proenzymes with minimal enzymatic activity that can be rapidly induced by activators, and each enzyme acts to activate the next enzyme in the cascade. Key targets include DNA (chromatin degraded into nucleosomal multimers), nuclear lamins (nucleus shrinks and fragments), cytoskeletal regulatory proteins, DNA repair enzymes, and others. The cell shrinks, its chromatin fragments, and the cell breaks apart forming apoptotic bodies.

The latent activity of caspases is tightly regulated to prevent the death of normal cells. Assembly of initiator caspases into active complexes occurs by two main mechanisms. Members of the tumor necrosis factor (TNF) receptor superfamily, including Fas (CD95), and DR4 and DR5 death receptors encode transmembrane proteins whose cytoplasmic domains encode protein association or docking domains, called *death domains* and *death effector domains* (DED). Ligand binding induces dimerization of death domains with recruitment to the membrane of an adaptor signaling protein called *Fas-associated death domain* (FADD). FADD forms a complex with procaspase 8 mediated by DED interactions; caspase 8 is activated by self-cleavage. Caspase 8 then cleaves effector caspase 3 into active heterodimeric subunits, and death ensues (Fig. 82-4). Regulation of this pathway occurs at the level of expression of Fas receptor and ligand and the secretion of death-inducing cytokines, TNF and *t*umor necrosis factor-*r*elated *a*poptosis-*i*nducing *l*igand (TRAIL) (ligand for DR4 and -5).

The second pathway of caspase activation encompasses responses to a greater variety of noxious signals including DNA damage, growth factor deprivation, reactive oxygen damage, and heat stress. The mitochondrion plays a key role in this pathway as the storehouse of protein cofactors required for the activation of caspases. Damage within the cell is detected by the mitochondria by unknown mechanisms. The mitochondria then lose membrane potential and release cytochrome c, which forms a complex with

apoptosis-activating factor (Apaf) 1. This complex binds to procaspase 9 via a caspase recruitment domain (CARD), and caspase 9 is activated. Caspase 9 then cleaves effector caspases and induces cell death. The release of cytochrome c from the mitochondria appears to be regulated by bc12.

The *bcl2* gene was discovered as the chromosome 18q contribution to the t(14;18) translocation in follicular lymphoma. The gene did not transform cells but prolonged the life of cells destined to die, greatly increasing a pool of cells available for subsequent genetic mutations. Members of the *bcl2* family fall into two groups: *bcl2* and *bcl*-$X_L$prevent cell death, whereas *bax*, *bad*, *bak*, and others promote cell death. The *bcl2* family members associate as homodimers or heterodimers; the combinatorial effects of the various dimers allow a fine level of control over cell survival. When any of the death promoters exist as homo- or heterodimers, the cell dies by apoptosis. When a death promoter heterodimerizes with either *bcl2* or *bcl*-X_L, cell death is prevented. Thus, the relative amounts of different *bcl2* family members determine whether a cell will survive potentially damaging insults. Furthermore, phosphorylation of *bcl2* family members by cellular kinases can alter the biologic activity of individual members, altering the balance in favor of death or survival.

In addition to its presumed role in the etiology of follicular lymphoma, *bcl2* is expressed in a number of cancers. It prevents the normal p53-mediated destruction of cells with damaged DNA and also appears to prevent the death of cells severely damaged by cancer chemotherapy. In addition, *bcl2* mediates drug resistance and contributes to neoplasia in a novel way, preventing the death that would normally eliminate the damaged cell, rather than promoting aberrant cell growth. Strategies to overcome *bcl2* function might well make available therapies more effective.

The apoptotic machinery is subject to regulation by multiple signal transduction pathways, and many of these are subverted in cancer cells to shift the balance toward survival of the malignant clone. In addition to *bcl2*, two other important links have been established between growth factor signaling and survival pathways. Activation of P13K by tyrosine kinases leads to activation of the serine/threonine kinase Akt. Akt directly promotes cell survival by phosphorylation of Bad and procaspase 9, inhibiting their apoptotic functions. Cancer cells can usurp the activity of Akt; in some cases, cells expressing a mutated Ras oncogene or increased levels of tyrosine kinase receptors (e.g., HER-2/*neu*) have upregulated the Akt pathway. An alternative genetic lesion leading to increased Akt kinase activity results in the loss of the PTEN tumor suppressor, a lipid phosphatase that normally downregulates the P13K pathway by dephosphorylating lipid second messengers. Another important pathway usurped by cancer cells involves NF-kB activation. NF-kB induces expression of the inhibitor of apoptosis (IAP) family of genes whose products inhibit caspase activity; one such, survivin, is expressed in lymphomas and other tumors.

Thus, cancer becomes more adaptive to its host from genetic events that alter apoptosis. Stimulation of proliferation or prevention of death can be complementary targets for cell transformation. Apoptosis pathways are important targets for treatment. Paclitaxel and other microtubule inhibitors induce the phosphorylation and inactivation of *bcl2*. One could make bone marrow cells highly resistant to chemotherapy-induced death by expressing a form of *bcl2* that lacks the loop domain in the BH1 region, as this

is the site that is phosphorylated to inhibit *bcl2* function. Tumor cells and normal cells express DR4 and -5 receptors; however, tumor cells fail to express decoy receptors that protect normal cells from the DR4 and -5 ligand, TRAIL. Thus, therapies directed at DR4 or -5 may be tumor selective.

CELL BIOLOGY AND CANCER

For a cancer to arise, mutations must occur that affect a variety of pathways. Often the G1 cell cycle checkpoint is affected. Apoptosis is averted by mutations in the p53 pathway or by other mechanisms. The expression of telomerase is a common feature in cancers. Overexpression of growth factors and their receptors is frequently detected. Activation of the *Ras* proto-oncogene or other changes leading to a constitutively activeMAPkinase cascade are common. Changes in cytoskeleton and responsiveness to contact-mediated growth inhibition are frequent in cancer cells. Usually when a mutation occurs in one component of a signaling pathway, other mutations are seen in other pathways rather than in another component of the same pathway. The high level of mutability of cancer cells facilitates adaptation to the environment, including the development of resistance to anticancer drugs. As tumors progress, they acquire the ability to secrete proteases that aid in the escape from local barriers so that they may metastasize (Chap. 83). Discrete steps in tumor progression lead to the production of factors by the tumor cells that permit neovascularization to supply nutrients to the growing tumor. Other mutations allow the tumor to escape immune surveillance mechanisms; for example, some tumors downregulate expression of class I major histocompatibility complex antigens so that they become invisible to T cells. The wide range of changes that must occur in a single cell to permit the behavior associated with a malignant neoplasm makes it clear why carcinogenesis is a multistep process and why human cancers may have 10 or more genetic lesions that account for the biology.

The characteristic of cancer cells that has dominated clinical thinking is their uncontrolled proliferation. However, the growth fraction of most human cancers is usually not higher than the growth fraction of normal gut epithelia or normal bone marrow, and most human tumor explants are difficult to propagate for long periods of time in culture. Cancer cell lines immortal in vitro may have additional genetic lesions that permit their growth in vitro. Naturally occurring tumors growing in vivo show a Gompertzian or exponential decline in their growth fraction because the daughter cells of a division are not uniformly capable of further division. The accumulation of genetic damage, poor oxygen or nutrient supply, and other unknown factors contribute to the senescence of some tumor cells, so that by the time a tumor becomes clinically apparent at a tumor burden of 10^8 to 10^9cells, most of the proliferative capability of the tumor is finished. Often by this time, more malignant and highly selected clonal derivatives of the tumor have metastasized to other sites where new tumor deposits with more aggressive characteristics are formed. Thus, cancer cells can be viewed as having lost the altruism that usually characterizes cell behavior in multicellular organisms. Cancer cells operate under natural selection imposed by a hostile environment. Ironically, the more successful they are at achieving independence from environmental influences, the more assured is the destruction of their host and ultimately themselves.

Many potential therapeutic agents are in clinical development based on our concepts of tumor cell biology. They include the development of growth factor and growth factor

receptor antagonists; inhibitors of phosphoryl transfer to block key kinases; selective inhibitors ofPKC, P13K, phospholipase C, and other targets; farnesyl transferase inhibitors that block the insertion of *Ras* into the membrane; mutant versions of proteins such as *Ras* and p53 that may make the cell vulnerable to immunologic attack if employed as a vaccine; and inhibitors of angiogenesis or the steps in metastasis that may limit tumor growth and prevent its spread. However, it seems unlikely that a single target will be the highly sought-after point of vulnerability. More likely, combinations of inhibitors will be required to improve antitumor effects. For example, the combination of chemotherapy and antibody toEGFreceptors appears to produce greater antitumor effects than the sum of the effects produced individually.

83. ANGIOGENESIS - *Judah Folkman*

Virtually every cell in the body lives adjacent to a capillary blood vessel, or at least no further than the mean oxygen diffusion distance of 100 to 200 um. Some cell types, such as beta cells in the pancreatic islets, fat cells, and skeletal muscle cells, are surrounded by at least two capillaries (Fig. 83-1). Capillaries of 8 to 20 um diameter are lined by a single layer of endothelial cells. These cells cover ~1000 m_2, an area the size of a tennis court. The length of capillary tubing in 1 mm_3 of human heart muscle is ~2500 mm, and 1 kg of fat contains ~3500 m of capillaries. During normal conditions vascular endothelial cell proliferation is barely detectable -- <0.01% of endothelial cells are in cycle. Endothelial cell turnover is >1000 days and in retinal vasculature may be >5000 days. In contrast, in the normal adult bone marrow, ~6 billion cell divisions occur per hour and the turnover time is ~5 days, (i.e., the time during which bone marrow is completely replaced). Endothelial cells can emerge from their resting state and proliferate as rapidly as bone marrow cells during formation of new capillaries. This process is called *angiogenesis* and leads to *neovascularization*.

Physiologic angiogenesis is tightly regulated and of limited duration. It is essential to reproduction and embryonic development. During postnatal and adult life, angiogenesis in wound repair and in exercised muscle is restricted to days or weeks.

Pathologic angiogenesis, in contrast, is usually persistent and unabated. Angiogenesis that continues for months or years supports the growth and progression of solid tumors and leukemias, provides a conduit for the entry of inflammatory cells into sites of chronic inflammation (e.g., Crohn's disease and chronic cystitis), is the most common cause of blindness, destroys cartilage in rheumatoid arthritis, contributes to growth and hemorrhage of atherosclerotic plaques, leads to intraperitoneal bleeding in endometriosis, is the basis of life-threatening hemangiomas of infancy, and permits prostate growth in benign prostatic hypertrophy. These are just a few of the "angiogenic disease processes," which are found in almost all specialties of medicine. Angiogenesis inhibitors are a new *class* of drugs that suppress or reverse the pathologic neovascularization upon which these diseases are dependent.

NEOPLASTIC DISEASE

HISTORIC BACKGROUND

Tumor hyperemia, observed during surgery since the 1870s, was for the next 100 years attributed to simple dilation of existing host vessels. Two reports, in 1939 and 1945, suggested that tumor vascularity was due to the induction of new blood vessels. This idea was dismissed by most investigators. The few who accepted it believed that new vessels were an inflammatory side effect of tumor growth.

In 1971, based on experiments carried out in the 1960s, a hypothesis was proposed that tumor growth could be angiogenesis-dependent, i.e., tumors could recruit their own private blood supply by releasing a diffusible chemical signal that stimulated angiogenesis. Tumor angiogenesis could then be a novel second target for anticancer therapy. These concepts were not accepted at the time. The conventional wisdom was that tumor neovascularization was (1) an inflammatory host response to necrotic tumor

cells, (2) a host response detrimental to the tumor, or (3) "established" vasculature that could not regress. From these assumptions most scientists concluded that it was fruitless to attempt to discover an angiogenesis stimulator, to say nothing of discovering angiogenesis inhibitors. Eventual acceptance of the 1971 hypothesis was slow because it would be 2 more years before the first vascular endothelial cells were successfully cultured in vitro, 8 more years before *capillary* endothelial cells could be cultured in vitro, 11 years before the discovery of the first angiogenesis inhibitor, and 13 years before the purification of the first angiogenic protein. By the mid-1980s, after a series of reports from several laboratories demonstrating that tumor growth was angiogenesis-dependent, this hypothesis had been confirmed by genetic methods.

THE ANGIOGENIC SWITCH

The Prevascular Phase Most human tumors arise without angiogenic activity and exist in situ as microscopic-sized lesions of 0.2 to 2 mm diameter for months to years, after which a small percentage may switch to the angiogenic phenotype. Autopsy studies of people who died of trauma but who never had cancer during their lifetime reveal that in women from 40 to 50 years of age, 39% had in situ carcinomas in their breast, but breast cancer is diagnosed in only 1% of women in this age range. In men from age 50 to 70, 46% had in situ prostate cancers at the time of death, but only 1% are diagnosed in this age range during life. In people from age 50 to 70, >98% had small carcinomas of the thyroid (Fig. 83-2), but thyroid cancer is diagnosed in only 0.1% in this age range. In the majority of human tumors, the angiogenic phenotype appears after the malignant phenotype is recognized histologically. However, for certain human tumors (e.g., carcinoma of the cervix), the preneoplastic stage of dysplasia becomes angiogenic before the malignant phenotype is recognized histologically. When a nonangiogenic in situ carcinoma emerges in avascular epidermis or mucosa (e.g., melanoma or breast cancer), it is separated from host vessels by a basement membrane (Fig. 83-3). If a nonangiogenic tumor emerges in the midst of a vascularized tissue (e.g., an islet cell carcinoma), it may form an in situ microcylinder of tumor cells around capillary vessels (called *cooption*).

At the clinical level the angiogenic switch is recognized by expansion of tumor mass to a detectable size, local bleeding, and metastasis. For example, a positive mammogram usually represents a neovascularized tumor -- a non-neovascularized in situ carcinoma is below the detectable limits of mammography. Hematuria in bladder cancer, melena in colorectal cancer, and hemoptysis in lung cancer all result from neovascularized tumors. Tumor cells are not usually shed into the circulation until after neovascularization has occurred. Furthermore, distant metastases themselves cannot be detected until they have "turned on" the angiogenic switch.

At the cellular level at least four mechanisms of the angiogenic switch have been identified in human and mouse tumors: (1) avascular in situ carcinomas can recruit their own blood supply by stimulating neovascularization in an adjacent host vascular bed -- the most common process in human tumors; (2) circulating precursor endothelial cells from bone marrow may incorporate into an angiogenic focus; (3) tumors may induce host fibroblasts and/or macrophages in the tumor bed to overexpress an angiogenic factor [e.g., vascular endothelial growth factor (VEGF)]; and (4) preexisting vessels can be coopted by tumor cells. The angiogenic switch may also include combinations of

these mechanisms. Once tumors have switched on angiogenesis, they rarely revert to the nonangiogenic phenotype. Neuroblastoma and retinoblastoma may be exceptions, but spontaneous loss of angiogenic activity (and tumor regression) is rare even in these two tumors. After the angiogenic switch, new microvessels converge on the tiny in situ tumor. Tumor cells grow as microcylinders, or "perivascular cuffs," around each new vessel. One endothelial cell can support from 5 to 100 tumor cells.

At the molecular level, the angiogenic switch operates as a shift in the balance of production by tumor cells of molecules that positively or negatively regulate angiogenesis. The overexpression of positive regulators of angiogenesis and the downregulation of inhibitors of angiogenesis during early tumor development are generally triggered by genetic mutations that control angiogenesis. For example, overexpression of the *ras* oncogene increases production of the angiogenic proteinVEGF, while a mutation in the p53 tumor-suppressor gene or its deletion decreases production of the angiogenesis inhibitor protein, thrombospondin-1. In the normal cell wild-type p53 upregulates thrombospondin-1 and downregulates VEGF.

The angiogenic switch can be further modified by environmental conditions such as hypoxia, endogenous angiogenesis inhibitors, and genetic background of the host.

1. *Hypoxia*: After a tumor has become neovascularized, its continued expansion may lead to increased tissue pressure. This increased interstitial pressure is caused mainly by plasma that leaks from new vessels but is slow to efflux from the tumor because of a dearth of intratumoral lymphatics. Microvessels in the center of the tumor are the first to be compressed, which leads to central necrosis. Hypoxia activates an hypoxia-inducible factor (HIF-1) binding sequence in theVEGFpromoter. This leads to transcription of VEGF mRNA, increased stability of VEGF message, and increased production of VEGF protein beyond what may have been triggered genetically. Tumors, therefore, do not "outgrow their blood supply" but compress it. A counterintuitive lesson is that in situ tumors arising in an avascular compartment (e.g., epidermis) are *not* hypoxic, but larger neovascularized tumors become hypoxic after compressing their blood supply. Low pH and low glucose in a tumor may also upregulate production of angiogenic factors, especially VEGF.

2. *Endogenous angiogenesis inhibitors*: At the molecular level, the angiogenic switch can also be modified by endothelial inhibitors that either circulate [e.g., interferon (IFN) b, platelet factor 4, angiostatin] or are releasable from extracellular matrix [e.g., endostatin, thrombospondin-1, and tissue inhibitors of metalloproteinases (TIMPs)]. Therapeutic administration of an endogenous angiogenesis inhibitor, such as angiostatin or endostatin, can tip the balance of the angiogenic switch so that angiogenic output of a tumor is opposed or abrogated.

3. *Genetic control of host response*: Just as the angiogenic output of a given tumor is governed by oncogenes and tumor-suppressor genes, the angiogenic response of the host is genetically regulated. It is known that hemangiomas predominate in white infants and that ocular neovascularization in macular degeneration is almost never found in black patients. The genes that regulate these effects are not yet known.

Endogenous Angiogenesis Promoters The known endogenous angiogenic promoters

are listed inTable 83-1. Virtually all of these proteins are produced by different types of tumors. However, acidic FGF (aFGF), basic FGF (bFGF),VEGF, and angiopoietin-1 and -2 are the most well studied and have been found in a wide variety of human tumors.

Fibroblast Growth Factors aFGF andbFGFstimulate endothelial cell mitosis and migration in vitro and are among the most potent angiogenic proteins in vivo. They have high affinity for heparin and heparan sulfate. They lack a signal sequence for secretion but are stored in extracellular matrix. An unsolved problem is how bFGF is exported from tumor cells in the absence of a signal sequence. Many different cells synthesize bFGF, including tumor cells of the central nervous system, sarcomas, genitourinary tumors, and even endothelial cells in the tumor vasculature. Proteinases and heparanases are thought to mobilize bFGF from the extracellular matrix. Furthermore, some tumors recruit macrophages and activate them to secrete bFGF, while others attract mast cells, which, because of their high heparin content, sequester bFGF. bFGF is not a specific endothelial mitogen but has several cell targets including fibroblasts, smooth-muscle cells, and neurons. However, experimental tumors transfected with bFGF containing an engineered signal sequence stimulate endothelial proliferation almost to the exclusion of smooth-muscle and fibroblast proliferation. This is similar to the process in human tumors. This selective attraction of vascular endothelial cells by bFGF released from a tumor may be explained by the smooth-muscle repellant activity of angiopoietin-2 elaborated from proliferating endothelial cells in a tumor bed (see below). bFGF interferes with adhesion of leukocytes to endothelium; thus, tumors that elaborate bFGF may produce a form of local immunologic tolerance.

Abnormally elevated levels ofbFGF are found in the serum and urine of cancer patients and in the cerebrospinal fluid of patients with different types of brain tumors. High bFGF levels in renal carcinoma correlate with poor outcome. Also, bFGF levels in the urine of children with Wilms' tumor correlate with stage of disease and tumor grade.

Vascular Endothelial Growth Factor/Vascular Permeability Factor The first proposal that tumor angiogenesis is associated with increased microvascular permeability led to the identification of vascular permeability factor (VPF). VPF was subsequently sequenced and shown to be a specific inducer of angiogenesis; it was called *vascular endothelial growth factor*.VEGF is an endothelial cell mitogen and motogen that is angiogenic in vivo. Its permeability effect on capillaries is more potent than histamine and contributes to ascites in ovarian cancer and to edema in brain tumors. Its expression correlates with blood vessel growth during embryogenesis and with angiogenesis in the female reproductive tract and in tumors. VEGF is a 40- to 45-kDa homodimeric protein with a signal sequence secreted by a wide variety of cells and by the majority of human tumor cells. For example,>60% of breast cancers overexpress VEGF. VEGF exists as five different isoforms of 121, 145, 165, 189, and 206 amino acids, of which $VEGF_{165}$is the predominant molecular species produced by a variety of normal and neoplastic cells. Two receptors for VEGF are found mainly on vascular endothelial cells, the 180-kDa fms-like tyrosine kinase (Flt-1) and the 200-kDa human kinase insert domain-containing receptor (KDR) and its mouse homologue, Flk-1. VEGF binds to both receptors, but KDR/Flk-1 transduces the signals for endothelial proliferation and chemotaxis. Other structural homologues of the VEGF family have recently been identified, including VEGF-B, -C, -D, and -E. VEGF-C stimulates lymphatic growth and binds to Flt4, which is preferentially expressed on lymphatic endothelium. Neuropilin-1, a neuronal guidance

molecule, is a recently discovered receptor for $VEGF_{165}$. Neuropilin is not a tyrosine kinase receptor and is expressed on nonendothelial cells including tumor cells. This allows VEGF that is synthesized by tumor cells to bind to their surface. Surface-bound VEGF could make endothelial cells chemotactic to tumor cells or it could act in a paracrine manner to mediate cooption of tumor cells around microvessels (Fig. 83-3).

VEGFexpression is upregulated by the *ras* oncogene. The farnesyl transferase inhibitors inhibit *ras* expression. One mechanism of their antitumor effect is to inhibit angiogenesis by inhibiting VEGF expression.

VEGFexpression is inhibited by the von Hippel-Lindau (VHL) protein. The VHL-tumor suppressor gene is inactivated in patients with VHL disease and in most sporadic clear-cell renal carcinomas, which leads to VEGF-mediated angiogenesis. The VHL gene normally suppresses hypoxia-inducible genes including erythropoietin. When VHL is mutated or deleted, these genes are overexpressed even under normoxic conditions. This explains why renal cell carcinomas driven by mutant VHL are associated with a high hematocrit.

Experimental evidence indicates thatbFGFfunction may be in part dependent uponVEGF. bFGF induces the expression of VEGF. The two endothelial mitogens act synergistically to stimulate capillary tube formation in vitro. Systemic administration of a soluble receptor for VEGF (flk-1) completely blocks cornea angiogenesis induced by implanted bFGF. An important implication of these studies is that angiogenesis inhibitors that block VEGF (currently in clinical trial) may also inhibit bFGF.

Angiopoietins Tie2 is a receptor found only on vascular endothelial cells. It is a specific tyrosine kinase whose ligand is angiopoietin-1. Angiopoietin-1 induces endothelial cells to recruit pericytes and smooth-muscle cells [mainly by producing platelet-derived growth factor (PDGF) BB] to become incorporated in the vessel wall. Vessels stimulated by angiopoietin-1 are not leaky and are analogous to new vessels in a healing wound. Angiopoietin-2 blocks the Tie-2 receptor and acts to repel pericytes and smooth muscle. It is produced by vascular endothelium in a tumor bed, but it is unclear how tumor cells mediate this. Nevertheless, tumor vessels remain thin "endothelial-lined tubes" even though some of these microvessels reach the diameter of venules (Fig. 83-3). A key point is that angiopoietin-2 andVEGFtogether increase angiogenesis. However, if VEGF is neutralized or withdrawn, endothelial cells in the absence of perivascular smooth muscle and pericytes undergo apoptosis and new microvessels regress. These differences indicate that angiogenesis in tumors may be more vulnerable to certain angiogenesis inhibitors than angiogenesis in healing wounds. Endostatin inhibits tumor growth in mice without delaying wound healing.

Endogenous Angiogenesis Inhibitors Certain endogenous inhibitors of angiogenesis are known to play a role in the angiogenic switch, including:IFN-aand platelet factor 4, and the class of angiostatic steroids typified by tetrahydrocortisol (Table 83-2).

Thrombospondin-1 The production of thrombospondin-1 has been shown to be inversely related to the ability of a cell line to produce a tumor and vessels in vivo; loss of thrombospondin-1 production allowed non-tumorigenic cells to become tumorigenic. Thrombospondin-1 is regulated by wild-type p53. Loss of p53 function in tumor cells

dramatically decreased the level of angiogenesis inhibitor. Restoration of p53 increased the inhibitor and suppressed the angiogenic activity of the tumor cells. The angiogenic switch was controlled by a negative regulator of angiogenesis generated by the tumor. The switch itself was viewed as a result of a shift in the "net balance" of angiogenesis stimulators and inhibitors. This led to the discovery of angiostatin, a second inhibitor found to be involved in the angiogenic switch.

Angiostatin, Endostatin, and Antiangiogenic Antithrombin III Several clinical and experimental observations suggested that certain tumors may produce angiogenesis inhibitors. The removal of certain tumors (e.g., breast carcinomas, colon carcinomas, and osteogenic sarcomas) can be followed by rapid growth of distant metastases. A primary tumor can suppress metastases from a different type of tumor, e.g., a breast cancer can inhibit melanoma metastases. In melanoma, partial spontaneous regression of the primary tumor may be followed by rapid growth of metastases. Regression of small cell lung cancer by ionizing radiation may be followed by rapid growth of distant metastases. If one portion of a primary tumor is removed (e.g., cytoreductive surgery for testicular cancer), the residual tumor increases its rate of expansion. A similar phenomenon is observed in animal tumors, i.e., certain primary tumors inhibit the growth, but not the number, of their own metastases. Surgical removal of a primary tumor increases growth rate of the residual tumors. Many primary tumors can suppress the growth of a second tumor inoculation. This "resistance" to a second tumor challenge is inversely proportional to the size of the tumor inoculum and directly proportional to the size of the first tumor. A threshold size is necessary for the inhibitory effect to occur.

At least three hypotheses have been advanced to explain these diverse observations and experiments: (1) "concomitant immunity" -- a primary tumor induces an immunologic response against a secondary tumor or a metastasis in the same host; (2) depletion of nutrients by the primary tumor; or (3) production of antimitotic factors from the primary tumor that directly inhibit the proliferation of the secondary tumor. However, none of these ideas offers a molecular mechanism to explain all of the experiments cited above, and overall they have not been confirmed. Concomitant immunity has been ruled out as a mechanism because tumors can suppress metastasis in mice with severe combined immunodeficiency (SCID).

Once it was realized that a tumor could generate both positive and negative regulators of angiogenesis, then it also became clear that a primary tumor, while stimulating angiogenesis in its own vascular bed, could possibly inhibit angiogenesis in the vascular bed of a distant metastasis. However, at least two conditions would be necessary: (1) the primary tumor (i.e., the first tumor to grow) would need to generate an angiogenic promoter in excess of an inhibitor in its own local vascular bed, and (2) the putative inhibitor would need to have a longer half-life in the circulation than the angiogenic promoter. Research done over the past decade has identified angiostatin, endostatin, and antiangiogenic antithrombin as negative regulators of angiogenesis.

Lewis lung carcinoma generated angiostatin, a 38-kDa cleavage product of plasminogen. Systemic administration of purified angiostatin completely inhibited growth of metastases, producing dormant tumors of microscopic size (<200 um in diameter) in the lung, and inhibited the growth of primary tumors. Angiostatin is not secreted by tumor cells but is generated through proteolytic cleavage of circulating plasminogen by

a series of enzymes released from the tumor cells. At least one of these tumor-derived enzymes, urokinase plasminogen activator (uPA), converts plasminogen to plasmin, while a phosphoglycerate kinase from hypoxic tumor cells then reduces the plasmin so that it can be converted to angiostatin by one of several different metalloproteinases. Other types of tumors have since been reported to generate angiostatin, e.g., human prostate cancer. Prostate-specific antigen generates angiostatin-like fragments from plasminogen.

Furthermore, when murine fibrosarcoma cells were transfected with angiostatin, primary subcutaneous tumors formed. Their growth was slowed in proportion to increased levels of angiostatin production by the tumor cells. In these tumors the *total angiogenic output* of the primary tumor was decreased by transfected angiostatin, which opposed the activity of the tumor's secreted angiogenic promoter in a dose-dependent manner, but never completely counteracted it. The rate of tumor growth (expansion of tumor mass) was directly proportional to the total angiogenic output of the tumor, inversely proportional to angiostatin production and to tumor cell apoptosis, and virtually independent of tumor cell proliferation.

Murine hemangioendothelioma generated endostatin, a 20-kDa cleavage product of collagen XVIII. Human non-small cell lung carcinoma generated a 53-kDa cleavage product of antithrombin III (antiangiogenic ATIII). (This tumor does not metastasize, but the circulating angiogenesis inhibitor was detected because a subcutaneous tumor suppressed the growth of a second tumor at a remote site). All three of these proteins specifically inhibit endothelial cell proliferation and not other cell types. They have no effect on tumor cells per se. Endostatin inhibits tumor angiogenesis but not wound angiogenesis. It has no effect on pregnant mice nor on normal neonatal mice. Endostatin is present in *C. elegans* as a product of collagen XVIII and so may be at least 600 million years old on an evolutionary time scale. Other endogenous angiogenesis inhibitors are presented in Table 83-2.

Angiogenesis Inhibitors in Clinical Trial Angiogenesis inhibitors are in clinical trials in the United States for patients with cancer (Table 83-3). While a few endogenous antiangiogenic proteins have entered clinical trial [e.g., angiostatin, endostatin, and interleukin (IL) 12], these are more difficult to manufacture, and it will take some time before large quantities of these inhibitors become available for large numbers of patients. The majority of angiogenesis inhibitors currently in clinical trial for cancer are antibodies or small-molecular-weight synthetic molecules that inhibit specific targets along the angiogenic pathway.

BYSTANDER MOLECULES IN THE ANGIOGENIC PATHWAY

A variety of molecules in the angiogenic pathway are not strictly endothelial cell mitogens or suppressors but operate as modifiers, markers, or receptors of the angiogenic process. They include: (1) integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$, which are upregulated on proliferating endothelial cells and act as receptors for fragments of fibronectin and other matrix components; (2) ephrins, which specify arterial or venous development of capillary vessels; (3) cyclooxygenase 2 (COX 2), the production of which is stimulated by bFGF and which converts lipid precursors to prostaglandin E_2 (PGE_2), an angiogenic stimulator; (4) plasminogen activator inhibitor 1 (PAI-1), which counteracts the

upregulation ofuPA that is produced by growing capillaries, thus restricting proteolysis to a local event at the tip of angiogenic vessels; (5) AC133, a specific marker for circulating endothelial precursor cells, which arise from bone marrow; and (6) nitric oxide synthase, which generates nitric oxide, that induces vasodilation in the vascular bed, a possible prerequisite for sprout formation.

METASTASES ARE ANGIOGENESIS-DEPENDENT

Before tumors have become neovascularized in experimental animals, tumor cells rarely, if ever, shed into the circulation and metastases are essentially nonexistent. After the primary tumor becomes neovascularized, the number of tumor cells shed into the circulation increases in proportion to the increased neovascularization. Metastases that survive at a distant site must become angiogenic to be detected. Nonangiogenic metastases remain dormant at a microscopic size (<0.2 mm) indefinitely. Therefore, angiogenesis is required at both ends of the metastatic cascade.

Clinical patterns in which metastases first present may also be explained by angiogenic mechanisms. Cancer metastases are known to present in at least four different common clinical patterns and in one rare pattern. These clinical observations have previously been unrelated to each other but may be unified by angiogenic principles from tumor-bearing animals.

1. The patient whose metastases appear, sometimes explosively, a few months after surgical removal of a primary tumor (e.g., osteogenic sarcoma) may have lost a circulating angiogenesis inhibitor generated by the primary tumor. A model for this clinical presentation is the murine Lewis lung carcinoma that generates angiostatin.

2. Metastases that are not being suppressed by the primary tumor may already be present when the primary tumor is first diagnosed. The experimental model is a Lewis lung carcinoma subline that does not generate angiostatin.

3. The "unknown," or "occult," primary describes a pattern of metastases that present in the absence of a primary tumor or before it is located. In the relevant animal model lung metastases grow so rapidly that they suppress the primary tumor. However, it has not yet been determined whether a circulating angiogenic inhibitor is generated by the metastases.

4. If metastases do not appear until years after surgical removal of the primary tumor, the patient may harbor dormant microscopic metastases that are not angiogenic. Those that eventually switch to the angiogenic phenotype can grow to detectable metastases. An example is the node-negative breast cancer patient who develops lung metastases 10 to 15 years after resection of the primary tumor. An animal model that mimics this pattern has been developed. Surgical removal of a B-16 melanoma from a syngeneic mouse leaves numerous viable lung metastases that are not angiogenic and do not expand beyond 0.1 to 0.2 mm diameter; they remain dormant for the life of the animal. They also remain viable, as evidenced by the fact that trauma to the lung or transplantation of a small piece of lung to the subcutaneous tissue of another mouse quickly generates a lethal tumor in both cases.

5. After surgical removal of a renal cell carcinoma, metastases will sometimes regress completely or partly. While this is an uncommon clinical pattern, V2 carcinoma in the rabbit most closely resembles it. Removal of a primary tumor in the leg is followed by regression of metastases. This does not appear to be an immune reaction because fresh tumor grows successfully in the same rabbit. One explanation is that the metastases were dependent upon high production of a circulating angiogenic stimulator, such as bFGFfrom the primary tumor. High plasma levels of bFGF have been found to correlate with high mortality in human renal cancer.

These clinical patterns are summarized in Fig. 83-4 as a unifying guide for clinicians. The hypothesis that these clinical patterns are linked by angiogenic mechanisms requires additional confirmation in the laboratory, but it provides a direction for further research.

LEUKEMIA IS ANGIOGENESIS-DEPENDENT

Leukemia was assumed not to be angiogenic because it had been thought of as "liquid tumor." However, when bone marrow biopsies from children with newly diagnosed acute lymphoblastic leukemia were stained with an antibody to von Willebrand factor to highlight vascular endothelium, microvessel density was increased six- to sevenfold when compared to children with "control" bone marrow biopsies taken at the time of diagnosis of a solid tumor. Confocal microscopy further revealed that new microvessels in leukemic bone marrow were surrounded by a perivascular cuff of tumor cells like solid tumors.bFGF in the urine of the leukemic children was approximately sevenfold higher than in controls. Acute myeloid leukemia and chronic myeloid leukemia in adults are also associated with intense bone marrow neovascularization. Cellular levels of the angiogenic factorVEGF are significantly increased in acute myeloid leukemia and provide a prognostic indicator of outcome. The close physical configuration of microvessels and bone marrow cells may facilitate a two-way paracrine pathway between vascular endothelial cells that produce mitogens for bone marrow cells [such as granulocyte colony stimulating factor (G-CSF)] and bone marrow cells that produce bFGF, a mitogen for endothelial cells.

Further work suggests that leukemia growth is dependent on angiogenesis. Murine leukemias can be suppressed or eradicated and survival of leukemia-bearing mice prolonged when they are treated with antiangiogenic therapy. The mice were treated either by systemic administration of endostatin or by chemotherapy administered on an "antiangiogenic" schedule. A conventional schedule of chemotherapy at a maximum tolerated dose was ineffective (see below).

Certain patients with multiple myeloma refractory to all conventional therapy have undergone successful remission when treated with thalidomide. This has initiated a debate about whether the beneficial effect of thalidomide is due to its antiangiogenic activity or to some other property such as its weak capacity to inhibit tumor necrosis factor (TNF-a) activity. This question arose because microvessel density did not decrease significantly in parallel with improvement of the disease. However, this result is not unexpected. In animal tumors that undergo steady regression in tumor volume as a result of antiangiogenic therapy, microvessel density (microvessels per square millimeter) may in some cases remain constant even as tumor volume is reduced by

one-half, because capillary dropout and tumor cell dropout are going on at a near constant ratio. Furthermore, other effects of antiangiogenic therapy, such as the reduction of plasma leakage from tumor vessels, would not be revealed by microvessel density. Further, thalidomide is among the weakest inhibitors of TNF-a. Four other compounds that inhibit TNF-a more potently than thalidomide have no antiangiogenic effect. Pentoxifylline inhibits TNF-aat a similar potency as thalidomide, yet thalidomide inhibits cornea angiogenesis and pentoxifylline does not. Ibuprofen *increases* TNF-a in the serum of mice by twofold, yet it inhibits angiogenesis. Finally dexamethasone is a more potent inhibitor of TNF-a than thalidomide, but dexamethasone does not inhibit angiogenesis or does so only weakly.

ANTIANGIOGENIC THERAPY CIRCUMVENTS ACQUIRED DRUG RESISTANCE

The emergence of drug-resistant tumor cells is a major problem accompanying almost all chemotherapy. Conventional cytotoxic chemotherapy targets the cancer cell, and it is the genetic instability and high mutation rate of these cells that are responsible in part for acquired drug resistance. However, vascular endothelial cells are genetically stable and have a low mutation rate, like bone marrow cells. Bone marrow cells do not appear to develop drug resistance against conventional chemotherapy. Thus, it is possible that tumor vessels will also maintain sensitivity to anti-angiogenic therapy.

MICROVESSEL DENSITY IS A USEFUL PROGNOSTIC INDICATOR

Neovascularization in human brain tumors correlates directly with tumor grade. Tumor vascularity in cutaneous melanoma also influences prognosis. Microvessel density is an independent prognostic indicator for human breast cancer. In fact, the majority of reports (52 different studies) confirm that microvessel density is a powerful and often an independent prognostic indicator for a variety of different human cancers. However, at least seven other reports fail to show the prognostic value of microvessel density. Some of these negative reports may be methodologic problems. Others may represent the co-existence of angiogenesis inhibitors and stimulators that cannot easily be measured in a tumor. Summaries of all published reports are given in (Tables 83-4,83-5,83-6,83-7,83-8, and83-9). The best prognostic information from a histologic microsection of a tumor is obtained when the highest area of microvessel density ("hot spot") is quantified. These areas may contain the most angiogenic tumor cells, which have the highest chance of becoming an angiogenic metastasis.

Despite its usefulness as a*prognostic* marker, quantification of microvessel density is not necessarily a useful *surrogate* marker for efficacy of antiangiogenic therapy. Although it is currently employed in a few early clinical trials of antiangiogenic therapy, experimental studies suggest that it will be of little value to predict efficacy of an angiogenesis inhibitor. Microvessel density is determined mainly by intercapillary distance, itself governed by the cuff thickness of tumor cells surrounding a microvessel. In experimental animals, microvessel density may remain constant as a tumor is shrinking under antiangiogenic therapy. Residual tumor cells can form cuffs around remaining vessels, so that the vessel density may not change significantly. Microvessel density also may not distinguish between benign and malignant tumors. The microvessel density in normal pituitary tissue is higher than in a pituitary adenoma, which is higher than in a pituitary carcinoma. In the normal pituitary gland, the

perivascular cuff is one to two cell layers. However, in the adenoma the perivascular cuff is increased as tumor cells adapt to lower oxygen tensions. Cuff thickness is even greater in the carcinoma, thus giving the lowest microvessel density. However, for other tumors, such as breast carcinoma, microvessel density is significantly higher than in normal breast tissue. In certain animal tumors, angiogenic output exceeds the growth capacity of the tumor cells. Initial antiangiogenic therapy will lead to a reduction in microvessel density, which may then remain constant as vascular density comes into balance with tumor cell population, whether the tumor remains stable or regresses. Finally, if the first microvessel density is obtained from an open biopsy and a subsequent follow-up microvessel density is from a needle biopsy, the second density will be higher. This artifact is due to tissue compression by the needle biopsy.

CYTOTOXIC CHEMOTHERAPY MAY BE ANGIOGENESIS-DEPENDENT

Certain cytotoxic chemotherapeutic agents may depend in part for their anticancer activity on their ability to inhibit proliferating endothelial cells. Proliferating and migrating microvascular endothelial cells are exposed to chemotherapeutic drugs before tumor cells. However, the endothelial cells have a chance to recover during the traditional 2-3 week off-therapy period designed to allow recovery of bone marrow. Recovering endothelium can resupply residual tumor cells with new vessels and with paracrine factors necessary for tumor cell survival. Tumor recurrence requires resumption of chemotherapy, which itself can lead to emergence of drug-resistant clones of tumor cells (but not of endothelial cells). The convention of *maximum tolerated dose* (MTD) virtually forces the prolonged off-therapy schedule.

If the schedule of the chemotherapeutic agent is altered (increased number of lower drug doses) to apply maximum cytotoxic pressure to the endothelial cells in the tumor bed (i.e., an "antiangiogenic schedule" instead of a "conventional schedule"), even large tumors in mice may be permanently cured. In contrast, all mice on the conventional schedule ofMTDtherapy died with drug-resistant tumors. The antiangiogenic schedule of the chemotherapeutic drug was more frequent but was administered at a threefold lower total lower dose per day so that bone marrow was not depressed. Thus, efficacy of cytotoxic chemotherapy can be improved (in mice) by applying new logic to an old drug. The new logic is that antiangiogenic properties of certain conventional cytotoxic agents are not revealed unless the drugs are administered frequently. Frequent administration requires lower doses.

These results in mice may help to explain why some patients who are receiving long-term maintenance or even palliative chemotherapy continue to have stable disease beyond the time that tumor cells would have been expected to develop drug resistance. For example, long-term stable disease has been observed in a few patients with metastatic breast cancer who have been on weekly paclitaxel for several years. Paclitaxel has been reported to have antiangiogenic activity in addition to its anticancer activity. In the future, formal clinical trials with antiangiogenic schedules of chemotherapy should be tested.

Although "fractionated" radiotherapy (i.e., increased frequency of exposures at lower doses) was found empirically to be more effective and to cause fewer side effects than higher radiation doses more widely spaced, the biologic basis of this approach may be

due, in part, to the effect of ionizing radiation on endothelial cells. Conventional radiotherapy of tumor-bearing animals is greatly enhanced and with fewer side effects when the radiotherapy is administered in combination with subtherapeutic doses of angiostatin.

GUIDELINES FOR CLINICAL TRIALS OF ANGIOGENESIS INHIBITORS

New guidelines are required to examine the clinical effects of angiogenesis inhibitors because this class of drugs differs so markedly from cytotoxic chemotherapy. First, end-points for efficacy require different definitions. For cytotoxic therapy, lack of tumor regression is considered a failure, and an end-point of stable disease is little valued because it has never been shown to improve patient survival. In contrast, stable disease brought about by antiangiogenic therapy may be a favorable end-point of antiangiogenic therapy if it can be shown to improve the quality or duration of life. Experience with endostatin in early phase I clinical trials shows that patients with advanced metastatic disease refractory to all conventional therapy and who have had stable disease on endostatin for up to 6 months so far have pain relief, increased appetite, normal bone marrow function, and no side effects. A similar experience has been gained fromIFN-aadministered daily at low dose (3 million units) for malignancies dependent upon overexpression ofbFGF as their sole or main angiogenic protein (i.e., giant cell tumors of bone, angioblastoma). In fact, five of six of these patients who had failed all conventional therapy had complete regressions of their tumors by 1 to 3 years and are now off therapy and remain tumor free. This illustrates a second difference from cytotoxic therapy: antiangiogenic therapy takes longer to achieve stable disease and tumor regression is slower. It is analogous to the use of tamoxifen or to the treatment of other chronic diseases such as tuberculosis. Nevertheless, patients enjoy a high quality of life during antiangiogenic therapy.

Third, tumor progression during a clinical trial of cytotoxic chemotherapy is considered as a failure, and patients are often discontinued from the trial. With antiangiogenic therapy, some patients with rapidly advancing metastatic disease may show some tumor progression before stable disease is achieved. In the first clinical trials of tamoxifen, some patients were discontinued early in the trials because of tumor progression. After the term *tamoxifen flare* was invented, patients stayed on long-term tamoxifen therapy for several years. Of course, very rapid tumor progression during antiangiogenic therapy requires that the inhibitor be discontinued and the patient offered a different therapy.

Fourth, unlike cytotoxic chemotherapy, antiangiogenic therapy is more effective if it is administered frequently, without gaps, for a long period of time (e.g., like tamoxifen) and at a dose that has little or no toxicity. The term*MTD*is less useful for angiogenesis inhibitors.

Fifth, angiogenesis inhibitors can be used in combination with conventional chemotherapy, radiotherapy, immunotherapy, gene therapy, or other modalities, usually without increasing side effects. Clinical trials of angiogenesis inhibitors in combination with chemotherapy or radiotherapy are already under way.

CLINICAL SIGNS IN CANCER PATIENTS BASED ON ANGIOGENESIS

Certain clinical signs and symptoms from tumor neovascularization are associated with specific tumor types. For example, retinoblastomas in the posterior eye induce iris neovascularization in the anterior chamber. Some brain tumors induce angiogenesis in remote areas of the brain. Bone pain in metastatic prostate cancer may be related in part to neovascularization. A problem in the diagnosis of a primary bone tumor is that if the biopsy specimen contains only the neovascular response at the periphery of the tumor, it may be mistaken for granulation tissue or inflammation. Several cancer syndromes, such as inappropriate hormonal activity, hypercoagulation, and cachexia, are secondary to the presence of biologically active peptides released into the circulation from vascularized tumors. Therefore, an early therapeutic effect of antiangiogenic therapy could be increased appetite, weight gain, and disappearance of a cancer syndrome. The angiogenesis induced by cervical cancer may be observed by colposcopy; the appearance of telangiectasia, or "vascular spiders," in a mastectomy scar may herald local recurrence of tumor; color Doppler imaging can demonstrate neovascularization in breast cancer and other tumors; bladder carcinoma is detected by cystoscopy based, in part, on its neovascularization; and mammography may reveal the vascularized rim of a breast tumor. A wide range of radiologic signs of cancer are based on "enhancement" of lesions by radiopaque dyes sequestered transiently in the neovasculature of a tumor. Moreover, in some tumors large central areas cannot be penetrated by radiopaque dyes because of vascular compression, a situation that is unusual in prevascular tumors.

CLINICAL MISPERCEPTIONS ABOUT TUMOR ANGIOGENESIS

Because angiogenesis research is such a broad and rapidly moving field (at least 30 reports each week), certain misperceptions have emerged.

One misperception is that angiogenesis is synonymous with malignancy. The presence of angiogenesis does not distinguish between a benign and a malignant tumor. Benign adrenal adenomas are highly neovascularized but appear to lack the growth potential to take advantage of the new blood vessels they have induced. Angiogenesis may not be necessary for certain tumor cells that can grow as a flat sheet between membranes, e.g., gliomatosis in the meninges. Large tumors are thought to have "established" vessels that would be refractory to antiangiogenic therapy. A few feeder vessels, usually arteries, may be observed in the midst of a histologic cross-section of a tumor and could be considered as established. However, tumor cells depend on *thin-walled microvessels* for diffusion of nutrients, growth factors, and oxygen, and it is these vessels that continue to undergo high turnover rates even in a large, slowly growing or indolent tumors. These microvessels require the continuous presence of endothelial growth factors such as VEGF. Withdrawal or blockade of VEGF leads to endothelial cell apoptosis and regression of microvessels. In both animals and humans, very large tumors have regressed in response to antiangiogenic therapy, but a longer time of therapy is required. For example, a high-grade giant cell tumor (refractory to all conventional therapy) of >1 kg in the pelvis of a 17-year-old girl underwent 90% regression after 1 year of daily systemic therapy withIFN-a(3 million units). It is commonly stated that tumors "outgrow their blood supply." This is inaccurate; growing tumors can gradually *compress* their blood supply because of increasing interstitial pressure (discussed above). These areas of vascular compression become ischemic

but are not avascular. Necrosis may follow. Vessel compression also interferes with the optimal delivery of therapeutic agents. Paradoxically, antiangiogenic therapy can decrease ischemia, apparently because it decreases interstitial pressure.

Another misperception is that antiangiogenic therapy will be less effective against slowly growing tumors, because this is true for cytotoxic chemotherapeutic agents. In fact the opposite has been found in experimental animals. Slowly growing mouse tumors respond more effectively to angiogenesis inhibitors (TNP-470 or angiostatin) than do rapidly growing tumors. Rapidly growing tumors require higher doses of angiogenesis inhibitors to suppress their growth to the same extent as slowly growing tumors. While cytotoxic therapy is dependent on tumor cell cycle, antiangiogenic therapy is not. It is widely assumed that only "highly vascularized" tumors are susceptible to antiangiogenic therapy. This misperception comes from attempts to estimate the angiogenic output of a tumor from an angiogram or a gross tumor specimen. A large, dark, unstained area in an angiogram is usually due to nonfilling of compressed vessels. This is often misinterpreted as "avascular" tumor. However, at the microscopic level, histologic sections reveal high microvessel density. A large tumor observed at the operating table, such as a neurofibrosarcoma, may be a hard white mass and assumed to be "poorly vascularized," when in fact the histologic microsections show intense neovascularization.

SUMMARY: TWO CELLULAR TARGETS IN A TUMOR

An important lesson from angiogenesis research is to think about a tumor as containing two cell compartments that stimulate each other: the endothelial cell compartment and the tumor cell compartment. Anticancer therapy may be more efficacious if each compartment is treated by drugs that selectively target each cell type. The mutational rate is high in the tumor cell compartment and low in the endothelial cell compartment. This is the reason why it may be possible to employ antiangiogenic therapy for the long term, together with conventional chemotherapy or other therapies and subsequently in the postchemotherapy period.

DISEASES OF OCULAR NEOVASCULARIZATION

Pathologic angiogenesis is the most common cause of blindness worldwide. Pathologic neovascularization can occur in each compartment of the eye. For example, of>21 diseases that cause pathologic neovascularization in the cornea, contact lens wear, trauma, prior surgery, herpes simplex, and herpes zoster are the most frequently associated with pathologic neovascularization. Of ~37 diseases associated with iris neovascularization, central retinal vein occlusion, neovascular glaucoma, diabetes mellitus, and retinoblastoma are the most frequent. Of 14 diseases associated with retinal neovascularization, age-related macular degeneration, diabetes mellitus, retinopathy of prematurity, central retinal vein occlusion, branch retinal vein occlusion, and sickle cell disease are the most frequent. In western countries, age-related macular degeneration and diabetic retinopathy are the diseases of ocular neovascularization that affect the most patients. The large number of diseases listed above that are associated with ocular neovascularization and that directly or indirectly cause blindness illustrates how few effective therapies are currently available. This outline also reveals how few of these therapies can be administered systemically and how great is the opportunity to

employ antiangiogenic therapy in clinical trials to reduce the incidence of blindness from pathologic neovascularization.

AGE-RELATED MACULAR DEGENERATION

In age-related macular degeneration, angiogenesis occurs in the choroid. In the severe form of the disease, microhemorrhages from these new vessels lead to blindness. Approximately 1.7 million individuals in the United States suffer from the severe form, which is the leading cause of blindness in those³64 years. Laser therapy is less effective than in diabetic retinopathy. The angiogenic proteinVEGF is markedly elevated in macular degeneration and may be a major mediator of this disease. Of the five angiogenesis inhibitors currently in clinical trials for ocular neovascularization (Table 83-10), four are employed in the treatment of macular degeneration. One inhibitor is an antibody that neutralizes VEGF, and the other is a synthetic low-molecular-weight compound that targets a VEGF receptor.

DIABETIC RETINOPATHY

Diabetic retinopathy affects ~1.2 million of the estimated 14 million U.S. diabetic patients. It is the leading cause of blindness in persons between ages 25 and 64. Pathologic angiogenesis occurs in the retina, and new microvessels grow into the vitreous where they bleed and cause vitreous retraction. Laser therapy is more successful than in macular degeneration, but it is painful and causes gradual obliteration of the peripheral retina and loss of accompanying visual fields. Overexpression of VEGFmay also mediate diabetic retinopathy but appears to be induced by upregulation of HIF-1 secondary to hypoxia in the retina. An orally available protein kinase Cb inhibitor of VEGF is in phase III clinical trial for diabetic retinopathy. An early primary cause of the hypoxia may be adhesion of leukocytes to endothelium in retinal vessels (by upregulation of intercellular adhesion molecule 1 on retinal microvascular endothelium), leading to slow flow or periods of no flow.

RETINOPATHY OF PREMATURITY

At the time of birth, both the retina and its vascular supply are still growing. Blood vessels that supply the retina in the premature baby and in the newborn are exquisitely sensitive to changes in oxygen, a mechanism that guarantees an adequate blood supply to the growing retina. In newborn cats exposed to oxygen,VEGFlevels are downregulated and vascular growth in the retina is slowed or inhibited. However, the retina continues to grow. Subsequently, when the animal is returned to room air, the mismatch between the delayed vascularization and the steadily growing retina leads to relative hypoxia, which triggers a surge of VEGF and retinal neovascularization. This may cause retinal detachment and microhemorrhage. In the United States there are currently ~180,000 cases of retinopathy of prematurity, also called *retrolental fibroplasia*.

The increased understanding of the angiogenic mechanism of retinopathy of prematurity has led to clinical trials in which infants are weaned from oxygen to room air very slowly in order to prevent the rapid rise ofVEGF. A recent report showed that in newborn animals returned to room air after exposure to oxygen, pathologic neovascularization was completely prevented while normal vascular development continued if the animals

were treated with angiostatin for 5 days, beginning with the first day of exposure to room air. It is not yet clear whether systemic therapy of retinopathy of prematurity will be feasible in infants.

ENDOGENOUS ANGIOGENESIS INHIBITORS IN THE EYE

Normally the components of the eye that transmit light (cornea, aqueous, lens, and vitreous) are avascular. The maintenance of this avascular state is accomplished, in part, by the presence of potent inhibitors of angiogenesis. Pigment epithelium-derived factor (PEDF) is a 50-kDa serpin and is a potent angiogenesis inhibitor that is produced by retinal cells. The amount of inhibitory PEDF produced by retinal cells is directly correlated with oxygen concentrations, suggesting that its loss plays a permissive role in ischemia-driven retinal neovascularization. In other words, when oxygen is decreased PEDF is decreased and VEGF is increased. Both changes facilitate neovascularization. PEDF has the unique characteristic of inhibiting endothelial migration toward a wide variety of angiogenic inducers tested. It may be the predominant angiogenesis inhibitor in the eye. When neutralizing antibody to PEDF (but not preimmune sera) is injected into the cornea, it becomes neovascularized. PEDF has also been found in tumors.

Thrombospondin-1 has also been found in ocular tissues such as cornea and in the retina. During hypoxia-driven retinal angiogenesis in newborn mice (returned to room air after oxygen exposure), a threefold increase in expression of thrombospondin-1 was seen corresponding to peak neovascularization and peakVEGFexpression. The increased thrombospondin-1 expression during ischemia-induced angiogenesis appears to be mediated by VEGF. This suggests that thrombospondin functions in a negative-feedback system to protect the eye against surges of VEGF. It is interesting that the same balance of positive and negative regulators of angiogenesis originally found in tumors operates in normal tissues and that a shift in the net balance of these regulators mediates pathologic angiogenesis as well as its return to the normal nonangiogenic state.

ANGIOGENESIS IN SKIN DISEASE

Many dermatologic diseases are associated with angiogenesis. A caveat is that, unlike neoplastic diseases, which are virtually all angiogenesis-dependent, not all nonneoplastic diseases that are angiogenic are also angiogenesis-dependent.

ANGIOGENESIS-ASSOCIATED VS. ANGIOGENESIS-DEPENDENT SKIN DISEASE

In certain diseases of the skin, angiogenesis may be an important side effect that facilitates healing or otherwise protects the host. Examples include ulcerations, delayed healing of wounds, and chronic infections, in which antiangiogenic therapy could be contraindicated. A few of the dermatologic diseases known to be angiogenesis-dependent are described.

Infantile Hemangiomas Hemangiomas consist of tumor-like clusters of proliferating capillaries. They occur in 1 out of 100 newborns and in 1 out of 4 premature infants, and by age 1 year are present in up to 10% of infants. In the first, or proliferating, stage, the lesions grow rapidly, reaching peak growth by ~4 months. By about 1 year they may

enter the involuting stage, where they stop growing, following which they regress over the next 3 to 5 years (the involuted stage) and then usually disappear. During the proliferating stage the endothelial cells overexpressbFGF,VEGF, and metalloproteinases, all of which appear in the urine at abnormally high levels. In normal skin, keratinocytes expressIFN-b, an angiogenesis inhibitor of similar strength as IFN-a. IFN-a or -b inhibit overexpression ofaFGF and bFGF. Glucocorticoids (prednisone, 5 mg/kg) are used as first-line therapy for hemangiomas that are destroying tissue, interfering with sight, or threatening life. A dramatic slowing and subsequent regression occur in ~30% of patients, but glucocorticoids fail in the remaining 70% (i.e., either no regression, but some slowing of the disease, or continued rapid growth of the lesions). The mechanism by which glucocorticoids act as antiangiogenic agents is not clear, but they do inhibit synthesis of metalloproteinases. When glucorticorticoids fail and the hemangioma is life-threatening, IFN-a is used at low dose, 3 million units/m^2daily subcutaneously for 8 to 12 months. While ~95% of hemangiomas regress spontaneously, 5% are sight- or life-threatening. Hemangiomas in the liver, heart, airway, or brain may be associated with a 50% mortality if untreated. IFN-a is antiangiogenic on the basis of its ability to inhibit overproduction of bFGF. Urinary levels of bFGF fall toward normal as hemangiomas regress, and bFGF levels can be used as a guide to dosing of IFN-a. While IFN-aaccelerates regression of hemangiomas in 85% of patients, it fails in the other 15% for unknown reasons. Many of the failures are Kaposi hemangioendotheliomas (KHE), a very aggressive form of hemangioma, often accompanied by platelet trapping and thrombocytopenia. IFN-a works well in only 50% of KHE. Regressions of hemangioma are slower with IFN-a than with glucocorticoids. In infants<1 year old, a side effect of IFN-a can be delayed walking. This occurs in ~4% of infants and can be detected early by spasticity of the lower limbs (*spastic diplegia*). It is reversible if IFN-a is discontinued; for this reason, all children on IFN-aare followed carefully by a neurologist.

A "cavernous hemangioma" is not a hemangioma but a venous malformation in which there is a dearth of smooth muscle in the wall of a large thin venous structure lined by endothelium. These never regress spontaneously, and neither glucorticoids norIFN-aare effective. Thus an adult with a cavernous hemangioma should not be treated with IFN-a.

Verruca Vulgaris Warts are caused by infection of keratinocytes in the skin by one of many subtypes of human papillomavirus (HPV). HPV contains two genes (E6/E7) that may increase angiogenesis. The E6 gene destabilizes the p53 tumor-suppressor gene, which upregulatesVEGF and downregulates thrombospondin-1, an angiogenesis inhibitor. The HPV E7 gene inactivates the tumor suppressor gene Rb. Antiangiogenic therapy may be beneficial in these lesions, which are usually highly neovascularized.

Psoriasis Psoriasis is a proliferative disorder of epidermis accompanied by increased vascularity in the dermis in the form of elongated and widened dermal capillaries. The disease is T lymphocyte mediated. Psoriatic lesions are angiogenic. The major angiogenic mediator in psoriasis appears to beVEGF, which is upregulated, as are its receptors. In patients with psoriasis, the increased vascularity induced by VEGF may act as a conduit for delivery of T lymphocytes to the epidermal target. VEGF itself may facilitate T lymphocyte targeting. When VEGF is overexpressed in a tumor vascular bed, leukocyte rolling and adhesion are enhanced.

Up to 5 million Americans have psoriasis, but ~500,000 have a severe form that requires long-term therapy, such as with methotrexate for several years. Both glucocorticoids and retinoids are weak angiogenesis inhibitors, and they may be suppressing the angiogenic component as well as the infiltration of immune cells. More potent angiogenesis inhibitors may be useful.

Basal Cell and Squamous Cell Carcinomas Both of these skin malignancies are highly angiogenic and follow the rules for other angiogenic-dependent tumors. Inactivation of the p53 tumor-suppressor gene (in part by ultraviolet light-induced mutations) is thought to be an early event in tumorigenesis, and its inactivation downregulates the angiogenesis inhibitor thrombospondin-1 and upregulatesVEGFexpression. Furthermore, the normal expression ofIFN-bin keratinocytes is markedly decreased, permitting upregulation of the angiogenic stimulatorbFGF. These lesions comprise >90% of the ~700,000 skin cancers that are treated each year in the United States.

Cutaneous Melanoma Melanoma in the skin begins in a radial or horizontal growth phase, which usually does not exceed a thickness of 0.75 mm. This stage is not neovascularized or is poorly neovascularized. It is analogous to the avascular phase of early in situ carcinoma. In the vertical growth phase, there are increased neovascularization, increased proliferation, and increased thickness of tumor beyond 0.75 mm, and intensity of vascularization correlates directly with increased metastatic risk and mortality. Progression of melanoma often begins with inactivation of the tumor-suppressor gene p16 and is followed later by expression of$\alpha_v\beta_3$integrin and by expression ofVEGFreceptors on the melanoma cells. *Ras* mutations that upregulate VEGF expression emerge later and may be followed by expression of the angiogenic proteins,IL-8, andbFGF. This sequential onset of expression of angiogenic proteins by a tumor cell is similar to progression of breast cancer. It is not clear if or how expression of$\alpha_v\beta_3$integrin as well as VEGF receptors on the melanoma cells themselves facilitates tumor growth, unless the VEGF is acting as an autocrine growth factor for the tumor cells, while at the same time acting as a paracrine stimulator of endothelial cells. A precedent for this mechanism has been reported for human pancreatic cancer. The angiogenesis inhibitor 2-methoxyestradiol currently in a phase I trial for breast cancer also showed efficacy against melanoma in animals.

Kaposi's Sarcoma (KS) This lesion, which acts like a malignancy in patients with AIDS, may instead be a chronic inflammatory reactive process that is highly angiogenic. The angiogenesis is driven mainly byVEGF and hepatocyte growth factor. The tat protein of the HIV virus also plays a role in the angiogenic pathway for KS, but this is still being elucidated. The origin of KS cells is also not clear, but they appear to arise from the vascular system, possibly from smooth-muscle cells or pericytes. Two different angiogenesis inhibitors in phase II trials, thalidomide and TNP-470, a synthetic analogue of fumagillin, have shown efficacy against KS. However, there are currently too few cases to make any general conclusions.

Neurofibromatosis These slow-growing benign skin tumors of Schwann cell origin can grow in other organs and become very large. Neurofibromas are very neovascularized and expressVEGF. This may be driven by overexpression of the *ras* oncogene. The gene for neurofibromin (NF1) is a negative regulator of *ras*, and mutation of this gene

increases *ras* expression. Because of their very slow growth rate and high angiogenic activity, neurofibromas illustrate a type of tumor for which long-term antiangiogenic therapy may be more effective than cytotoxic chemotherapy. They are rich in mast cells, which may enhance tumor angiogenesis by mobilization ofbFGF. If a patient with a neurofibroma had abnormally high plasma or urine levels of bFGF, dailyIFN-acould be used at a low dose of 3 million units/$m^2$for a prolonged period of 2 to 3 years, with slow regression as a goal.

Recessive Dystrophic Epidermolysis Bullosa This autosomal recessive disorder is characterized by subepidermal blistering, scarring, fusion of digits, and severe pruritus. Epidermis separates from dermis, in part due to a loss of collagen VII, which participates in the anchoring of these two cellular layers. Aggressive cutaneous squamous cell carcinoma, which emerges from this lesion, is the most common cause of death. Very high levels ofbFGFhave been found in the urine of these patients but not in patients with other blistering disorders. The source of bFGF could be its mobilization from heparan sulfate proteoglycans in the defective epidermal-dermal junction. bFGF not only stimulates angiogenesis directly but also stimulates the production ofCOX 2, which converts lipid precursors to prostaglandin E_2, another angiogenic stimulator. Keratinocyte growth is also stimulated by bFGF. Continuous keratinocyte proliferation may be a precursor to the development of squamous cell carcinoma. COX 2 inhibitors have antiangiogenic and antitumor activity in mice and may be useful in angiogenic diseases in man. Another antiangiogenic approach could be low-doseIFN-a, based on the same rationale for reducing high bFGF expression in life-threatening hemangiomas.

ANGIOGENESIS IN ARTHRITIS

The role of angiogenesis in rheumatoid arthritis and in other forms of arthritis can be most simply conceptualized as two phases: prevascular and vascular. The prevascular phase is analogous to an acute inflammatory state in which the synovium is invaded by inflammatory and immune cells, with macrophages, mast cells, and T cells predominating, among others. These cells may be the source of the angiogenic stimulators found in synovial fluid, which includeVEGF,bFGF,IL-8, and hepatocyte growth factor. Activated endothelial cells can also release hepatocyte growth factor. The growth of a neovascular pannus from the synovium begins the vascular phase of arthritis. The vascular pannus can invade and destroy cartilage, a process that is enhanced by the generation of enzymatic activity, mainly metalloproteinases, at the advancing front of new proliferating endothelium. This neovascular pannus overcomes endogenous angiogenesis inhibitors in the cartilage that normally protect it from vascular invasion and maintain its avascularity. These inhibitors include, among others,TIMPs 1, 2, 3 and 4 (ranging from 21 to 29 kDa); thrombospondin-1; and troponin I. Experimental evidence that arthritis is angiogenesis-dependent is based on suppression of rat adjuvant arthritis by an angiogenesis inhibitor, TNP-470 (a synthetic analogue of fumagillin).

This somewhat simplistic model does not do justice to the complexity of the angiogenic response in arthritis, which is beyond the scope of this chapter. Nevertheless, it provides a platform to think about antiangiogenic therapy of arthritis. In principle, inhibition of neovascularization in the joint should interrupt a conduit for continuous traffic of inflammatory cells into the joint and prevent destruction of cartilage. TheCOX

2inhibitors currently in wide use for arthritis have been found to be potent angiogenesis inhibitors capable of inhibiting tumor growth in mice. Other angiogenesis inhibitors currently in clinical trial for cancer may eventually also find use in antiarthritis therapy. An interesting potential candidate would be 2-methoxyestradiol.

ANGIOGENESIS IN GYNECOLOGIC DISEASE

Angiogenesis in the female reproductive tract is being actively studied because it is the principal example of physiologic angiogenesis. Angiogenesis in the ovarian follicle is driven mainly bybFGF andVEGFalthough other angiogenic regulatory molecules are being studied. However, while VEGF is known to be upregulated by estrogen, it is not clear whether endogenous angiogenesis inhibitors operate in combination with declining estrogen to turn off angiogenesis in the ovarian follicle. When angiogenesis is increased in any one follicle, it is suppressed in all other follicles. This is analogous to the suppression of angiogenesis in distant metastases by a primary tumor, but it is not known if the ovarian system utilizes similar endogenous inhibitors as have been discovered in various tumor systems.

A variety of diseases of the female reproductive tract are based on angiogenic processes. A few of these are mentioned here briefly to illustrate that similar molecules mediate angiogenesis in tumors and in gynecologic disease, although they may be regulated differently.

Endometriosis In this disease, endometrial glands or stroma are present outside the uterine cavity, e.g., in the ovaries, uterine ligaments, rectovaginal septum, and pelvic peritoneum. The foci of endometrium are usually under the control of the ovarian hormones and undergo cyclic menstrual changes with periodic bleeding, which is painful and may lead to fibrosis. At least one angiogenic protein,VEGF, is known to mediate the neovascularization in these lesions. VEGF is upregulated by increased estrogen and downregulated by withdrawal of estrogen. It has been suggested that endometriotic tissue may produce its own estrogen because it contains aromatase cytochrome P450, not found in normal endometrium. Approximately 780,000 women in the United States suffer from endometriosis. No clinical trials of angiogenesis inhibitors for endometriosis are currently under way, but this class of drugs holds promise as an additional treatment of endometriosis, perhaps on a monthly basis. At least three angiogenesis inhibitors are produced in the female reproductive system: 2-methoxyestradiol, proliferin-related protein, and a 16-kDa fragment of prolactin. It would be of interest to know if any of these would be therapeutic for endometriosis.

Other Pathology Angiogenesis may be increased in dysfunctional uterine bleeding such as breakthrough bleeding from contraceptives. The edema and ascites of the ovarian hyperstimulation syndrome is thought to be mediated by the ability ofVEGF to increase vascular permeability. Preeclampsia during pregnancy may be related to abnormal vascular remodeling, although it is not clear how the hypertension and cerebral edema associated with this disease are mediated by an endothelial cell product.

Carcinoma of the Ovary, Endometrium, and Cervix These common gynecologic tumors are all angiogenesis-dependent. As a result, they share certain characteristics

discussed under "Neoplastic Disease," above. Microvessel density in histologic sections provides independent prognostic indicators of metastatic risk and/or mortality.VEGF is a major angiogenic mediator in these tumors. The ascites in ovarian carcinoma contains concentrations of VEGF of up to 100 times higher than those in serum in the same patient. Endometrial carcinoma, which can be induced by long-term tamoxifen therapy, may operate through upregulation ofIL-8 in the endometrium. The potential value of angiogenesis inhibitors in the treatment of gynecologic tumors refractory to conventional therapy is suggested by two reports: (1) experimental ovarian cancer was inhibited by administration of angiostatin and endostatin, which acted synergistically; and (2) malignant ascites and growth of human ovarian cancer were inhibited in experimental animals by inhibiting a receptor for VEGF.

ANGIOGENESIS IN CARDIOVASCULAR DISEASE

Angiogenesis in the cardiovascular system occurs under three different conditions: (1) neovascularization in atherosclerotic plaques, (2) formation of collateral vessels to an area of ischemic myocardium or ischemic muscle in a limb, and (3) neovascularization at the edges of a myocardial infarction during its repair.

Angiogenesis in Atherosclerotic Plaques Angiogenesis occurs in atherosclerotic plaques, and hypoxia is thought to be a major stimulus. The mediators of angiogenesis found in most plaques arebFGF,VEGF, transforming growth factor b(TGF-b), andPDGF-BB. Smooth-muscle cells in plaques are a source of VEGF and PDGF-BB. Macrophages, mast cells, and T cells, which are also found to infiltrate plaques, can produce bFGF and TGF-b. However, the angiogenic factor(s) directly responsible for plaque angiogenesis and the sequential order in which these factors act during the evolution of a plaque have not been worked out. The new microvessels in a plaque can be the source of intraplaque microhemorrhage. Furthermore, the production of metalloproteinases at the advancing tips of new microvessels may contribute to plaque rupture.

The evidence that atherosclerotic plaques are angiogenesis-dependent. However, some supporting experimental evidence has been obtained in transgenic mice deficient in the gene for apoliprotein E (ApoE-/-). When these mice are fed a western diet containing 0.15% cholesterol, they develop atherosclerotic plaques in the aorta over 6 months. Early plaques <250 um thick are not neovascularized. Cells in the center of such a plaque would lie within the oxygen diffusion limit of oxygen arriving from the normal vasa vasorum or from the arterial lumen. However, intense neovascularization occurred as plaques enlarged to >250 um. When mice were treated during the development of a plaque with either of the angiogenesis inhibitors TNP-470 (a synthetic fumagillin analogue in phase II clinical trial) or endostatin (in phase I clinical trial), total plaque area was reduced by 70% and 85%, respectively. This finding has important clinical implications.

If long-term antiangiogenic therapy inhibits plaque growth or reduces plaque microhemorrhage or rupture, then it will be important to document this in cancer patients who are receiving angiogenesis inhibitors over a period of [3]1 to 2 years. Furthermore, if antiangiogenic therapy blocks plaque angiogenesis, plaque growth, bleeding, or rupture, would this obviate the need for coronary collateral vessels? If so, then this would

remove the theoretical concern that long-term antiangiogenic therapy for cancer might decrease collateral development. Another extenuating circumstance is that collateral vessels in general are thick-walled and coated with smooth muscle. They are less likely to undergo regression during exposure to an angiogenesis inhibitor than the thin-walled endothelial tubes, which are not covered or stabilized by smooth muscle in a tumor bed.

Therapeutic Angiogenesis in Ischemic Vascular Disease Experimental and clinical attempts to increase angiogenesis in ischemic tissues are very recent and have generally followed two strategies: injection into the ischemic tissue of angiogenic proteins (eitherVEGF or FGFs) or injection of genetic material that codes for these angiogenic stimulators. The animal data show that it is possible to increase the density of new blood vessels and flow to an ischemic area beyond what can be accomplished by hypoxia defense mechanisms in the body. It is not yet clear how durable the new vessels will be once they are induced in an ischemic tissue. We understand much more about stopping angiogenesis than starting it. However, once the techniques for therapeutic angiogenesis are further developed, the clinical need could be enormous.

FUTURE DIRECTIONS

Many other diseases are dominated by the angiogenic process. These include Crohn's disease, thyroiditis, benign prostatic hypertrophy, glomerulonephritis, ectopic bone formation, keloids, and others. However, they were not included in this chapter because the evidence that they are angiogenesis-dependent is not yet sufficiently compelling.

The diseases that were included *are* more clearly angiogenesis-dependent and serve to illustrate an important direction for the future. Oncologists, dermatologists, ophthalmologists, rheumatologists, gynecologists, and cardiologists are dealing with diseases that appear on the surface to be completely different from each other. Advances in therapy of these diseases are reported at different meetings and in different journals, and the specialists who treat them rarely go to each other's meetings or talk to each other. Nevertheless, all of these diseases are dominated by pathologic angiogenesis. The angiogenesis is driven by a small but similar set of molecules, which are regulated differently in each disease. Furthermore, a new class of drugs, the angiogenesis inhibitors, is becoming available and may permit improvements in therapy for many of these diseases. Thus, angiogenesis is a unifying process that has heuristic value across many medical specialties. The "angiogenesis-dependency" of many diseases, neoplastic and nonneoplastic, is of course not sufficiently quantitative to be called a theory, but it is similar to Stephen Wolfram's definition of a theory as "a compressed package of information, applicable to many cases."

84. PRINCIPLES OF CANCER TREATMENT - *Edward A. Sausville*, *Dan L. Longo*

The goal of cancer treatment is first to eradicate the cancer. If this primary goal cannot be accomplished, the goal of cancer treatment shifts to palliation, the amelioration of symptoms, and preservation of quality of life while striving to extend life. The dictum *primum non nocere* is *not* the guiding principle of cancer therapy. Every cancer treatment has the potential to cause harm, and treatment may be given that produces toxicity with no benefit. The therapeutic index of many interventions is quite narrow, and most treatments are given to the point of toxicity. The guiding principle of cancer treatment is *primum succerrere*, first hasten to help. Radical surgical procedures, large-field hyperfractionated radiation therapy, high-dose chemotherapy, and maximum tolerable doses of cytokines such as interleukin (IL) 2 are all used in certain settings where 100% of the patients will experience toxicity and side effects from the intervention, and only a fraction of the patients will experience benefit. One of the challenges of cancer treatment is to use the various treatment modalities alone and together in a fashion that maximizes the chances for patient benefit.

Cancer treatments are divided into four main groups: surgery, radiation therapy (including photodynamic therapy), chemotherapy (including hormonal therapy), and biologic therapy (including immunotherapy, differentiating agents, and agents targeting cancer cell biology). The modalities are often used in combination, and agents in one category can act by several mechanisms. For example, cancer chemotherapy agents can induce differentiation, and antibodies (a form of immunotherapy) can be used to deliver radiation therapy. Surgery and radiation therapy are considered local treatments, though their effects can influence the behavior of tumor at remote sites. Chemotherapy and biologic therapy are usually systemic treatments.

Cancer behaves in many ways as an organ that regulates its own growth. However, cancers have not set an appropriate limit on how much growth should be permitted. Normal organs and cancers share the property of having a population of cells in cycle and actively renewing and a population of cells not in cycle. In cancers, cells that are not dividing are heterogeneous; some have sustained too much genetic damage to replicate but have defects in their death pathways that permit their survival; some are starving for nutrients and oxygen; and some are reversibly out of cycle poised to be recruited back into cycle and expand if needed. Severely damaged and starving cells are unlikely to kill the patient. The problem is that the cells that are reversibly not in cycle are capable of replenishing tumor cells physically removed or damaged by radiation and chemotherapy.

Tumors follow a Gompertzian growth curve (Fig. 84-1); the growth fraction of a neoplasm starts at 100% with the first transformed cell and declines exponentially over time until by the time of diagnosis at a tumor burden of 1 to 5´10^9tumor cells, the growth fraction is usually 1 to 4%. Cancers are actually trying to limit their own growth but are not completely successful at doing so. The peak growth rate occurs before the tumor is detectable. Folkman has suggested that tumors restrict their growth by elaborating angiogenesis inhibitors (Chap. 83). Other cellular mechanisms to withdraw cells from the cell cycle probably exist as well. Several observations support the idea of autoregulation of tumor growth. Metastases can be observed to grow more rapidly than the primary tumor, consistent with the idea that an inhibitory factor slows the growth of

larger tumor masses. When a tumor recurs after surgery or chemotherapy, frequently its growth is accelerated and the growth fraction of the tumor is increased. This pattern is similar to that seen in regenerating organs. Partial resection of the liver results in the recruitment of cells into the cell cycle, and the resected liver volume is replaced. Similarly, chemotherapy-damaged bone marrow increases its growth to replace cells killed by chemotherapy. However, cancers do not recognize a limit on their expansion. Monoclonal gammopathy of uncertain significance may be an example of a clonal neoplasm with intrinsic features that stop its growth before a lethal tumor burden is reached. A fraction of patients with this disorder go on to develop fatal multiple myeloma, but probably this occurs because of the accumulation of additional genetic lesions. Elucidation of the mechanisms that regulate this organ-like behavior may provide additional clues to cancer control and treatment.

PRINCIPLES OF CANCER SURGERY

Surgery is used in cancer prevention, diagnosis, staging, treatment (for both localized and metastatic disease), palliation, and rehabilitation.

PREVENTION

Cancer can be prevented by surgery in people who have premalignant lesions resected (e.g., premalignant lesions of skin, colon, cervix) and in those who are at higher-than-normal risk of cancer from either an underlying disease (colectomy in those with pancolonic involvement with ulcerative colitis), the presence of genetic lesions (familial polyposis -- colectomy; multiple endocrine neoplasia type II -- thyroidectomy; familial breast or ovarian cancer -- mastectomy, oophorectomy), or a developmental anomaly (orchiectomy in those with an undescended testis). In some cases, prophylactic surgery is more radical than the surgical procedures used to treat the cancer after it develops. The assessment of risk involves many factors and should be undertaken with care before advising a patient to undergo a major procedure. For breast cancer prevention, many experts use a 20% risk of developing breast cancer over the next 5 years as a threshold. However, patient fears play a major role in defining candidates for cancer prevention surgery. Counseling and education may not be enough to allay the fears of someone who has lost close family members to a malignancy.

DIAGNOSIS

The ideal diagnostic procedure varies with the type of cancer, its anatomic location, and the medical condition of the patient. However, the underlying principle is to obtain as much tissue as safely possible. Tumors may be heterogeneous in appearance. Pathologists are better able to make the diagnosis when they have more tissue to examine. In addition to light-microscopic inspection of a tumor for pattern of growth, degree of cellular atypia, invasiveness, and morphologic features that aid in the differential diagnosis, sufficient tissue is of value in searching for genetic abnormalities and protein expression patterns that may aid in differential diagnosis or provide information about prognosis or likely response to treatment. Such testing requires that the tissue be handled properly (e.g., immunologic detection of proteins is more effective in fresh-frozen tissue rather than in formalin-fixed tissue); thus, coordination among the

surgeon, pathologist, and primary care physician is essential to ensure that the amount of information learned from the biopsy material is maximized.

These goals are best met by an *excisional biopsy* in which the entire tumor mass is removed with a small margin of normal tissue surrounding it. If an excisional biopsy cannot be performed, *incisional biopsy* is the procedure of second choice. A wedge of tissue is removed, and an effort is made to include the majority of the cross-sectional diameter of the tumor in the biopsy to minimize sampling error. When the diagnosis is being made through an endoscope or via fluoroscopy, it may be necessary to obtain a *core-needle biopsy* of the mass; considerably less tissue is obtained and the diagnosis may be less certain. However, this procedure often provides enough information to plan a definitive surgical procedure. Least reliable in diagnosis of primary cancer is *fine-needle aspiration*. This technique generally obtains only a suspension of cells from within a mass. This approach (with stereotactic guidance of the needle) is the procedure of choice in the diagnosis of brain tumors and may be useful in diagnosing thyroid nodules and in confirming persistent or recurrent disease in a patient with known cancer, but the procedure is overutilized in primary diagnosis. It would be preferable to perform a larger open operation to obtain more tissue in most sites. The biopsy techniques that involve cutting into tumor carry with them a risk of facilitating the spread of the tumor.

STAGING

As noted in Chap. 79, an important component of patient management is defining the extent of disease. Radiographic and other imaging tests can be helpful in defining the clinical stage; however, pathologic staging requires defining the extent of involvement by documenting the histologic presence of tumor in tissue biopsies obtained through a surgical procedure. Axillary lymph node sampling in breast cancer and lymph node sampling at laparotomy for lymphomas and testicular, colon, and other intraabdominal cancers provide crucial information for treatment planning and may determine the extent and nature of primary cancer treatment.

TREATMENT

Surgery is perhaps the most effective means of treating cancer. About 40% of cancer patients are cured today by surgery. Unfortunately, a large fraction of patients with solid tumors (perhaps 60%) have metastatic disease that is not accessible for removal. However, even when the disease is not curable by surgery alone, the removal of tumor can obtain important benefits, including local control of tumor, preservation of organ function, debulking that permits subsequent therapy to work better, and staging information on extent of involvement. Cancer surgery aiming for cure is usually planned to excise the tumor completely with an adequate margin of normal tissue (the margin varies with the tumor and the anatomy), touching the tumor as little as possible to prevent vascular and lymphatic spread, and minimizing operative risk. Extending the procedure to resect draining lymph nodes obtains prognostic information, but such resections alone generally do not improve survival.

Increasingly, laparoscopic approaches are being taken to the primary tumor. Lymph node spread may be assessed using the *sentinel node approach*, in which the first

draining lymph node a tumor would encounter is defined by injecting a dye at operation and resecting the first node to turn blue. The sentinel node evaluation is continuing to undergo clinical testing but appears to provide reliable information without the risks (lymphedema, lymphangiosarcoma) associated with resection of all the regional nodes. Advances in adjuvant chemotherapy and radiation therapy following surgery have permitted a substantial decrease in the extent of primary surgery necessary to obtain the best outcomes. Thus, lumpectomy with radiation therapy is as effective as modified radical mastectomy for breast cancer, and limb-sparing surgery followed by adjuvant radiation therapy and chemotherapy has replaced radical primary surgical procedures involving amputation and disarticulation for childhood rhabdomyosarcomas. More limited surgery is also being employed to spare organ function, as in larynx and bladder cancer. The magnitude of operations necessary to optimally control and cure cancer has also been diminished by technical advances; for example, the circular anastomotic stapler has allowed narrower (<2 cm) margins in colon cancer without compromise of local control rates, and many patients who would have had colostomies are able to maintain normal anatomy.

In some settings, e.g., bulky testicular cancer or stage III breast cancer, surgery is not the first treatment modality employed. After an initial diagnostic biopsy, chemotherapy and/or radiation therapy are delivered to reduce the size of the tumor and control clinically undetected metastatic disease, and such therapy is followed by a surgical procedure to remove residual masses. This is called *neoadjuvant therapy*. Because the sequence of treatment is critical to success and is different from the standard surgery-first approach, coordination among the surgical oncologist, radiation oncologist, and medical oncologist is crucial.

Surgery may be curative in a subset of patients with metastatic disease. Patients with lung metastases from osteosarcoma may be cured by resection of the lung lesions. In patients with colon cancer who have fewer than five liver metastases restricted to one lobe and no extrahepatic metastases, hepatic lobectomy may produce long-term disease-free survival in 25% of selected patients. Surgery can also be associated with systemic antitumor effects. In the setting of hormonally responsive tumors, oophorectomy and/or adrenalectomy may control estrogen production and orchiectomy may reduce androgen production, both with effects on metastatic tumor growth. If resection of the primary lesion takes place in the presence of metastases, any noted change in tumor behavior is most often acceleration of growth, perhaps based on the removal of a source of angiogenesis inhibitors and mass-related growth regulators in the tumor. However, on rare occasions (certain renal cancers), primary tumor resection is accompanied by regression of metastatic lesions. Similarly, splenectomy in some cases of lymphoma may be associated with regression of disease at remote sites. This phenomenon is attributed to the removal of a source of growth or angiogenic factors upon which the remote sites depend for growth.

PALLIATION

Surgery is employed in a number of ways for supportive care: insertion of central venous catheters, diagnostic evaluation of pulmonary infiltrates, control of pleural and pericardial effusions and ascites, caval interruption for recurrent pulmonary emboli, stabilization of cancer-weakened weight-bearing bones, and control of hemorrhage,

among others. Surgical bypass of gastrointestinal, urinary tract, or biliary tree obstruction can alleviate symptoms and prolong survival. Surgical procedures may provide relief of otherwise intractable pain or reverse neurologic dysfunction (cord decompression). Splenectomy may relieve symptoms and reverse hypersplenism. Intrathecal or intrahepatic therapy relies on surgical placement of appropriate infusion portals. Surgery may correct other treatment-related toxicities such as adhesions or strictures.

REHABILITATION

Surgical procedures are also valuable in restoring a cancer patient to full health. Orthopedic procedures may be necessary to assure proper ambulation. Breast reconstruction can make an enormous impact on the patient's perception of successful therapy. Plastic and reconstructive surgery can correct the effects of disfiguring primary treatment.

PRINCIPLES OF RADIATION THERAPY

PHYSICAL PROPERTIES AND BIOLOGIC EFFECTS

Radiation therapy is a physical form of treatment that damages any tissue in its path. Tumor cells seem somewhat more sensitive to the lethal effects of radiation than normal tissues primarily because of differences in ability to repair sublethal DNA and other damage. In the target tissue, radiation damages DNA (usually single strand breaks) and generates free radicals from cell water that are capable of damaging cell membranes, proteins, and organelles. Radiation damage is dependent on oxygen; hypoxic cells are more resistant. Augmentation of oxygen is the basis for radiation sensitization. Sulfhydryl compounds interfere with free radical generation and may act as radiation protectors. The challenge for radiation treatment planning is to deliver the radiation to the tumor volume with as little normal tissue in the field as possible.*Principles of radiation injury are discussed in Chap. 394.*

Therapeutic radiation is delivered in three ways: teletherapy with beams of radiation generated at a distance and aimed at the tumor within the patient, brachytherapy with encapsulated sources of radiation implanted directly into or adjacent to tumor tissues, and systemic therapy with radionuclides targeted in some fashion to a site of tumor. Teletherapy is the most commonly used form of radiation therapy.

Radiation from any source decreases in intensity as a function of the square of the distance from the source (inverse square law). Thus, if the radiation source is 5 cm above the skin surface and the tumor is 5 cm below the skin surface, the intensity of radiation in the tumor will be $5^2/10^2$, or 25% of the intensity at the skin. By contrast, if the radiation source is moved to 100 cm from the patient, the intensity of radiation in the tumor will be $100^2/105^2$, or 91% of the intensity at the skin. Teletherapy maintains intensity over a larger volume of target tissue by increasing the source-to-surface distance. In brachytherapy, the source-to-surface distance is small; thus, the effective treatment volume is small.

X-rays and *gamma rays* are the forms of radiation most commonly used to treat cancer.

They are both electromagnetic, nonparticulate waves that cause the ejection of an orbital electron when absorbed. This orbital electron ejection is called *ionization*. X-rays are generated by linear accelerators; gamma rays are generated from decay of atomic nuclei in radioisotopes such as cobalt and radium. These waves behave biologically as packets of energy, called *photons*. Particulate forms of radiation are also used in certain circumstances. Electron beams have a very low tissue penetrance and are used to treat skin conditions such as mycosis fungoides. Neutron beams may be somewhat more effective than x-rays in treating salivary gland tumors. However, aside from these specialized uses, particulate forms of radiation such as neutrons, protons, and negative p mesons, which should do more tissue damage because of their higher linear energy transfer (LET) and be less dependent on oxygen, have not yet found wide applicability to cancer treatment.

A number of parameters influence the damage done to tissue by radiation. Hypoxic cells are relatively resistant. Nondividing cells are more resistant than dividing cells. In addition to these biologic parameters, physical parameters of the radiation are also crucial. The *energy* of the radiation determines its ability to penetrate tissue. Low-energy orthovoltage beams (150 to 400 kV) scatter when they strike the body, much like light diffuses when it strikes particles in the air. Such beams result in more damage to adjacent normal tissues and less radiation delivered to the tumor. Megavoltage radiation (³1 MeV) has very low lateral scatter; this produces a skin-sparing effect, more homogeneous distribution of the radiation energy, and greater deposit of the energy in the tumor, or *target volume*. The tissues that the beam passes through to get to the tumor is called the *transit volume*. The maximum dose in the target volume is often the cause of complications to tissues in the transit volume, and the minimum dose in the target volume influences the likelihood of tumor recurrence. Dose homogeneity in the target volume is the goal.

Radiation is quantitated on the basis of the amount of radiation absorbed in the patient, not based upon the amount of radiation generated by the machine. A rad (radiation absorbed dose) is 100 ergs of energy per gram of tissue; a gray (Gy) is 100 rad. Radiation dose is measured by placing detectors at the body surface or calculating the dose based on radiating phantoms that resemble human form and substance. Radiation dose has three determinants: total absorbed dose, number of fractions, and time. A frequent error is to omit the number of fractions and the duration of treatment. This is analogous to saying that a runner completed a race in 20 s; without knowing how far he or she ran, the result is difficult to interpret. The time could be very good for a 200-m race or very poor for a 100-m race. Thus, a typical course of radiation therapy should be described as 4500 cGy delivered to a particular target (e.g., mediastinum) over 5 weeks in 180-cGy fractions. Most radiation treatment programs are delivered once a day, 5 days a week in 150- to 200-cGy fractions.

The killing of tumor cells in vivo by radiation is described in detail inChap. 394. Although radiation can interfere with many cellular processes, many experts feel that a cell must undergo a double-stranded DNA break from radiation in order to be killed. The factors that influence tumor cell killing include the D_0 of the tumor (the dose required to deliver an average of one lethal hit to all the cells in a population), the D_q of the tumor (the threshold dose -- a measure of the cell's ability to repair sublethal damage), hypoxia, tumor mass, growth fraction, and cell cycle time and phase (cells in late G_1 and S are

more resistant). Rate of clinical response is not predictive; some cells do not die after radiation exposure until they attempt to replicate.

Compounds that incorporate into DNA and alter its stereochemistry (e.g., halogenated pyrimidines, cisplatin) augment radiation effects. Hydroxyurea, another DNA synthesis inhibitor, also potentiates radiation effects. Compounds that deplete thiols (e.g., buthionine sulfoximine) can also augment radiation effects. Hypoxia is the main factor that interferes with radiation effects.

APPLICATION TO PATIENTS

Radiation therapy can be used alone or together with chemotherapy to produce cure of localized tumors and control of the primary site of disease in tumors that have disseminated. Therapy is planned based on the use of a simulator with the treatment field or fields designed to accommodate an individual patient's anatomic features. Individualized treatment planning employs lead shielding tailored to shape the field and limit the radiation exposure of normal tissue. Often the radiation is delivered from two or three different positions. Conformal three-dimensional treatment planning is permitting the delivery of higher doses of radiation to the target volume without increasing complications in the transit volume.

Radiation therapy is a component of curative therapy for a number of diseases including breast cancer, Hodgkin's disease, head and neck cancer, prostate cancer, and gynecologic cancers. Radiation therapy can also palliate disease symptoms in a variety of settings: relief of bone pain from metastatic disease, control of brain metastases, reversal of cord compression and superior vena caval obstruction, shrinkage of painful masses, and opening threatened airways. In high-risk settings, radiation therapy can prevent the development of leptomeningeal disease and brain metastases in acute leukemia and lung cancer.

Brachytherapy involves placing a sealed source of radiation into or adjacent to the tumor and withdrawing the radiation source after a period of time precisely calculated to deliver a chosen dose of radiation to the tumor. This approach is often used to treat brain tumors and cervical cancer. The difficulty with brachytherapy is the short range of radiation effects (the inverse square law) and the inability to shape the radiation to fit the target volume. Normal tissue may receive substantial exposure to the radiation, with attendant radiation enteritis or cystitis in cervix cancer or brain injury in brain tumors.

TOXICITY

Though radiation therapy is most often administered to a local region, systemic effects, including fatigue, anorexia, nausea, and vomiting, may develop related in part to the volume of tissue irradiated, dose fractionation, radiation fields, and individual susceptibility. Bone is among the most radioresistant organs, radiation effects being manifested mainly in children through premature fusion of the epiphyseal growth plate. By contrast, the male testis, female ovary, and bone marrow are the most sensitive organs. Any bone marrow in a radiation field will be eradicated by therapeutic irradiation. Organs with less need for cell renewal, such as heart, skeletal muscle, and nerves, are more resistant to radiation effects. In radiation-resistant organs, the vascular

endothelium is the most sensitive component. Organs with more self-renewal as a part of normal homeostasis, such as the hematopoietic system and mucosal lining of the intestinal tract, are more sensitive. Acute toxicities include mucositis, skin erythema (ulceration in severe cases), and bone marrow toxicity. Often these can be alleviated by interruption of treatment.

Chronic toxicities are more serious. Radiation of the head and neck region usually produces thyroid failure. Cataracts and retinal damage can lead to blindness. Salivary glands stop making saliva, which leads to dental carries and poor dentition. Taste and smell can be affected. Mediastinal irradiation leads to a threefold increased risk of *fatal* myocardial infarction. Other late vascular effects include chronic constrictive pericarditis, lung fibrosis, viscus stricture, spinal cord transection, and radiation enteritis. The most serious late toxicity is the development of second solid tumors in or adjacent to the radiation fields. Such tumors can develop in any organ or tissue and occur at a rate of about 1% per year beginning in the second decade after treatment. Some organs vary in susceptibility to radiation carcinogenesis. Women under age 30 experience a 100-fold or greater increase in the incidence of breast cancer after chest or mantle field radiation; women treated after age 30 have little or no increased risk of breast cancer. No data suggest that a threshold dose of therapeutic radiation exists below which the incidence of second cancers is decreased. High rates of second tumors have been documented in people who received as little as 1000 cGy.

RADIONUCLIDES AND RADIOIMMUNOTHERAPY

Nuclear medicine physicians or radiation oncologists may administer radionuclides with therapeutic effects. Iodine-131 is used to treat thyroid cancer as iodine is naturally taken up preferentially by the thyroid. It emits gamma rays that destroy the normal thyroid as well as the tumor. Strontium-89 and samarium-153 are two radionuclides that are preferentially taken up in bone, particularly sites of new bone formation. Both are capable of controlling bone metastases and the pain associated with them, but the dose-limiting toxicity is myelosuppression.

Monoclonal antibodies and other ligands can be attached to radioisotopes by conjugation (for nonmetal isotopes) or by chelation (for metal isotopes), and the targeting moiety can result in the accumulation of the radionuclide preferentially in tumor. Iodine-131-labeled anti-CD20 and yttrium-90-labeled anti-CD20 are active in B cell lymphoma, and other labeled antibodies are being evaluated. Thyroid uptake of labeled iodine is blocked by cold iodine. Dose-limiting toxicity is myelosuppression.

PHOTODYNAMIC THERAPY

Some chemical structures (porphyrins, phthalocyanines) are selectively taken up by cancer cells by mechanisms not fully defined. When light, usually delivered by laser, is shone on cells containing these compounds, free radicals are generated and the cells die. Hematoporphyrins and light are being used with increasing frequency to treat skin cancer; ovarian cancer; and cancers of the lung, colon, rectum, and esophagus. Palliation of recurrent locally advanced disease can sometimes be dramatic and last many months.

PRINCIPLES OF CHEMOTHERAPY

HISTORIC BACKGROUND

The treatment of patients with cancer using chemicals in the hope of causing regressions of established tumors or to slow the rate of tumor growth arose by analogy to the proposition of Ehrlich that bacteria could be killed selectively by compounds acting as "magic bullets." Candidate compounds that might have selectivity for cancer cells were suggested by the marrow-toxic effects of sulfur and nitrogen mustards and led, in the 1940s, to the first notable regressions of hematopoietic tumors following use of these compounds by Gilman and colleagues. As these compounds caused covalent modification of DNA, the structure of DNA was thereby identified as a potential target for drug design efforts. Biochemical studies demonstrating the requirement of growing tumor cells for precursors of nucleic acids led to nearly contemporaneous studies by Farber of folate analogues. The cure of patients with advanced choriocarcinoma by methotrexate in the 1950s provided further impetus to define the value of chemotherapeutic agents in many different tumor types. This resulted in efforts to understand unique metabolic requirements for biosynthesis of nucelic acids and led to the design, rational for the time, of compounds that might selectively interdict DNA synthesis in proliferating cancer cells. The capacity of hormonal manipulations including oophorectomy and orchiectomy to cause regressions of breast and prostate cancers, respectively, provided a rationale for efforts to interdict various aspects of hormone function in hormone-dependent tumors. The serendipitous finding that certain poisons derived from bacteria or plants could affect normal DNA or mitotic spindle function allowed completion of the classic armamentatrium of "cancer chemotherapy agents" with proven safety and efficacy in the treatment of certain cancers.

END-POINTS OF DRUG ACTION

Chemotherapy agents may be used for the treatment of active, clinically apparent cancer.Table 84-1A lists those tumors considered curable by conventionally available chemotherapeutic agents. Most commonly, chemotherapeutic agents are used to address metastatic cancers. If a tumor is localized to a single site, serious consideration of surgery or primary radiation therapy should be given, as these treatment modalities may be curative as local treatments. Chemotherapy may be employed after the failure of these modalities to eradicate a local tumor, or as part of multimodality approaches to offer primary treatment to a clinically localized tumor. In this event, it can allow *organ preservation* when given with radiation, as in larynx or other upper airway sites; or sensitize tumors to radiation when given, for example, to patients concurrently receiving radiation for lung or cervix cancer (Table 84-1B). Chemotherapy can be administered as an *adjuvant* to surgery (Table 84-1C) or radiation, a use that may have curative potential in breast, colon, or anorectal neoplasms. In this use, chemotherapy attempts to eliminate clinically unapparent tumor that may have already disseminated. Chemotherapy can be used in *conventional dose* regimens. In general, these doses produce reversible acute side effects primarily consisting of transient myelosuppression with or without gastrointestinal toxicity (nausea), which are readily managed. *High-dose* chemotherapy regimens are predicated on the observation that the concentration-effect curve for many anticancer agents is rather steep, and increased dose can produce markedly increased therapeutic effect, although at the cost of potentially life-threatening

complications that require intensive support, usually in the form of bone marrow or stem cell support from the patient (*autologous*) or from donors matched for histocompatibility loci (*allogeneic*). High-dose regimens nonetheless have definite curative potential in defined clinical settings (Table 84-1D).

Karnofsky was among the first to champion the evaluation of a chemotherapeutic agent's benefit by carefully quantitating its effect on tumor size and using these measurements to decide objectively the basis for further treatment of a particular patient or further clinical evaluation of a drug's potential. A partial response (PR) is defined conventionally as a decrease by at least 50% in a tumor's bi-dimensional area; a complete response (CR) connotes disappearance of all tumor; progression of disease signifies increase by>25% from baseline or best response; and "stable" disease fits into none of the above categories.

If cure is not possible, chemotherapy may be undertaken with the goal of palliating some aspect of the tumor's effect on the host. Common tumors that may be meaningfully addressed with palliative intent are listed inTable 84-1E. Usually tumor-related symptoms may manifest as pain, weight loss, or some local symptom related to the tumor's effect on normal structures. Patients treated with palliative intent should be aware of their diagnosis and the limitations of the proposed treatment, have access to suitable palliative strategies in the event that no treatment is elected, and have a suitable "performance status" [according to assessment algorithms such as the one developed by Karnofsky or by the Eastern Cooperative Oncology Group (ECOG)]. ECOG performance status 0 (PS0) patients are without symptoms; PS1 patients have mild symptoms not requiring treatment; PS2, symptoms requiring some treatment; PS3, disabling symptoms, but allowing ambulation for>50% of the day; PS4, ambulation<50% of the day. Only PS0 to PS2 patients are generally considered suitable for palliative (noncurative) treatment. If there is curative potential, even poor performance status patients may be treated, but their prognosis is usually inferior to those of good performance patients treated with similar regimens.

PATH FOR NEW DRUG DISCOVERY AND DEVELOPMENT

The usefulness of any drug is governed by the extent to which a given dose causes a useful result (therapeutic effect; in the case of anticancer agents, toxicity to tumor cells) as opposed to a toxic effect. The therapeutic index is the degree of separation between toxic and therapeutic doses. Really useful drugs have large therapeutic indices, and this usually occurs when the drug target is expressed in the disease-causing compartment as opposed to the normal compartment. Classically, selective toxicity of an agent for an organ is governed by the expression of an agent's target; or differential accumulation into or elimination from compartments where toxicity is experienced or ameliorated, respectively. Current antineoplastic agents have the unfortunate property that their targets are present in both normal and tumor tissues. In the main they therefore have relatively narrow therapeutic indices.

Agents with promise for the treatment of cancer have in the past been detected empirically through screening for antiproliferative effects in animal or human tumors in rodent hosts or through inhibition of tumor cells growing in tissue culture. An optimal schedule for demonstrating antitumor activity in animals is defined in further preclinical

studies, as is the optimal drug formulation for a given route and schedule. Safety testing in two species on an analogous schedule of administration defines the starting dose for a phase I trial in humans, where escalating doses of the drug are given until reversible toxicity is observed. *Dose-limiting toxicity* (DLT) defines a dose that conveys greater toxicity than would be acceptable in routine practice, allowing definition of a *maximal tolerated dose* (MTD). The occurrence of toxicity is correlated if possible with plasma drug concentrations. The MTD or a dose just lower than the MTD is usually the dose suitable for phase II trials, where a fixed dose is administered to a relatively homogeneous set of patients in an effort to define whether the drug causes regression of tumors. An "active" agent conventionally has partial response rates of at least 20 to 25% with reversible non-life-threatening side effects, and it may then be suitable for study in phase III trials to assess efficacy in comparison to standard or no therapy. Response is but the most immediate indicator of drug effect. To be clinically valuable, responses must translate into effects on *overall survival* or at least *time to progression* as important indicators of an ultimately useful drug. More recently, active efforts to quantitate effects of anticancer agents on *quality of life* as an important outcome are being developed. Cancer drug clinical trials conventionally use a toxicity grading scale where grade I toxicities do not require treatment; grade II often require symptomatic treatment but are not life-threatening; grade III toxicities are potentially life-threatening if untreated; grade IV toxicities are actually life-threatening; and grade V toxicities ultimately lead to patient death.

The process of cancer drug development is likely to evolve in significant ways in the near future as (1) the molecular analysis of human tumors defines more precisely the molecular targets that can be the focus of drug discovery efforts, and (2) clinical trials are undertaken only after means of assessing the behavior of the drug in relation to its target have been developed. The basis for optimism and anticipated change in clinical trials methodology extends from emerging understanding of the basis for cancer incidence and progression. Cancer arises from genetic lesions that cause an excess of cell growth or division, with inadequate cell death (Chap. 82). In addition, failure of cellular differentiation results in altered cellular position and capacity to proliferate while cut off from normal cell regulatory signals. An overall schema for understanding cancer progression can be seen inFig. 84-2. Normally, cells in a differentiated state are stimulated to enter the cell cycle from a quiescent state, or "G0," or continue after completion of a prior cell division cycle in response to environmental cues including growth factor and hormonal signals. Cells progress through G1 and enter S phase after passing through "checkpoints," which are biochemically regulated transition points, to assure that the genome is ready for replication. One important checkpoint is mediated by the p53 tumor-suppressor gene product, acting through its upregulation of the $p21^{WAF1}$inhibitor of cyclin-dependent kinase (CDK) function, acting on CDKs 4 or 6. These molecules can also be inhibited by the $p16^{INK4A}$and $p27^{KIP1}$CDK inhibitors and, in turn, are activated by cyclins of the D family (which appear during G1) and the proper sequence of regulatory phosphorylations. Activated CDKs 4 or 6 phosphorylate and thus inactivate the product of the retinoblastoma susceptibility gene, pRb, which in its nonphosphorylated state complexes with transcription factors of the E2F family. Phosphorylated pRb releases E2Fs, which activate genes important in completing DNA replication during S phase, progression through which is promoted by CDK2 acting in concert with cylins A and E. During G2, another checkpoint occurs, in which the cell assures the completion of correct DNA synthesis. Cells then progress into M phase

under the influence of CDK1 and cyclin B. Cells may then go on to a subsequent division cycle or enter into a quiescent, differentiated state.

Also shown inFig. 84-2 are the sites of action of protooncogenes, regulators of cellular proliferation that, in an active state, promote cell growth, and whose deregulation produces oncogenes, originally discovered as the genes encoded by tumor-forming viruses in animals. Oncogenes can be divided into two families: (1) those that act in the cytoplasm to disrupt normal growth factor-related signaling, including *ras*, *raf*, and the tyrosine kinases of the *src* and *erb*B or *sis* families; and (2) nuclear oncogenes, including *jun*, *fos*, *myc*, and *myb*, that act to alter transcriptional control of cassettes of genes. In contrast, tumor-suppressor genes, including p53 and pRb, act as cellular "brakes" whose normal function is to inhibit or prevent unregulated cellular growth. The capacity to divide indefinitely is provided by activation of *telomerase*, which allows continued replication of chromosomes by addressing the unique need of chromosome ends to be continually renewed to a proper length to allow normal mitosis. The capacity to invade and metastasize is conveyed by elaboration of *matrix metalloproteases* and *plasminogen activators* and the capacity to recruit host stromal cells at the site of invasion through tumor-induced *angiogenesis*.

As will become apparent below, currently used drugs for the treatment of cancer focus principally on the proximate biochemistry of nucleic acid and mitotic spindle structure or function. Drugs of the future may seek to replace lost function of tumor-suppressor genes; counter the action of activated oncogenes; influence the capacity of cells to die; prevent normal chromosomal end replication; actually infect cells with viruses designed to replicate in the milieu of the cancer but not the normal cell; cause differentiation of cells with exit from the cell cycle by activating the appropriate genes; and utilize immunologic strategies, including antibodies and engineered cells to be directed at novel proteins expressed on the surface of cancer cells.

BIOLOGIC BASIS FOR CANCER CHEMOTHERAPY

The classic view of how cancer chemotherapeutic agents cause regressions of tumors focused on models such as the L1210 murine leukemia system, where cancer cells grow exponentially after inoculation into the peritoneal cavity of an isogenic mouse. The interaction of drug with its biochemical target in the cancer cell was proposed to result in "unbalanced growth" that was not sustainable and therefore resulted in cell death, directly as a result of interacting with the drug's proximal target. Agents could be categorized (Fig. 84-3) as cell cycle-active, phase-specific (e.g., antimetabolites, purines, and pyrimidines in S phase; vinca alkaloids in M), and phase-nonspecific agents (e.g., alkylators, and antitumor antibiotics including the anthracyclines, actinomycin, and mitomycin), which can injure DNA at any phase of the cell cycle but appear to then block in G2 before cell division at a checkpoint in the cell cycle. Cells arrested at a checkpoint may repair DNA lesions. Checkpoints have been defined at the G1 to S transition, mediated by the tumor-suppressor gene p53 (giving rise to the characterization of p53 as a "guardian of the genome"); at the G2 to M transition, mediated by the *chk1* kinase influencing the function ofCDK1; and during M phase, to ensure the integrity of the mitotic spindle. The importance of the concept of checkpoints extends from the hypothesis that repair of chemotherapy-mediated damage can occur while cells are stopped at a checkpoint; therefore, manipulation of checkpoint function

emerges as an important basis of affecting resistance to chemotherapeutic agents.

Resistance to drugs was postulated to arise either from cells not being in the appropriate phase of the cell cycle or from decreased uptake, increased efflux, metabolism of the drug, or alteration of the target, e.g., by mutation or overexpression. Indeed, the *p170PGP* (p170 P-glycoprotein; *mdr* gene product) was recognized from experiments with cells growing in tissue culture as mediating the efflux of chemotherapeutic agents in resistant cells. Certain neoplasms, particularly hematopoietic tumors, have an adverse prognosis if they express high levels of p170PGP, and modulation of this protein's function has been attempted by a variety of strategies.

Combinations of agents were proposed to afford the opportunity to affect many different targets or portions of the cell cycle at once, particularly if the toxic effects for the host of the different components of the combination were distinct. Combinations of agents were actually more effective in animal model systems than single agents, particularly if the tumor cell inoculum was high. This thinking led to the design of "combination chemotherapy" regimens, where drugs acting by different mechanisms (e.g., an alkylating agent plus an antimetabolite plus a mitotic spindle blocker) were combined. Particular combinations were chosen to emphasize drugs whose individual toxicities to the host were, if possible, distinct.

This view of cancer drug action is grossly oversimplified. Most tumors do not grow in an exponential pattern but rather follow Gompertzian kinetics, where the rate of tumor growth decreases as tumor mass increases (Fig. 84-1). Thus, a tumor has quiescent, differentiated compartments; proliferating compartments; and both well-vascularized and necrotic regions. Also, cell death is itself now understood to be a closely regulated process. *Necrosis* refers to cell death induced, for example, by physical damage with the hallmarks of cell swelling and membrane disruption. *Apoptosis*, or programmed cell death, refers to a highly ordered process whereby cells respond to defined stimuli by dying, and it recapitulates the necessary cell death observed during the ontogeny of the organism. *Anoikis* refers to death of epithelial cells after removal from the normal milieu of substrate, particularly from cell-to-cell contact. Cancer chemotherapeutic agents can cause both necrosis and apoptosis. Apoptosis is characterized by chromatin condensation (giving rise to "apoptotic bodies"); cell shrinkage; and, in living animals, phagocytosis by surrounding stromal cells without evidence of inflammation. This process is regulated either by signal transduction systems that promote a cell's demise after a certain level of insult is achieved or in response to specific cell-surface receptors that mediate cell death signals. Modulation of apoptosis by manipulation of signal transduction pathways has emerged as a basis for understanding the actions of currently used drugs and designing new strategies to improve their use.

The current view envisions that the interaction of a chemotherapeutic drug with its target causes or is itself a signal that initiates a "cascade" of signaling steps to trigger an "execution phase" where proteases, nucleases, and endogenous regulators of the cell death pathway are activated. Effective cancer chemotherapeutic agents are efficient activators of apoptosis through signal transduction pathways (Fig. 84-4). For example, in the cytokine-mediated pathway, exogenous ligands such as the Fas ligand (FasL) bind to cell-surface receptors (CD95; Fas), or tumor necrosis factor (TNF) or its homologue

Apo2L binds to its cognate receptors and directly recruits accessory molecules to activate a protease cascade (utilizing members of the caspase family of *c*ysteine *asp*artyl prote*ases*), resulting in apoptosis. In a second pathway, growth factor deprivation elicits poorly defined signals that result in protease activation. Chemotherapeutic agents create molecular lesions (in DNA or cellular membranes) as a consequence of combining with their respective molecular targets. These lesions are sensed by a cellular "damage sensor," whose molecular nature is unclear, which leads to mitochondrial damage. Release of mitochondrial factors (e.g., APAF1, cytochrome c) promotes the activation of another set of caspases. Damage to the plasma membrane, e.g., from free radicals generated by certain chemotherapeutic agents, leads to activation of acid sphingomyelinase to release lipid components including ceramides, which then promote apoptosis through a variety of pathways including direct mitochondrial damage.

While apoptotic mechanisms are important in regulating cellular proliferation and the behavior of tumor cells in vitro, in vivo it is unclear whether all of the actions of chemotherapeutic agents to cause cell death can be attributed to apoptotic mechanisms. Loss of clonogenic survival (conventionally detecting the capacity of a few cells to survive) may predict clinical value more reliably than detection of apoptotic changes in the majority of tumor cells. However, changes in molecules that regulate apoptosis are clearly correlated with clinical outcomes (e.g., *bcl2* overexpression in certain lymphomas conveys poor prognosis; proapototic *bax* expression is associated with a better outcome in ovarian carcinoma). Further efforts to understand the relationship of cell death and cell survival mechanisms will be necessary.

CHEMOTHERAPEUTIC AGENTS USED FOR CANCER TREATMENT

Table 84-2 lists commonly used cancer chemotherapy agents and pertinent clinical aspects of their use. The drugs may be usefully grouped into three general categories: those affecting DNA, those affecting microtubules, and those acting at hormone-like receptors.

Direct DNA-Interactive Agents

Formation of covalent DNA adducts Alkylating agents as a class break down, either spontaneously or after normal organ or tumor cell metabolism, to reactive intermediates that covalently modify bases in DNA. This leads to cross-linkage of DNA strands or the appearance of breaks in DNA as a result of repair efforts. "Broken" or cross-linked DNA is intrinsically unable to complete normal replication or cell division; in addition, it is a potent activator of cell cycle checkpoints and signaling pathways that can activate apoptosis. As a class, alkylating agents share similar toxicities, including myelosuppression, alopecia, gonadal dysfunction, mucositis, and pulmonary fibrosis. They differ greatly in a spectrum of normal organ toxicities.

Nitrogen mustard (mechlorethamine) is the prototypic agent of this class, decomposing rapidly in aqueous solution to yield potentially a bifunctional carbonium ion. It must be administered shortly after preparation into a rapidly flowing intravenous line. It is powerful vesicant, and infiltration may be symptomatically ameliorated by infiltration of the affected site with 1/6 *M* thiosulfate. Even without infiltration, aseptic thrombophlebitis

is frequent. It can be used topically as a dilute solution in cutaneous lymphomas, with a notable incidence of hypersensitivity reactions. It causes moderate nausea after intravenous administration.

Cyclophosphamide is inactive unless metabolized by the liver to 4-hydroxyl-cyclophosphamide, which decomposes into alkylating species, as well as to chloroacetaldehyde and acrolein. The latter causes chemical cystitis, and therefore excellent hydration must be maintained while using cyclophosphamide. If severe, the cystitis may be effectively treated by mercaptoethanesulfonate (MESNA). Liver disease impairs drug activation. Sporadic interstitial pneumonitis leading to pulmonary fibrosis can accompany the use of cyclophosphamide, and high doses used in conditioning regimens for bone marrow transplant can cause cardiac dysfunction. Ifosfamide is a cyclophosphamide analogue also activated in the liver, but more slowly, and it requires mandatory coadministration of MESNA to prevent bladder injury. Central nervous system (CNS) effects, including somnolence, confusion, and psychosis, can follow ifosfamide use, and the incidence appears related to low body surface area or the presence of nephrectomy.

There are several less commonly used alkylating agents. Chlorambucil causes predictable myelosuppression, azospermia, nausea, and pulmonary side effects. Busulfan can cause profound myelosuppression, alopecia, and pulmonary toxicity but is relatively "lymphocyte sparing." Its routine use in treatment of chronic myeloid leukemia has been curtailed in favor of hydroxyurea or interferon (IFN), but it still is employed in marrow transplant preparation regimens. Melphalan shows variable oral bioavailability and undergoes extensive binding to albumin anda_1-acidic glycoprotein. Mucositis appears more prominently.

Nitrosoureas break down to carbamoylating species that not only cause a distinct pattern of DNA base pair-directed toxicity but also can covalently modify proteins. They share the feature of causing relatively delayed bone marrow toxicity, which can be cumulative and long-lasting. Streptozotocin is unique in that its glucose-like structure conveys specific toxicity to the islet cells of the pancreas (for whose derivative tumor types it is prominently indicated) as well as causing renal toxicity in the form of Fanconi's syndrome, including amino aciduria, glycosuria, and renal tubular acidosis. Methyl CCNU (lomustine) causes direct glomerular as well as tubular damage, cumulatively related to dose and time of exposure.

Procarbazine is metabolized in the liver and possibly in tumor cells to yield a variety of free radical and alkylating species. In addition to myelosuppression, it causes hypnotic and other CNS effects, including vivid nightmares. It can cause a disulfiram-like syndrome on ingestion of ethanol. Hexamethylmelamine and thiotepa can chemically give rise to alkylating species, although the nature of the DNA damage has not been well characterized in either case. Thiotepa can be used for intrathecal treatment of neoplastic meningitis. Dacarbazine (DTIC) is activated in the liver to yield the highly reactive methyl diazonium cation. It causes only modest myelosuppression from 21 to 25 days after a dose but causes prominent nausea on day 1.

Cisplatin was discovered fortuitously by observing that bacteria present in electrolysis solutions could not divide. Only the cis diamine configuration is active as an antitumor

agent. It is hypothesized that in the intracellular environment, a chloride is lost from each position, being replaced by a water molecule. The resulting positively charged species is an efficient bifunctional interactor with DNA, forming Pt-base cross-links. Cisplatin requires administration with adequate hydration, including forced diuresis with mannitol to prevent kidney damage; even with the use of hydration, gradual decrease in kidney function is common. Hypomagnesemia frequently attends cisplatin use and can lead to hypocalcemia and symptomatic tetany. Other common toxicities include neurotoxocity with "stocking and glove" sensorimotor neuropathy. Hearing loss occurs in 50% of patients treated with conventional doses. Cisplatin is intensely emetogenic, requiring prophylactic antinausea agents. Myelosuppression is less evident than with other alkylating agents. Chronic vascular toxicity is a more unusual toxic phenomena, including Raynaud's syndrome and coronary artery disease. In an effort to obviate these toxicities, carboplatin was developed and clearly displays less nephro-, oto- and neurotoxicity. However, myelosuppression is more frequent, and as the drug is exlusively cleared through the kidney, adjustment of dose for creatinine clearance must be accomplished through use of various dosing nomograms.

Antitumor Antibiotics and Topoisomerase Poisons Antitumor antibiotics are substances produced by bacteria that in nature appear to provide chemical defense against other hostile microorganisms. As a class they bind to DNA directly and can frequently undergo electron transfer reactions to generate free radicals in close proximity to DNA, leading to DNA damage in the form of single strand breaks or cross-links. *Topoisomerase poisons* include natural products or semi-synthetic species derived ultimately from plants, and they modify enzymes that regulate the capacity of DNA to unwind to allow normal replication or transcription.

Doxorubicin is the most widely active and frequently used antineoplastic agent. It can intercalate into DNA, thereby altering DNA structure, replication, and topoisomerase function. It can also undergo redox cycling by accepting electrons into its quinone ring system. It causes predictable myelosuppression, alopecia, nausea, and mucositis. In addition, it causes acute cardiotoxicity in the form of atrial and ventricular dysrhythmias, but these are rarely of clinical significance. In contrast, cumulative doses >550 $mg/m_2$are associated with a 10% incidence of chronic cardiomyopathy. The incidence of cardiomyopathy appears to be related to schedule (peak serum concentration), with low dose, frequent treatment, or continuous infusions better tolerated than intermittent higher dose exposures. Radiation recall or interaction with radiation to cause local site complications is frequent. The drug is a powerful vesicant, with necrosis of tissue apparent 4 to 7 days after an extravasation; therefore it should be administered into a rapidly flowing intravenous line. The drug is metabolized by the liver, so doses must be reduced by 50 to 75% in the presence of liver dysfunction. Daunorubicin is closely related to doxorubicin and was actually introduced first into leukemia treament, where it remains part of curative regimens and has been shown preferable to doxorubicin owing to less mucositis and colonic damage. Idarubicin is an orally acting doxorubicin analogue, whose ultimate place in therapy is uncertain.

Bleomycin refers to a mixture of glycopeptides that have the unique feature of forming complexes with Fe^{2+}while bound to DNA. Oxidation gives rise to superoxide and hydroxyl radicals. The drug is of interest clinically as it causes little, if any, myelosuppression. The drug is cleared rapidly, but augmented skin and pulmonary

toxicity in the presence of renal failure has led to the recommendation that doses be reduced by 50 to 75% in the face of a creatinine clearance<25 mL/min. Bleomycin is not a vesicant, and can be administered intravenously, intramuscularly, or subcutaneously. Common side effects include fever and chills, facial flush, and Raynaud's syndrome. Hypertension can follow rapid intravenous administration, and the incidence of anaphylaxis with early preparations of the drug has led to the practice of administering a test dose of 0.5 to 1 unit before the rest of the dose. The most feared complication of bleomycin treatment is pulmonary fibrosis, which increases in incidence at >300 cumulative units administered and is at best minimally responsive to treatment (e.g., glucocorticoids). The earliest indicator of an adverse effect is a decline in the DL_{CO}, although cessation of drug immediately upon documentation of a decrease in DL_{CO} may not prevent further decline in pulmonary function. Bleomycin is inactivated by a bleomycin hydrolase, whose concentration is diminished in skin and lung. Because bleomycin-dependent electron transport is dependent on O_2, bleomycin toxicity may become apparent after exposure to transient very high inspired P_{O2}. Thus, during surgical procedures, patients with prior exposure to bleomycin should be maintained on the lowest inspired P_{O2}consistent with maintaining adequate tissue oxygenation.

D-Actinomycin intercalates into DNA and appears to have less, but not absent, capacity to undergo electron transfer reactions. It causes severe myelosuppression, nausea, alopecia, and mucositis. It is a notable vesicant. Mithramycin historically was used against testicular and other neoplasms; however, in addition to causing nausea, myelosuppression, and vesicant properties, it causes an "acute hemorrhagic syndrome" consisting of platelet function defects in association with indicators of disseminated intravascular coagulation. It is used in current practice to control hypercalcemia. In addition, renal and hepatic dysfunction may complicate its use.

Mitomycin C undergoes reduction of its quinone function to generate a bifunctional DNA alkylating agent. It is a broadly active antineoplastic agent with a number of unpredictable toxicities, including delayed bronchospasm 12 to 14 h after dosing and a chronic pulmonary fibrosis syndrome more frequent at doses of 50 to 60 mg/m_2. Cardiomyopathy has been described, particularly in the setting of prior radiation therapy. A hemolytic-uremic syndrome carries an ultimate mortality rate of 25 to 50% and is poorly treated by conventional component support and exchange transfusion. Mitomycin is a notable vesicant and causes substantial nausea and vomiting. It can be used for intravesical instillation for curative treatment of superficial transitional bladder carcinomas and, with radiation therapy, for curative treatment of anal carcinoma.

Mitoxantrone is a synthetic compound that was designed to recapitulate features of doxorubicin but with less cardiotoxicity. It is quantitatively less cardiotoxic (comparing the ratio of cardiotoxic to therapeutically effective doses), but its status in therapy is unclear as doses of 150 mg/$m_2$have produced evidence of 10% incidence of cardiotoxicity; it also causes alopecia.

Etoposide was synthetically derived from the plant product podophyllotoxin, and it binds directly to topoisomerase II and DNA in a reversible ternary complex. In that capacity, it stabilizes the covalent intermediate in the enzyme's action where the enzyme is covalently linked to DNA. This "alkali-labile" DNA bond was historically a first hint that an activity such as topoisomerase exists. The drug therefore causes a prominent G2 arrest,

reflecting the action of a DNA damage checkpoint. Prominent clinical effects include myelosuppression, nausea, and transient hypotension related to the speed of administration of the agent. Etoposide is a mild vesicant but is relatively free from other "large organ" toxicities. Teniposide is a structural relative with unique activity in childhood lymphoblastic leukemia. When given at high doses or very frequently, topoisomerase inhibitors may cause acute leukemia associated with chromosome 11q23 abnormalities in up to 1% of exposed patients.

Camptothecin was isolated from extracts of a Chinese tree and had notable antileukemia activity. Early clinical studies with the sodium salt of the hydrolyzed camptothecin lactone showed evidence of notable toxicity with little activity. Identification of topoisomerase I as the target of camptothecins and the need to preserve lactone structure allowed additional efforts to identify active members of this series. Topoisomerase I is responsible for unwinding the DNA strand by introducing single strand breaks and allowing rotation of one strand about the other. In S phase, topoisomerase I-induced breaks that are not promptly resealed lead to progress of the replication fork off the end of a DNA strand. The DNA damage is a potent signal for induction of apoptosis. Camptothecins promote the stabilization of the DNA linked to the enzyme in a so-called cleavable complex, analogous to the action of etoposide with topisomerase II. Topotecan is a camptothecin derivative approved for use in ovarian tumors. Toxicity is limited to myelosuppression and mucositis. CPT-11, or irinotecan, is a camptothecin with evidence of activity in colon carcinoma. In addition to myelosuppression, it causes a secretory diarrhea, which can be treated effectively with loperamide or octreotide.

Indirect Effectors of DNA Function: Antimetabolites A broad definition of antimetabolites would include compounds with structural similarity to precursors of purines or pyrimidines or that interfere with purine or pyrimidine synthesis. Antimetabolites can cause DNA damage indirectly, through misincorporation into DNA, abnormal timing or progression through DNA synthesis, or altered function of pyrimidine and purine biosynthetic enzymes. They tend to convey greatest toxicity to cells in S phase, and the degree of toxicity increases with duration of exposure. Common toxic manifestations include stomatitis, diarrhea, and myelosuppression. Second malignancies are not associated with their use.

Methotrexate inhibits dihydrofolate reductase, which regenerates reduced folates from the oxidized folates produced when thymidine monophosphate is formed from deoxyuridine monophosphate. Without reduced folates, cells die a "thymineless" death. N_5tetrahydrofolate or N_5formyltetrahydrofolate (leucovorin) can bypass this block and rescue cells from methotrexate, which is maintained in cells by polyglutamylation. The drug and other reduced folates are transported into cells by the folate carrier, and high concentrations of drug can bypass this carrier and allow diffusion of drug directly into cells. These properties have suggested the design of "high-dose" methotrexate regimens with leucovorin rescue of normal marrow and mucosa, part of curative approaches to osteosarcoma in the adjuvant setting, and hematopoietic neoplasms of children and adults. Methotrexate is cleared by the kidney by both glomerular filtration and tubular secretion, and toxicity is augmented by renal dysfunction and drugs such as salicylates, probenecid, and nonsteroidal anti-inflammatory agents that undergo tubular secretion. With normal renal function, 15 mg/$m_2$leucovorin will rescue $10^{-8}$to 10^{-6}*M*

methotrexate in three to four doses. However, with decreased creatinine clearance, doses of 50 to100 mg/$m^2$are continued until methotrexate levels are $<5\acute{}10^{-8}M$. In addition to bone marrow suppression and mucosal irritation, methotrexate can cause renal failure itself at high doses owing to crystallization in renal tubules; therefore high-dose regimens require alkalinization of urine with increased flow by hydration. Methotrexate can be sequestered in third space collections and leech back into the general circulation, causing prolonged myelosuppression. Less frequent adverse effects include reversible increases in transaminases and a hypersensitivity-like pulmonary syndrome. Chronic low-dose methotrexate can cause hepatic fibrosis. When administered to the intrathecal space, methotrexate can cause chemical arachnoiditis andCNSdysfunction. Trimetrexate is a methotrexate derivative that is not polyglutamylated and does not use the reduced folate carrier.

5-Fluorouracil (5FU) represents an early example of "rational" drug design in that it originated from the observation that tumor cells incorporate uracil more efficiently into DNA than normal cells, especially gut. 5FU is metabolized in cells to 5¢FdUMP, which inhibits thymidylate synthetase (TS). In addition, misincorporation can lead to single strand breaks, and RNA can aberrantly incorporate FUMP. 5FU is metabolized by dihydropyrimidine dehydrogenase, and deficiency of this enzyme can lead to excessive toxicity from 5FU. Oral bioavailability varies unreliably. Intravenous administration leads to bone marrow suppression after short infusions but to more evidence of stomatitis after prolonged infusions. Leucovorin augments the toxicity and activity of 5FU by promoting formation of the ternary covalent complex of 5FU, the reduced folate, and TS. Less frequent toxicities includeCNSdysfunction, with prominent cerebellar signs, and endothelial toxicity manifested by thrombosis, including pulmonary embolus and myocardial infarction.

Cytosine arabinoside (ara-C) is incorporated into DNA after formation of ara-CTP, resulting in S phase-related toxicity. Continuous infusion schedules allow maximal efficiency of effect, with uptake maximal at 5 to 7 u*M*. Ara-C can be administered intrathecally. Adverse effects include nausea, diarrhea, stomatitis, chemical conjunctivitis, and cerebellar ataxia. Gemcitabine is a cytosine derivative that is similar to ara-C in that it is incorporated into DNA after anabolism to the triphosphate, rendering DNA susceptible to breakage and repair synthesis, which differs from that in ara-C in that lesions including the analogue are very inefficiently removed. In contrast to ara-C, gemcitabine appears to have useful activity in a variety of solid tumors, with limited nonmyelosuppressive toxicities. 6-Thioguanine and 6-mercaptopurine (6MP) are used in the treatment of acute lymphoid leukemia. Although administered orally, they display very variable bioavailability. 6MP is metabolized by xanthine oxidase and therefore requires dose reduction when used with allopurinol.

Fludarabine phosphate is a prodrug of F-ara-A, which in turn was designed to diminish the susceptibility of ara-A to adenosine deaminase. Ara-A is incorporated into DNA and can cause delayed cytotoxicity even in cells with low growth fraction, including chronic lymphocytic leukemia and follicular B cell lymphoma.CNSdysfunction and T cell depletion leading to opportunistic infections can occur in addition to myelosuppression. 2-Chlorodeoxyadenosine is a similar compound with activity in hairy cell leukemia. 2-Deoxycoformycin inhibits adenosine deaminase, with resulting increase in dATP levels. This causes inhibition of ribonucleotide reductase as well as augmented

susceptibility to apoptosis, particularly in T cells. Renal failure and CNS dysfunction are notable toxicities in addition to immunosuppression.

Hydroxyurea inhibits ribonucleotide reductase, resulting in S phase block. It is orally bioavailable and the drug of choice for the acute management of myeloproliferative states. Asparaginase is not classically considered an antimetabolite as it causes breakdown of extracellular asparagine required for protein synthesis in certain leukemic cells. However, it effectively stops DNA synthesis by preventing the requisite concurrent protein synthesis, and therefore it has a similar functional outcome as the classic antimetabolites. As asparaginase is a foreign protein, hypersensitivity reactions are common, as are effects on organs such as pancreas and liver that require continuing protein synthesis. This results in decreased insulin secretion with hyperglycemia, with or without hyperamylasemia and clotting function abnormalities. The latter may be associated withCNS and dural vein thrombosis.

Mitotic Spindle Inhibitors Microtubules are cellular structures that form the mitotic spindle and in interphase cells are responsible for the cellular "scaffolding" along which various motile and secretory processes occur. Microtubules are composed of repeating noncovalent multimers of a hetrodimer ofa and b subunits of the protein tubulin. Vincristine binds to the tubulin dimer with the result that microtubules are disaggregated. This results in the block of growing cells in M phase; however, toxic effects in G1 and S phase are also evident. The drug is bound to blood-formed elements, leading to its occasional use as vinca-loaded platelets to treat autoimmune thrombocytopenia. The drug is metabolized by the liver, and dose adjustment in the presence of hepatic dysfunction is required. It is a powerful vesicant, and infiltration can be treated by local heat and infiltration with hyaluronidase. The drug is lethal if inadvertantly administered by the intrathecal route. At clinically used intravenous doses, neurotoxicity in the form of glove-and-stocking neuropathy is frequent. Children tolerate 2 mg/m_2, but adult doses may be capped at 2 mg total to lower the incidence of disabling chronic neuropathy; whether this compromises needed dose intensity in curative regimens is uncertain. Acute neuropathic effects include jaw pain, paralytic ileus, urinary retention, and the syndrome of inappropriate antidiuretic hormone secretion. Myelosuppression is not seen. Vinblastine is similar to vincristine, except that it tends to be more myelotoxic, with more frequent thrombocytopenia and also mucositis and stomatitis. Vinorelbine is a recently introduced vinca alkaloid that appears to have differences in resistance patterns in comparison to vincristine and vinblastine; it may be administered orally.

The taxanes include paclitaxel and docetaxel. These agents differ from the vinca alkaloids in that the taxanes stabilize microtubules against depolymerization. The "stabilized" microtubules function abnormally and are not able to undergo the normal dynamic changes of microtubule function necessary for cell cycle completion. Taxanes are among the most broadly active antineoplastic agents for use in solid tumors, with evidence of activity in ovarian cancer, breast cancer, Kaposi's sarcoma, and lung tumors. They are administered intravenously, and paclitaxel requires use of a cremophore-containing vehicle that can cause hypersensitiviy reactions. Premedication with regimens including dexamethasone (20 mg orally or intravenously 12 and 6 h before treatment), diphenhydramine (50 mg), and cimetidine (300 mg) both 30 min before treatment decreases but does not eliminate the risk of hypersensitivity reactions to the paclitaxel vehicle. Docetaxel uses a polysorbate 80 formulation, which can cause

fluid retention in addition to hypersensitivity reactions, and dexamethasone premedication with or without antihistamines is frequently used. Paclitaxel causes hypersensitivity reactions, myelosuppression, neurotoxicity in the form of glove-and-stocking numbness, and paresthesia. Cardiac rhythm disturbances were observed in phase I and II trials, most commonly asymptomatic bradycardia but, much more rarely, varying degrees of heart block. These have not emerged as clinically significant in the majority of patients. Infrequently occurring evidence of myocardial ischemia during paclitaxel administration cannot yet be clearly related to the drug. Docetaxel causes comparable degrees of myelosuppression and neuropathy. Hypersensitivity reactions, including bronchospasm, dyspnea, and hypotension, are less frequent but occur to some degree in up to 25% of patients. Fluid retention appears to result from a vascular leak syndrome that can aggravate preexisting effusions. Rash can complicate docetaxel administration, appearing prominently as a pruritic maculopapular rash affecting the forearms, but it has also been associated with fingernail ridging, breakdown, and skin discoloration. Stomatitis appears to be somewhat more frequent than with paclitaxel.

Estramustine was originally synthesized as a mustard derivative that might be useful in neoplasms that possessed estrogen receptor sites. However, no evidence of interaction with DNA was observed. Surprisingly, the drug caused metaphase arrest, and subsequent study revealed that it binds to microtubule-associated proteins, resulting in abnormal microtubule function. Estramustine binds to estramustine-binding proteins (EMBP), which have particular presence in prostate tumor tissue. The drug is approved for treatment of metastatic prostate cancer as an oral formulation. Gastrointestinal and cardiovascular adverse effects related to the estrogen moiety occur in up to 10% of patients, including worsened heart failure and thromboembolic phenomena. Gynecomastia and nipple tenderness can also occur.

Hormonal Agents The family of steroid hormone receptor-related molecules have emerged as prominent targets for "small molecules" useful in cancer treatment. When bound to their cognate ligands, these receptors can alter gene transcription and, in certain tissues, induce apoptosis. The pharmacologic effect is a mirror or parody of the normal effects of the agent acting in nontransformed tissue, although the effects on tumors are mediated by indirect effects in some cases.

Glucocorticoids are generally given in "pulsed" high-dose exposure in leukemias and lymphomas, where they induce apoptosis in tumor cells. Cushing's syndrome or inadvertent adrenal suppression on withdrawal from high-dose glucocorticoids can be significant complications, along with infections common in immunosuppressed patients, in particular *Pneumocystis* pneumonia, which classically appears a few days after completing a course of high-dose steroids. Tamoxifen is a partial estrogen receptor antagonist; it has a tenfold greater degree of antitumor activity in breast cancer patients whose tumors express estrogen receptors than in those who have low or no levels of expression. Side effects include a somewhat increased risk of estrogen-related cardiovascular complications, such as thromboembolic phenomena, and a small increased incidence of endometrial carcinoma, which appears after chronic use. Progestational agents including medroxyprogesterone acetate, androgens including halotestin, and, paradoxically, estrogens have approximately the same degeree of activity in primary hormonal treatment of breast cancers that have elevated levels of

estrogen receptors. Estrogen is not used often owing to prominent cardiovascular and uterotropic activity.

Prostate cancer is classically treated by diethylstilbesterol (DES) acting as an estrogen at the level of the hypothalamus to downregulate hypothalamic luteinizing hormone (LH) production, resulting in decreased elaboration of testosterone by the testicle. For this reason, orchiectomy is equally as effective as moderate-dose DES, inducing responses in ~80% of previously untreated patients with prostate cancer but without the prominent cardiovascular side effects of DES, including thrombosis and exacerbation of coronary artery disease. In the event that orchiectomy is not accepted by the patient, testicular androgen suppression can also be effected by luteinizing hormone-releasing hormone (LHRH) agonists such as leuprolide and goserelin. These agents cause tonic stimulation of the LHRH receptor, with the loss of its normal pulsatile activation resulting in its desensitization and decreased output of LH by the anterior pituitary. Therefore, as primary hormonal manipulation in prostate cancer one can choose orchiectomy or leuprolide, not both. The addition of actual antagonists of androgens acting at the androgen receptor, including flutamide or bicalutamide, is of uncertain additional benefit in extending overall response duration, but it clearly prevents the activation of androgen receptors by adrenal androgens, and the combined use of orchiectomy or leuprolide plus flutamide is referred to as "total androgen blockade."

Interestingly, tumors that respond to a primary hormonal manipulation may frequently respond to second and third hormonal manipulations. Thus, breast tumors that had previously responded to tamoxifen have, on relapse, notable response rates to withdrawal of tamoxifen itself or to subsequent addition of a progestin. Likewise, initial treatment of prostate cancers with leuprolide plus flutamide may be followed after disease progression by response to withrawal of flutamide. These responses may result from the removal of antagonists from mutant steroid hormone receptors that have come to depend on the presence of the antagonist as a growth-promoting influence.

Additional strategies to treat refractory breast and prostate cancers that possess steroid hormone receptors may also address adrenal capacity to produce androgens and estrogens, even after orchiectomy or oophorectomy, respectively. Thus, aminoglutethimide or ketoconazole can be used to block adrenal synthesis by interfering with the enzymes of steroid hormone metabolism. Administration of these agents requires concomitant hydrocortisone replacement and additional glucocorticoid doses administered in the event of physiologic stress. Steroid hormone-inducing "aromatase" activity may be present in tumor tissue, and second- or third-line approaches to inhibition of aromatase activity may also be effected by such agents as anastrazole and letrozole.

Humoral mechanisms can also result in complications of an underlying malignancy. Adrenocortical carcinomas can cause Cushing's syndrome as well as syndromes of androgen or estrogen excess. Mitotane can counteract these by decreasing synthesis of steroid hormones. Islet cell neoplasms can cause debilitating diarrhea, treated with the somatostatin analogue octreotide. Prolactin-secreting tumors can be effectively managed by the dopaminergic agononist bromocriptine.

An additional strategy related conceptually to the use of steroid hormones is the use of

retinoids, including tretinoin, the all-*trans*-isomer of retinoic acid, or isotretinoin, the 13-*cis* isomer of retinoic acid, to cause "differentiation" by acting on the retinoid receptor, which is in the steroid hormone receptor family. In particular, tretinoin is part of curative regimens for acute promyelocytic leukemia (PML) and appears to act by causing accelerated degradation of the fusion protein created by the t(15;17) translocation fusing the retinoic acid receptor a and the PML transcription factor. Acute side effects related to differentiation of promyelocytes to mature granulocytes may result in pulmonary symptoms related to granulocyte sequestration in the pulmonary vasculature; these are treated by respiratory support and glucocorticoids. Squamous neoplasms, including those of the skin and cervix, also appear to be uniquely responsive in certain cases to retinoids.

ACUTE COMPLICATIONS OF CANCER CHEMOTHERAPY

Myelosuppression The common cytotoxic chemotherapeutic agents almost invariably affect bone marrow function. Titration of this effect determines in many cases the MTD of the agent on a given schedule. The normal kinetics of blood cell turnover influence the sequence and sensitivity of each of the formed elements. Polymorphonuclear leukocytes (PMNs; $T_{1/2}$= 6 to 8 h), platelets ($T_{1/2}$= 5 to 7 days), and red blood cells (RBC; $T_{1/2}$~ 120 days) have most, less, and least susceptibility to usually administered cytotoxic agents, respectively. The *nadir count* of each cell type in response to classes of agents is characteristic. Maximal neutropenia occurs 6 to 14 days after conventional doses of anthracyclines, antifolates, and antimetabolites. Alkylating agents differ in timing of cytopenias. Nitrosoureas, DTIC, and procarbazine can display delayed marrow toxicity, first appearing 6 weeks after dosing.

Complications of myelosuppression result from the predictable sequelae of the missing cells' function. *Febrile neutropenia* refers to the clinical presentation of fever (one temperature³38.5°C or three readings ³38°C but£38.5°C per 24 h) in a cytopenic patient with an uncontrolled neoplasm involving the bone marrow or, more usually, in a patient undergoing treatment with cytotoxic agents. Mortality from uncontrolled infection varies inversely with thePMNcount. If the nadir PMN count is >1000/uL, there is little risk; if <500/uL, risk of death is markedly increased. Management of febrile neutropenia has conventionally included empirical coverage with antibiotics for the duration of neutropenia (Chap. 85). Selection of antibiotics is governed by the expected association of infections with certain underlying neoplasms; careful physical examination (with scrutiny of catheter sites, dentition, mucosal surfaces, and perirectal and genital orifices by gentle palpation); chest x-ray; and Gram stain and culture of blood, urine and sputum (if any) to define a putative site of infection. In the absence of any originating site, a broadly acting b-lactam with anti-*Pseudomonas* activity, such as ceftazidime, is begun empirically. The addition of vancomycin to cover potential cutaneous sites of origin (until these are ruled out or shown to originate from methicillin-sensitive organisms) or metronidazole or imipenem for abdominal or other sites favoring anaerobes reflects modifications tailored to individual patient presentations. The coexistence of pulmonary compromise raises a distinct set of potential pathogens, including *Legionella*, *Pneumocystis*, and fungal agents, that may require further diagnostic evaluations such as bronchoscopy with bronchoalveolar lavage. Febrile neutropenic patients can be stratified broadly into two prognostic groups. The first, with expected short duration of neutropenia and no evidence of hypotension or abdominal or other localizing symptoms,

may be expected to do well even with less complex, oral regimens, e.g., ciprofloxacin plus amoxicillin/clavulinic acid. Detailed evaluation of such simple oral programs and intravenous regimens is ongoing. A less favorable prognostic group are patients with expected prolonged neutropenia, evidence of sepsis, and end-organ compromise, particularly pneumonia. These patients clearly require tailoring of their antibiotic regimen to their underlying presentation, with frequent empirical addition of antifungal agents if fever persists for 7 days without identification of an adequately treated organism or site.

Transfusion of granulocytes has no role in the management of febrile neutropenia, owing to their exceedingly short half-life, mechanical fragility, and clinical syndromes of pulmonary compromise with leukostasis after their use. Instead, *colony stimulating factors* (CSFs) are used to augment bone marrow production ofPMNs. These include "early-acting" factors such asIL-1, IL-3, and stem cell factor, which act on multiple lineages, and "late-acting" lineage-specific factors such as G-CSF (granulocyte colony stimulating factor) or GM-CSF (granulocyte-macrophage colony stimulating factor), erythropoietin, thrombopoietin, IL-6, and IL-11. CSFs are overused in oncology practice. The settings in which their use has been proven effective are limited. G-CSF, GM-CSF, erythropoietin, and IL-11 are currently approved for use. The American Society of Clinical Oncology has developed practice guidelines for the use of G-CSF and GM-CSF (Table 84-3). Primary administration (i.e., shortly after completing chemotherapy to reduce the nadir) of G-CSF to patients receiving cytotoxic regimens associated with a 40% incidence of febrile neutropenia has reduced the incidence of febrile neutropenia in several studies by about 50%. Most patients, however, receive regimens that do not have such a high risk of expected febrile neutropenia, and therefore most patients initially should not receive G-CSF or GM-CSF. Special circumstances such as a documented history of febrile neutropenia with the regimen in a particular patient; extensive compromise of marrow by prior radiation or chemotherapy; or active, open wounds or deep-seated infection may support primary treatment with G-CSF or GM-CSF. Administration of G-CSF or GM-CSF to afebrile neutropenic patients or to patients with "low-risk" febrile neutropenia (secondary administration, use after neutropenia has developed) as defined above is not recommended, although administration to "high-risk" patients with febrile neutropenia and evidence of organ compromise is reasonable. G-CSF or GM-CSF is conventionally started 24 to 72 h after completion of chemotherapy and continued until a PMN count of 10,000/uL is achieved. Also, patients with myeloid leukemias undergoing induction therapy may have a slight reduction in the duration of neutropenia if G-CSF (not GM-CSF) is commenced after completion of therapy and may be of particular value in elderly patients, but the influence on long-term outcome has not been defined. GM-CSF probably has a more restricted utility than G-CSF, with its use currently limited to patients after autologous bone marrow transplants, although proper "head-to-head" comparisons with G-CSF have not been conducted in most instances. GM-CSF may be associated with more systemic side effects.

Dangerous degrees of thrombocytopenia do not frequently complicate the management of patients with solid tumors receiving cytotoxic chemotherapy (carboplatin-containing regimens are frequently involved), but they are frequent in patients with certain hematologic neoplasms where marrow is infiltrated with tumor. Severe bleeding related to thrombocytopenia occurs with increased frequency at platelet counts<20,000/uL and is very prevalent at counts<5000/uL. Prophylactic transfusions to keep platelets

>20,000/uL are warranted in patients with leukemia (the threshold for transfusion is 10,000/uL in patients with solid tumors and no other bleeding diathesis). Careful review of medication lists to prevent exposure to nonsteroidal anti-inflammatory agents and maintenance of clotting factor levels adequate to support near-normal prothrombin and partial thromboplastin time tests are of import in minimizing the risk of bleeding in the thrombocytopenic patient. Certain cytokines in clinical investigation have shown ability to increase platelets (e.g.,IL-6, IL-1, thrombopoietin), but clinical benefit and safety are not yet proven. IL-11 (oprelvekin) is approved for use in the setting of expected thrombocytopenia, but its effects on platelet counts are small and it is associated with side effects such as headache, fever, malaise, syncope, cardiac arrhythmias, and fluid retention.

Anemia associated with chemotherapy can be managed by transfusion of packedRBCs. Transfusion is not undertaken until the hemoglobin falls to<80 g/L (8 g/dL), or if compromise of end-organ function occurs or an underlying condition (e.g., coronary artery disease) calls for maintenance of hemoglobin >90 g/L (9 g/dL). Patients who are to receive therapy for >2 months on a "stable" regimen and who are likely to require continuing transfusions are also candidates for erythropoietin to maintain hemoglobin of 90 to 100 g/L (9 to 10 g/dL). In the setting of adequate iron stores and serum erythropoietin levels<100 ng/mL, erythropoietin, 150 U three times a week, can produce a slow increase in hemoglobin over about 2 months of administration. Quality of life is better at higher hemoglobin concentrations, but expense is a concern with erythropoietin use.

Nausea and Vomiting The most common side effect of chemotherapy administration is nausea, with or without vomiting. Antineoplastic agents vary in their capacity to cause nausea and vomiting. Nitrogen mustard, nitrosoureas, streptozotocin, DTIC, cisplatin, and actinomycin are highly emetogenic and produce vomiting in virtually all patients. Doxorubicin, daunorubicin, and conventional-dose cyclophosphamide are moderately emetogenic. Antimetabolites are dose- and schedule-dependent, with single doses of methotrexate and fluorouracil producing at worst anorexia; while 5-day regimens of 5-fluorouracil and high-dose methotrexate produce nausea in ~50% of patients. Other agents such as chlorambucil, melphalan, and busulfan in conventional doses produce little tendency to emesis.

Emesis is a reflex caused by stimulation of the vomiting center in the medulla. Input to the vomiting center comes from the chemoreceptor trigger zone (CTZ) and afferents from the peripheral gastrointestinal tract, cerebral cortex, and heart. In addition, a conditioned reflex may contribute to anticipatory nausea arising after repeated cycles of chemotherapy. Accordingly, antiemesis agents differ in their locus of action. Combining agents from different classes or the sequential use of different classes of agent is the cornerstone of successful management of chemotherapy-induced nausea and vomiting. Of great importance are the prophylactic administration of agents and the use of psychological techniques including the maintenance of a supportive milieu, counseling, and relaxation to augment the action of antiemetic agents.

Antidopaminergic phenothiazines act directly at theCTZ, and include prochlorperazine (Compazine), 10 mg intramuscularly or intravenously, 10 to 25 mg orally, or 25 mg per rectum every 4 to 6 h for up to four doses; and thiethylperazine (Torecan), 10 mg by all

the above routes every 6 h. Haloperidol (Haldol) is a butyrophenone dopamine antagonist given at 0.5 to 1.0 mg intramuscularly or orally every 8 h. Antihistamines such as diphenhydramine (Benadryl) have little intrinsic antiemetic capacity but are frequently given to prevent or treat dystonic reactions that can complicate use of the antidopaminergic agents. Lorazepam (Ativan) is a short-acting benzodiazepine that provides an anxiolytic effect to augment the effectiveness of a variety of agents when used at 1 to 2 mg intramuscularly, intravenously, or orally every 4 to 6 h. Dexamethasone (Decadron) likewise augments the action of a variety of agents when used at 4 to 40 mg intravenously or orally, given before treatment and repeated up to 10 mg orally every 6 h four times. Metoclopramide (Reglan) acts on peripheral dopamine receptors to augment gastric emptying and is used in high doses for highly emetogenic regimens (1 to 2 mg/kg intravenously 30 min before chemotherapy and every 2 h for up to three additional doses as needed); intravenous doses of 10 to 20 mg every 4 to 6 h as needed or 50 mg orally 4 h before and 8 and 12 h after chemotherapy are used for moderately emetogenic regimens. Serotonin antagonists are useful in moderately to severely emetogenic regimens; ondansetron (Zofran) is given as 0.15 mg/kg intravenously for three doses just before and at 4 and 8 h after chemotherapy, and granisetron (Kytril) is given as a single dose of 0.01 mg/kg just before chemotherapy.d-9-Tetrahydrocannabinol (Marinol) is a rather weak antiemetic compared to other available agents, but it may be useful for persisting nausea and is used orally at 10 mg every 3 to 4 h as needed.

Alopecia Chemotherapeutic agents vary widely in causing alopecia, with anthracyclines, alkylating agents, and topoisomerase inhibitors reliably causing near total alopecia when given at therapeutic doses. Antimetabolites are more variably associated with alopecia. Psychologic support and the use of cosmetic resources are to be encouraged, and "chemo caps" that reduce scalp temperature to decrease the degree of alopecia should be discouraged.

Gonadal Dysfunction and Pregnancy Cessation of ovulation and azoospermia reliably result from alkylating agent- and topoisomerase poison-containing regimens. The duration of these effects varies with age and sex. Males treated for Hodgkin's disease with mechlorethamine- and procarbazine-containing regimens are effectively sterile, while fertility usually returns after regimens including cisplatin, vinblastine or etoposide, and bleomycin for testicular cancer. Sperm banking before treatment may be considered to support patients likely to be sterilized by treatment. Females experience amenorrhea with anovulation after alkylating agent therapy but are likely to recover normal menses if treatment is completed before age 30 and unlikely to recover menses after age 35. Even those who regain menses usually experience premature menopause. As the magnitude and extent of decreased fertility can be difficult to predict, patients should be counseled to maintain effective contraception, preferably by barrier means, during and after therapy. Resumption of efforts to conceive should be considered in the context of the likely prognosis of the patient. Hormone-replacement therapy should be undertaken in women who do not have a hormonally responsive tumor.

Chemotherapy agents have variable effects on the success of pregnancy (Chap. 7). All agents tend to have increased risk of adverse outcomes when administered during the first trimester, and strategies to delay chemotherapy if possible until after this milestone should be considered if the pregnancy is to continue to term. Patients in their second or

third trimester can be treated with most regimens for the common neoplasms afflicting women in their child-bearing years with the exception of antimetabolites, particularly antifolates, which have notable teratogenic or fetotoxic effects throughout pregnancy. The need for anticancer chemotherapy per se is infrequently a clear basis to recommend termination of a concurrent pregnancy, although each treatment strategy in this circumstance must be tailored to the individual needs of the patient.*Chronic effects of cancer treatment are reviewed in Chap. 103.*

BIOLOGIC THERAPY

No postulates resembling principles have emerged from efforts to develop biologic approaches to cancer treatment. The goal of biologic therapy is to manipulate the host-tumor interaction in favor of the host. Theoretically, biologic approaches should reflect a bell-shaped dose-response curve where the maximum biologic effect is less than the MTD. Empirical trial and error has led to the discovery that a number of biologic treatment approaches may produce antitumor effects, but nearly all of them are most active at their MTD.

IMMUNE MEDIATORS OF ANTITUMOR EFFECTS

The very existence of a cancer in a person is testimony to the failure of the immune system to deal effectively with the cancer. Tumors have a variety of means of avoiding the immune system: (1) they are often only subtly different from their normal counterparts; (2) they are capable of downregulating their major histocompatibility complex antigens, effectively masking them from recognition by T cells; (3) they are inefficient at presenting antigens to the immune system; (4) they can cloak themselves in a protective shell of fibrin to minimize contact with surveillance mechanisms; and (5) they can produce a range of soluble molecules, including potential immune targets, that can distract the immune system from recognizing the tumor cell. Some of the cell products initially polarize the immune response away from cellular immunity (shifting from Th1 to Th2 responses, Chap. 305) and ultimately lead to defects in T cells that prevent their activation and cytotoxic activity. Cancer treatment further suppresses host immunity. A variety of strategies are being tested to overcome these barriers.

Cell-Mediated Immunity The strongest evidence that the immune system can exert clinically meaningful antitumor effects comes from allogeneic bone marrow transplantation. Adoptively transferred T cells from the donor expand in the tumor-bearing host, recognize the tumor as being foreign, and mediate impressive antitumor effects (graft-versus-tumor effects). Three types of experimental interventions are being developed to take advantage of the ability of T cells to kill tumor cells.

1. Allogeneic T cells are being transferred to cancer-bearing hosts in three major settings: in the form of allogeneic bone marrow transplantation, as pure lymphocyte transfusions following bone marrow recovery after allogeneic bone marrow transplantation, and as pure lymphocyte transfusions following immunosuppressive (but not myeloablative) therapy (so-called minitransplants). In each of these settings, the effector cells are donor T cells that recognize the tumor as being foreign, probably through minor histocompatibility differences. The main risk of such therapy is the development of graft-versus-host disease because of the minimal difference between

the cancer and the normal host cells. This approach has been highly effective in hematologic cancers.

2. Autologous T cells are being removed from the tumor-bearing host, manipulated in several ways in vitro, and given back to the patient. The two major classes of autologous T cell manipulation are: (1) to develop tumor antigen-specific T cells and expand them to large numbers over many weeks ex vivo before administration, and (2) to activate the cells with polyclonal stimulators such as anti-CD3 and anti-CD28 after a short period ex vivo and try to expand them in the host after adoptive transfer with stimulation byIL-2, for example. Short periods removed from the patient permit the cells to overcome the tumor-induced T cell defects, and such cells traffic and home to sites of disease better than cells that have been in culture for many weeks. Individual centers have successful experiences with one or the other approach but not both, and whether one is superior to the other is not known.

3. Tumor vaccines are aimed at boosting T cell immunity. The finding that mutant oncogenes that are expressed only intracellularly can be recognized as targets of T cell killing greatly expanded the possibilities for tumor vaccine development. No longer is it difficult to find something different about tumor cells from normal cells. However, major difficulties remain in getting the tumor-specific peptides presented in a fashion to prime the T cells. Tumors themselves are very poor at presenting their own antigens to T cells at the first antigen exposure (*priming*). Priming is best accomplished by professional antigen-presenting cells (dendritic cells). Thus, a number of experimental strategies are aimed at priming host T cells against tumor-associated peptides. Vaccine adjuvants such asGM-CSFappear capable of attracting antigen-presenting cells to a skin site containing a tumor antigen. Such an approach has been documented to eradicate microscopic residual disease in follicular lymphoma and give rise to tumor-specific T cells. Purified antigen-presenting cells can be pulsed with tumor, its membranes, or particular tumor antigens and delivered as a vaccine. Tumor cells can be transfected with genes that attract antigen-presenting cells. Other ideas are also being tested. In a variation on the theme of adoptive transfer, the tumor vaccine may be given to the normal bone marrow and lymphoid cell donor of an allogeneic transplant so that the donor immune system has more cells capable of recognizing the tumor specifically. Vaccines against viral cancers (papillomavirus in cervical cancer), lymphomas, and melanomas have had modest clinical success.

Antibodies In general, antibodies are not very effective at killing cancer cells. Because the tumor seems to influence the host toward making antibodies rather than generating cellular immunity, it is inferred that antibodies are easier to defend against. Many patients can be shown to have serum antibodies directed at their tumors, but these do not appear to influence disease progression. However, the ability to grow very large quantities of high-affinity antibody directed at a tumor by the hybridoma technique has led to the application of antibodies to the treatment of cancer. The first study of a monoclonal antibody in cancer was published in 1980 and demonstrated many hurdles that needed to be overcome to make the approach successful. It seemed best to attack a determinant that was not shed or modulated by the tumor. A target that was involved in an important function for the tumor cells might be superior to a physiologically irrelevant target. Murine antibodies were not very effective because they did not mediate human effector mechanisms well and the host nearly always made antibodies against

the therapeutic antibody that prevented it from finding the target.

The lessons were learned; humanized antibodies against the CD20 molecule expressed on B cell lymphomas (rituximab) and against the HER-2/neu receptor overexpressed on epithelial cancers, especially breast cancer (herceptin), have become reliable tools in the oncologists armamentarium. Each used alone can cause tumor regression (rituximab> herceptin), and both appear to potentiate the effects of combination chemotherapy given just after antibody administration. It is likely that other antibodies against other important tumor targets will be available soon. Conjugation to drugs, toxins, isotopes, photodynamic agents, and other killing moieties may also be effective. Radioconjugates are the closest to approval. Other conjugates are associated with problems that have not yet been solved (e.g., antigenicity, instability, poor tumor penetration).

Cytokines There are>70 separate proteins and glycoproteins with biologic effects in humans:IFN-a, -b, -g;IL-1 through -18 (so far); the tumor necrosis factor (TFN) family [including lymphotoxin, TFN-related apoptosis-inducing ligand (TRAIL), CD40 ligand, and others]; and the chemokine family. Only a fraction of these has been tested against cancer; only IFN-a and IL-2 are in routine clinical use.

About 20 different genes encodeIFN-a, and their biologic effects are indistinguishable. Interferon induces the expression of many genes, inhibits protein synthesis, and exerts a number of different effects on diverse cellular processes. Its antitumor effects appear to be antagonized in vitro by thymidine, suggesting that de novo thymidylate synthesis is also affected. The two recombinant forms that are commercially available are IFN-a2a and -a2b. In general, interferon antitumor effects are dose-related, and IFN is most effective at itsMTD. Interferon is not curative for any tumor but can induce partial responses in follicular lymphoma, hairy cell leukemia, chronic myeloid leukemia, melanoma, and Kaposi's sarcoma. It has been used in the adjuvant setting in stage II melanoma, multiple myeloma, and follicular lymphoma. Its effects on survival are controversial. It produces fever, fatigue, a flulike syndrome, malaise, myelosuppression, and depression and can induce clinically significant autoimmune disease.

IL-2 must exert its antitumor effects indirectly through augmentation of immune function. Its biologic activity is to promote the growth and activity of T cells and natural killer (NK) cells. High doses of IL-2 can produce tumor regressions in ~20% of patients with metastatic melanoma and renal cell cancer. About 5% of patients may experience complete remissions that are durable, unlike any other treatment for these tumors. IL-2 is associated with myriad clinical side effects: intravascular volume depletion, capillary leak syndrome, adult respiratory distress syndrome, hypotension, fever, chills, skin rash, and impaired renal and liver function. Patients may require blood pressure support and intensive care to manage the toxicity. However, once the agent is stopped, most of the toxicities reverse completely within 3 to 6 days.

85. INFECTIONS IN PATIENTS WITH CANCER - *Robert Finberg*

Infections are a common cause of death and an even more common cause of morbidity in patients with a wide variety of neoplasms. Autopsy studies show that most deaths from acute leukemia and half of deaths from lymphoma are caused directly by infection. With more intensive chemotherapy, patients with solid tumors have become more likely to die of infection rather than their underlying disease.

A physical predisposition to infection (Table 85-1) can be a result of the neoplasm's production of a break in the skin; for example, a squamous cell carcinoma may cause local invasion of the epidermis, which allows bacteria to gain access to the subcutaneous tissue and permits the development of cellulitis. The artificial closing of a normally patent orifice can also predispose to infection: Obstruction of a ureter by a tumor can cause urinary tract infection, and obstruction of the bile duct can cause cholangitis. Part of the host's normal defense against infection depends on the continuous emptying of a viscus; without emptying, a few bacteria present as a result of bacteremia or local transit can multiply and cause disease.

A similar problem can affect patients whose lymph node integrity has been disrupted by radical surgery, particularly patients who have had radical node dissections. A common clinical problem following radical mastectomy is the development of cellulitis (usually caused by streptococci or staphylococci) because of lymphedema and/or inadequate lymph drainage. In most cases, this problem can be addressed by local measures designed to prevent fluid accumulation and breaks in the skin, but antibiotic prophylaxis has been necessary in refractory cases.

A life-threatening problem common to many cancer patients is the loss of the reticuloendothelial capacity to clear microorganisms after splenectomy. Splenectomy is common in patients with Hodgkin's disease and in the management of hairy cell leukemia, chronic lymphocytic leukemia (CLL), and refractory idiopathic thrombocytopenic purpura. Even after curative therapy for the underlying disease, the lack of a spleen predisposes such patients to rapidly fatal infections. The loss of the spleen through trauma similarly predisposes the normal host to overwhelming infection as long as 25 years after splenectomy. The splenectomized patient should be counseled about the risks of infection with certain organisms, such as the protozoan *Babesia* (Chap. 214) and *Capnocytophaga canimorsus* (formerly dysgonic fermenter 2 or DF-2), a bacterium carried in the mouths of animals (Chap. 127). Since encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) are the organisms most commonly associated with postsplenectomy sepsis, splenectomized persons should be vaccinated (and revaccinated; Table 85-2) against the capsular polysaccharides of these organisms. Many clinicians recommend giving splenectomized patients a small supply of antibiotics effective against *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* to avert rapid, overwhelming sepsis in the event that they cannot present for medical attention immediately after the onset of fever or other symptoms of bacterial infection.

The level of suspicion of infections with certain organisms should depend on the type of cancer diagnosed (Table 85-3). Diagnosis of multiple myeloma orCLLshould prompt the measurement of immunoglobulin levels and the consideration of either antibody

replacement or antibiotic prophylaxis. (In the case of CLL, antibiotic prophylaxis for likely pathogens has proven a cost-effective preventive measure.) Similarly, patients with acute lymphocytic leukemia (ALL), patients with non-Hodgkin's lymphoma, and all cancer patients treated with high-dose glucocorticoids (or glucocorticoid-containing chemotherapy regimens) should receive antibiotic prophylaxis for *Pneumocystis carinii* infection (Table 85-3).

In addition to exhibiting susceptibility to certain infectious organisms, patients with cancer are likely to manifest their infections in characteristic ways.

SYSTEM-SPECIFIC SYNDROMES

SKIN-SPECIFIC SYNDROMES (SEE PLATE IID-57)

Skin lesions are common in cancer patients, and their appearance may permit the diagnosis of systemic bacterial or fungal infection. While cellulitis caused by skin organisms such as *Streptococcus* or *Staphylococcus* is common, neutropenic patients and those with impaired blood or lymphatic drainage may develop infections with unusual organisms. Innocent-looking macules or papules may be the first sign of bacterial or fungal sepsis in immunocompromised patients. In the neutropenic host, a macule progresses rapidly to ecthyma gangrenosum (Fig. 19-CD1), a usually painless, round, necrotic lesion consisting of a central black or gray-black eschar with surrounding erythema. Ecthyma gangrenosum is located in nonpressure areas (as distinguished from necrotic lesions associated with lack of circulation) and is often associated with *Pseudomonas aeruginosa* bacteremia (Chap. 155) but may be caused by other bacteria.

Candidemia (Chap. 205) is also associated with a variety of skin conditions and commonly presents as a maculopapular rash. Punch biopsy of the skin may be the best method for diagnosis.

Cellulitis, an acute spreading inflammation of the skin, is most often caused by infection with group A *Streptococcus* or *Staphylococcus aureus*, virulent organisms normally found on the skin (Chap. 128). Although cellulitis tends to be circumscribed in normal hosts, it may spread rapidly in neutropenic patients [those with fewer than 500 functional polymorphonuclear leukocytes (PMNs) per microliter]. A tiny break in the skin may lead to spreading cellulitis, which is characterized by pain and erythema; in such patients, signs of infection (e.g., purulence) are often lacking. What might be a furuncle in a normal host may require amputation because of uncontrolled infection in a patient presenting with leukemia. A dramatic response to an infection that might be trivial in a normal host can mark the first sign of leukemia. Fortunately, granulocytopenic patients are likely to be infected with certain types of organisms (Table 85-4); thus the selection of an antibiotic regimen is somewhat easier than it might otherwise be. (See discussion below on the selection of antibiotics for use in neutropenic patients.) It is essential to recognize cellulitis early and to treat it aggressively. Patients who are neutropenic or have previously received antibiotics for other reasons may develop cellulitis with unusual organisms (e.g., *Escherichia coli*, *Pseudomonas*, or fungi). Early treatment, even of innocent-looking lesions, is essential to prevent necrosis and loss of tissue. Debridement to prevent spread may sometimes be necessary early in the course of

disease, but it can often be performed after chemotherapy, when thePMNcount increases.

Sweet's syndrome, or *febrile neutrophilic dermatosis*, was originally described in women with elevated white blood cell counts. The disease is characterized by the presence of leukocytes in the lower dermis, with edema of the papillary body. Ironically, this disease now is usually seen in neutropenic patients with cancer, most often in association with acute leukemia but also in association with a variety of other malignancies. Sweet's syndrome usually presents as red or bluish-red papules or nodules that may coalesce and form sharply bordered plaques. The edema may suggest vesicles, but on palpation the lesions are solid, and vesicles probably never arise in this disease. The lesions are most common on the face, neck, and arms. On the legs, they may be confused with erythema nodosum. The development of lesions is often accompanied by high fevers and an elevated erythrocyte sedimentation rate. Both the lesions and the temperature elevation respond dramatically to glucocorticoids. Treatment begins with high doses of glucocorticoids (60 mg of prednisone per day) followed by tapered doses over the next 2 to 3 weeks.

Data indicate that *erythema multiforme* with mucous membrane involvement is often associated with herpes simplex virus (HSV) infection and is distinct from Stevens-Johnson syndrome, which is associated with drugs and tends to have a more widespread distribution. Since cancer patients are both immunosuppressed (and therefore susceptible to herpes infections) and heavily treated with drugs (and therefore subject to Stevens-Johnson syndrome), both of these conditions are common in this population.

Cytokines, which are used as adjuvants or primary treatments for cancer, can themselves cause characteristic rashes, further complicating the differential diagnosis. This phenomenon is a particular problem in bone marrow transplant recipients (Chap. 136), who, in addition to having the usual chemotherapy-, antibiotic-, and cytokine-induced rashes, are plagued by graft-versus-host disease.

CATHETER-RELATED INFECTIONS

Because intravenous catheters are commonly used in cancer chemotherapy and are prone to infection (Chap. 135), they pose a major problem in the care of patients with cancer. Reviews have emphasized that some infected catheters can be treated with antibiotics while others must be removed. If the patient has a "tunneled" catheter (which consists of an entrance site, a subcutaneous tunnel, and an exit site), a red streak over the subcutaneous part of the line (the tunnel) is grounds for immediate removal of the catheter. Failure to remove catheters under these circumstances may result in extensive cellulitis and tissue necrosis.

More common than tunnel infections are exit-site infections, often with erythema around the area where the line penetrates the skin. Most authorities (Chap. 139) recommend treatment (usually with vancomycin) for an exit-site infection caused by a coagulase-negative *Staphylococcus*. Treatment of coagulase-positive staphylococcal infection is associated with a poorer outcome, and it is advisable to remove the catheter. Similarly, many clinicians remove catheters associated with infections due to *P.*

aeruginosa and *Candida* species, since such infections are difficult to treat and bloodstream infections with these organisms are likely to be deadly.

GASTROINTESTINAL TRACT-SPECIFIC SYNDROMES

Upper Gastrointestinal Tract Disease

Infections of the Mouth The oral cavity is rich in aerobic and anaerobic bacteria (Chap. 167) that normally live in a commensal relationship with the host. The antimetabolic effects of chemotherapy cause a breakdown of host defenses, leading to ulceration of the mouth and the potential for invasion by resident bacteria. Mouth ulcerations afflict most patients receiving chemotherapy and have been associated with viridans streptococcal bacteremia. A variety of topical rinses and elixirs have been proposed to treat these ulcerations. Although some may have a local anesthetic effect, the efficacy of any of these therapies in the prevention of disease is unproven. Similarly, the efficacy of mouthwashes in the prevention of esophagitis or invasive candidiasis is doubtful. Fluconazole, on the other hand, is clearly effective in the treatment of both local infections (thrush) and systemic infections (esophagitis) due to *C. albicans*.

Noma (or *cancrum oris*), commonly seen in malnourished children, is a penetrating disease of the soft and hard tissues of the mouth and adjacent sites, with resulting necrosis and gangrene. It has a counterpart in immunocompromised patients and is thought to be due to invasion of the tissues by *Bacteroides*, *Fusobacterium*, and other normal inhabitants of the mouth. It is associated with debility, poor oral hygiene, and immunosuppression.

Viruses, particularlyHSV, are a prominent cause of morbidity in immunocompromised patients, in whom they are associated with severe mucositis. The use of acyclovir, either prophylactically or therapeutically, is of value.

Esophageal Infections The differential diagnosis of esophagitis (usually presenting as substernal chest pain upon swallowing) includes herpes simplex and candidiasis, both of which are readily treatable.

Lower Gastrointestinal Tract Disease Hepatic candidiasis (Chap. 205) results from seeding of the liver (usually from a gastrointestinal source) in neutropenic patients. It is most common in patients being treated for acute leukemia and usually develops around the time the neutropenia resolves. The characteristic picture is that of persistent fever unresponsive to antibiotics; abdominal pain and tenderness or nausea; and elevated serum levels of alkaline phosphatase in a patient with hematologic malignancy who has recently recovered from neutropenia. The diagnosis of this disease (which may present in an indolent manner and persist for several months) is based on the finding of yeasts or pseudohyphae in granulomatous lesions. Hepatic ultrasound or computed tomography (CT) may reveal bull's-eye lesions. In some cases, magnetic resonance imaging (MRI) reveals small lesions not visible by other imaging modalities. The pathology (a granulomatous response) and the timing (with resolution of neutropenia and an elevation in granulocyte count) suggest that the host response to *Candida* is an important component of the manifestations of disease. In many cases, although organisms are visible, cultures of biopsied material may be negative. The designation

hepatosplenic candidiasis or *hepatic candidiasis* is a misnomer because the disease often involves the kidneys and other tissues; the term *chronic disseminated candidiasis* may be more appropriate. Because of the risk of bleeding with liver biopsy, diagnosis is often based on radiographic abnormalities. Amphotericin B is traditionally used for therapy (often for several months, until all manifestations of disease have disappeared), but fluconazole may be useful for outpatient therapy.

Typhlitis *Typhlitis*, sometimes referred to as necrotizing colitis, neutropenic colitis, necrotizing enteropathy, ileocecal syndrome, or cecitis, is a clinical syndrome of fever and right-lower-quadrant tenderness in an immunosuppressed host. This syndrome is almost always seen in neutropenic patients after chemotherapy with cytotoxic drugs. It may be more common among children than among adults and appears to be much more common among patients with acute myelocytic leukemia (AML) orALL than among those with other types of cancer. Physical examination reveals right-lower-quadrant tenderness, with or without rebound tenderness. Associated diarrhea (often bloody) is common, and the diagnosis can be confirmed by the finding of a thickened cecal wall onCT or ultrasonography. Plain films may reveal a right-lower-quadrant mass, but CT with contrast orMRI is a much more sensitive means of making the diagnosis. Although surgery is sometimes attempted to avoid perforation from ischemia, most cases resolve with medical therapy alone. The disease is sometimes associated with positive blood cultures (usually for aerobic gram-negative bacilli), and therapy is recommended for a broad spectrum of bacteria (particularly gram-negative bacilli, likely bowel flora). Recurrence is rare, and most patients recover uneventfully.

***Clostridium difficile*-Induced Diarrhea** Cancer patients seem to be predisposed to the development of *C. difficile* diarrhea (Chap. 145) as a consequence of chemotherapy alone. Thus, they may have positive toxin tests before receiving antibiotics. Obviously, such patients are also subject to *C. difficile*-induced diarrhea as a result of antibiotic pressure. It is worth noting that toxins other than *C. difficile* may be associated with diarrhea; therefore, the detection of nonspecific toxins in the stool -- without a specific neutralization test -- does not prove that *C. difficile* infection is present.

CENTRAL NERVOUS SYSTEM-SPECIFIC SYNDROMES

Meningitis While meningitis in immunocompetent adults is likely to be caused by *S. pneumoniae*, the same is not true in immunocompromised patients. As noted previously, splenectomized patients are susceptible to rapid overwhelming infection with encapsulated bacteria (including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*). Similarly, patients who are antibody-deficient (such as patients withCLL, those who have received intensive chemotherapy, or those who have undergone bone marrow transplantation) are likely to have infections with these bacteria. Other cancer patients, however, because of their defective cellular immunity, are likely to be infected with other pathogens (Table 85-3). The presentation of meningitis in patients with lymphoma, patients receiving chemotherapy (particularly with glucocorticoids) for solid tumors, and patients who have received bone marrow transplants suggests a diagnosis of cryptococcal or listerial infection.

Encephalitis The spectrum of disease resulting from viral encephalitis is expanded in immunocompromised patients. Infection with varicella-zoster virus (VZV) has been

associated with encephalitis that may be caused by VZV-related vasculitis. The slow viruses (e.g., Creutzfeldt-Jakob agent) may also be associated with dementia and encephalitic presentations, and a diagnosis of progressive multifocal leukoencephalopathy should be considered when a patient who has received chemotherapy presents with dementia. Other abnormalities of the central nervous system (CNS) that may be confused with infection include normal-pressure hydrocephalus and vasculitis resulting from CNS irradiation. It may be possible to differentiate these conditions byMRI.

Brain Abscess Brain abscesses in immunocompromised patients are likely to be due to *Cryptococcus* (particularly in patients with lymphoma or those receiving glucocorticoids), *Nocardia*, or *Aspergillus*. *Aspergillus* may enter via the lungs or -- like *Mucor* -- may invade the hard and soft palates to cause pneumonia (see below) with or without brain abscesses.

PULMONARY INFECTIONS

Pneumonia (Chap. 255) in immunocompromised patients may be difficult to diagnose because conventional methods of diagnosis depend on the presence of neutrophils. Bacterial pneumonia in neutropenic patients may present without purulent sputum -- or, in fact, without any sputum at all -- and may not produce physical findings suggestive of chest consolidation (rales or egophony).

In granulocytopenic patients with persistent or recurrent fever, the chest x-ray pattern may help to localize an infection and thus to determine which investigative tests and procedures should be undertaken and which therapeutic options should be considered (Table 85-5). The difficulties encountered in the management of pulmonary infiltrates relate in part to the difficulties of performing diagnostic procedures on the patients involved. When platelet counts can be increased to adequate levels by transfusion, microscopic and microbiologic evaluation of the fluid obtained by endoscopic bronchial lavage is often diagnostic. Lavage fluid should be cultured for *Mycoplasma*, *Chlamydia*, *Legionella*, *Nocardia*, fungi, and more common bacterial pathogens. In addition, the possibility of *P. carinii* pneumonia should be considered, especially in patients withALL or lymphoma who have not received prophylactic trimethoprim-sulfamethoxazole. The characteristics of the infiltrate may be helpful in decisions about further diagnostic and therapeutic maneuvers. Nodular infiltrates suggest fungal pneumonia (e.g., that caused by *Aspergillus* or *Mucor*). Such lesions may best be approached by visualized biopsy procedures.

Aspergillus species (Chap. 206) can colonize the skin and respiratory tract or cause fatal systemic illness. Although *Aspergillus* may cause aspergillomas in a previously existing cavity or may produce allergic bronchopulmonary aspergillosis, the major problem posed by this genus in neutropenic patients is invasive disease due to *A. fumigatus* or *A. flavus*. The organisms enter the host through colonization of the respiratory tract, with subsequent invasion of the blood vessels. The disease is likely to present as a thrombotic or embolic event because of the ability of the organisms to invade blood vessels. The risk of infection with *Aspergillus* correlates directly with the duration of neutropenia. In prolonged neutropenia, positive surveillance cultures for colonization of the nasopharynx with *Aspergillus* may predict the development of

disease.

Patients with *Aspergillus* infection often present with pleuritic chest pain and fever, which are sometimes accompanied by cough. Hemoptysis may be an ominous sign. Chest x-rays may reveal new focal infiltrates or nodules. ChestCT may reveal a characteristic halo consisting of a mass-like infiltrate surrounded by an area of low attenuation. The presence of a "crescent sign" on a chest x-ray or a chest CT scan, in which the mass progresses to central cavitation, is characteristic of invasive *Aspergillus* infection but may develop only with the resolution of the lesions.

In addition to causing pulmonary presentations, *Aspergillus* may invade through the nose or palate, with deep sinus penetration. The appearance of a discolored area in the nasal passages or on the hard palate should prompt a search for invasive *Aspergillus*. This situation is likely to require surgical debridement. Treatment (Chap. 206) with high doses of amphotericin B has been successful in curing granulocytopenic patients of invasive *Aspergillus* infection after the return of granulocytes. Catheter infections with *Aspergillus* usually require both removal of the catheter and antifungal therapy.

Diffuse interstitial infiltrates suggest viral, parasitic, or *P. carinii* pneumonia. If the patient has a diffuse interstitial pattern on chest x-ray, it may be reasonable to institute empirical treatment with trimethoprim-sulfamethoxazole (for *Pneumocystis*) and an erythromycin derivative or a quinolone (for *Chlamydia*, *Mycoplasma*, and *Legionella*) while considering invasive diagnostic procedures. Noninvasive procedures, such as staining of sputum smears for *Pneumocystis* and serum cryptococcal antigen tests, may be helpful on occasion. In transplant recipients who are seropositive for cytomegalovirus (CMV), culture of a nonpulmonary site for CMV may be worthwhile. Infections with viruses that cause only upper respiratory symptoms in immunocompetent hosts, such as respiratory syncytial, influenza, and parainfluenza viruses, may be associated with fatal pneumonitis in immunocompromised hosts. An attempt at early diagnosis by nasopharyngeal aspiration should be considered so that appropriate treatment can be instituted.

While bleomycin is the most common cause of chemotherapy-induced lung disease, other causes include alkylating agents (such as cyclophosphamide, chlorambucil, and melphalan), nitrosoureas [carmustine (BCNU), lomustine (CCNU), and methyl-CCNU], busulfan, procarbazine, methotrexate, and hydroxyurea. Both infectious and noninfectious (drug- and/or radiation-induced) pneumonitis can cause fever and abnormalities on chest x-ray; thus, the differential diagnosis of an infiltrate in a patient receiving chemotherapy encompasses a broad range of conditions (Table 85-5). Since the treatment of radiation pneumonitis (which may respond dramatically to glucocorticoids) or drug-induced pneumonitis is different from that of infectious pneumonia, a biopsy may be important in the diagnosis. Unfortunately, no definitive diagnosis can be made in approximately 30% of cases, even after bronchoscopy.

Open-lung biopsy is the "gold standard" of diagnostic techniques. Biopsy via a visualized thoracostomy can replace an open procedure in many cases. When a biopsy cannot be performed, empirical treatment can be undertaken with erythromycin (or an erythromycin derivative such as azithromycin) and trimethoprim-sulfamethoxazole (in the case of diffuse infiltrates) or with amphotericin B (in the case of nodular infiltrates).

The risks should be weighed carefully in these cases. If inappropriate drugs are administered, empirical treatment may prove toxic or ineffective; either of these outcomes may be riskier than biopsy.

CARDIOVASCULAR INFECTIONS

Patients with Hodgkin's disease are prone to persistent infections by *Salmonella*, sometimes (and particularly often in elderly patients) affecting a vascular site. The use of intravenous catheters deliberately lodged in the right atrium is associated with a high incidence of bacterial endocarditis (presumably related to valve damage followed by bacteremia). Nonbacterial thrombotic endocarditis has been described in association with a variety of malignancies (most often solid tumors) and may follow bone marrow transplantation as well. The presentation of an embolic event with a new cardiac murmur suggests this diagnosis. Blood cultures are negative in this disease of unknown pathogenesis.

ENDOCRINE SYNDROMES

In addition to infections of the skin, gastrointestinal tract, and pulmonary system, infections of the endocrine system have been described in immunocompromised patients. *Candida* infection of the thyroid during neutropenia can be defined by indium-labeled white-cell scans or gallium scans after neutrophil counts increase.CMVinfection can cause adrenalitis with or without resulting adrenal insufficiency. The presentation of a sudden endocrine anomaly in an immunocompromised patient may be a sign of infection in the involved end organ.

MUSCULOSKELETAL INFECTIONS

Infection that is a result of vascular compromise (resulting in gangrene) can occur when a tumor compromises the blood supply to muscles, bones, or joints. The process of diagnosis and treatment of such infection is similar to that in normal hosts, with the following caveats: (1) In terms of diagnosis, a lack of physical findings resulting from a lack of granulocytes in the granulocytopenic patient should make the clinician more aggressive in obtaining tissue rather than relying on physical signs. (2) In terms of therapy, aggressive debridement of infected tissues may be required, but it is usually difficult to operate on patients who have recently received chemotherapy, both because of a lack of platelets (which results in bleeding complications) and because of a lack of white blood cells (which may lead to secondary infection). A blood culture positive for *Clostridium perfringens* (an organism commonly associated with gas gangrene) can have a number of meanings (Chap. 145). Bloodstream infections with intestinal organisms like *Streptococcus bovis* and *C. perfringens* may arise spontaneously from lower gastrointestinal lesions (tumor or polyps); alternatively, these lesions may be harbingers of invasive disease. The clinical setting must be considered in order to define the appropriate treatment for each case.

RENAL AND URETERAL INFECTIONS

Infections of the urinary tract are common among patients whose ureteral excretion is compromised (Table 85-1). *Candida*, which has a predilection for the kidney, can invade

either from the bloodstream or in a retrograde manner (via the ureters or bladder) in immunocompromised patients. The presence of "fungus balls" or persistent candiduria suggests invasive disease. Persistent funguria (with *Aspergillus* as well as *Candida*) should prompt a search for a nidus of infection in the kidney.

Certain viruses are typically seen only in immunosuppression. BK virus (polyomavirus hominis 1) has been documented in the urine of bone marrow transplant recipients and, like adenovirus, may be associated with hemorrhagic cystitis. BK-induced cystitis usually remits with decreasing immunosuppression. Anecdotal reports have described the treatment of adenovirus with ribavirin in cases of severe hemorrhagic cystitis in immunocompromised patients.

ABNORMALITIES THAT PREDISPOSE TO INFECTION

THE LYMPHOID SYSTEM

It is beyond the scope of this chapter to detail how all the immunologic abnormalities that result from cancer or from chemotherapy for cancer lead to infections. Disorders of the immune system are discussed in other sections of this book. As has been noted, patients with antibody deficiency are predisposed to overwhelming infection with encapsulated bacteria (including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*). Infections that result from the lack of a functional cellular immune system are described inChap. 309. It is worth mentioning, however, that patients undergoing intensive chemotherapy for any form of cancer will have not only defects due to granulocytopenia but also lymphocyte dysfunction, which may be profound. Thus, these patients -- especially those receiving glucocorticoid-containing regimens -- should be given prophylaxis for *P. carinii* pneumonia.

THE HEMATOPOIETIC SYSTEM

Initial studies in the 1960s revealed a dramatic increase in the incidence of infections (fatal and nonfatal) among cancer patients with a granulocyte count of<500/uL. Recent studies have cited a figure of 48.3 infections per 100 neutropenic patients (<1000 granulocytes per microliter) with hematologic malignancies and solid tumors, or 46.3 infections per 1000 days at risk.

Neutropenic patients are unusually susceptible to infection with a wide variety of bacteria; thus, antibiotic therapy should be initiated promptly to cover likely pathogens if infection is suspected. Indeed, early initiation of antibacterial agents is mandatory to prevent deaths. These patients are susceptible to gram-positive and gram-negative organisms found commonly on the skin and in the bowel (Table 85-4). Because treatment with narrow-spectrum agents leads to infection with organisms not covered by the antibiotics used, the initial regimen should target pathogens likely to be initial causes of bacterial infection in neutropenic hosts (Fig. 85-1).

TREATMENT

Antibacterial Therapy Hundreds of antibacterial regimens have been tested for use in neutropenic patients with cancer. Many of the relevant studies involved small

populations in which the outcomes were generally good, and most lacked the statistical power to detect differences among the regimens studied. Each febrile neutropenic patient should be approached as a unique problem, with particular attention given to previous infections and recent exposures to antibiotics. Several general guidelines are useful in the initial treatment of neutropenic patients with fever (Fig. 85-1):

1. It is necessary to use antibiotics active against both gram-negative and gram-positive bacteria (Table 85-4) in the initial regimen.

2. An aminoglycoside or an antibiotic without good activity against gram-positive organisms (e.g., ciprofloxacin) alone is not adequate in this setting.

3. The agents used should reflect both the epidemiology and the antibiotic resistance pattern of the hospital. For example, in hospitals where there is gentamicin resistance, amikacin-containing regimens should be considered; in hospitals with frequent *P. aeruginosa* infections, a regimen with the highest level of activity against this pathogen (such as tobramycin plus a semisynthetic penicillin) would be reasonable for initial therapy.

4. A single third-generation cephalosporin constitutes an appropriate initial regimen in many hospitals (if the pattern of resistance justifies its use).

5. Most standard regimens are designed for patients who have not previously received prophylactic antibiotics. The development of fever in a patient receiving antibiotics affects the choice of subsequent therapy (which should target resistant organisms and organisms known to cause infections in patients being treated with the antibiotics already administered).

6. Randomized trials have indicated that it is safe to use oral antibiotic regimens to treat "low-risk" patients with fever and neutropenia. Outpatients who are expected to remain neutropenic for <10 days and who have no concurrent medical problems (such as hypotension, pulmonary compromise, or abdominal pain) can be classified as low risk and treated with a broad-spectrum oral regimen. On the basis of large studies, it can be concluded that this therapy is safe and effective, at least when delivered in the inpatient setting. Outpatient treatment has been assessed in small studies, but data from large randomized trials demonstrating the safety of outpatient treatment of fever and neutropenia are not yet available.

The initial antibacterial regimen should be refined on the basis of culture results (Fig. 85-1). Blood cultures are the most relevant on which to base therapy; surface cultures of skin and mucous membranes may be misleading. In the case of gram-positive bacteremia or another gram-positive infection, it is important that the antibiotic be optimal for the organism isolated. If the infection is caused by certain gram-negative pathogens (such as *P. aeruginosa*), a synergistic combination of antibiotics (usually a semisynthetic penicillin, such as piperacillin, plus an aminoglycoside) may be appropriate. Although it is not desirable to leave the patient unprotected, the addition of more and more antibacterial agents to the regimen is not appropriate unless there is a clinical or microbiologic reason to do so. *Planned progressive therapy* (the serial, empirical addition of one drug after another without culture data) is not efficacious in

most settings and may have unfortunate consequences. Simply adding another antibiotic for fear that a gram-negative infection is present is a dubious practice. The synergy exhibited by b-lactams and aminoglycosides against certain gram-negative organisms (especially *P. aeruginosa*) provides the rationale for using two antibiotics in this setting. Mere addition of a quinolone or another antibiotic not likely to exhibit synergy for "double coverage" has not been shown to be of benefit and may cause additional toxicities and side effects. Cephalosporins can cause bone marrow suppression, and vancomycin is associated with neutropenia in some healthy people (Chap. 137). Furthermore, the addition of multiple cephalosporins may induce b-lactamase production by some organisms; cephalosporins and double b-lactam combinations should probably be avoided altogether in *Enterobacter* infections.

Antifungal Therapy Fungal infections in cancer patients are most often associated with neutropenia. Neutropenic patients are predisposed to the development of invasive fungal infections, most commonly those due to *Candida* and *Aspergillus* species and occasionally those caused by *Fusarium*, *Trichosporon*, and *Bipolaris*. Cryptococcal infection, which is common among patients taking immunosuppressive agents, is uncommon among neutropenic patients receiving chemotherapy forAML. Invasive candidal disease is usually caused by *C. albicans* or *C. tropicalis* but can be caused by *C. krusei*, *C. parapsilosis*, and *C. glabrata*.

Most clinicians add amphotericin B to antibacterial regimens if a neutropenic patient remains febrile despite 4 to 7 days of treatment with antibacterial agents. The rationale for the empirical addition of amphotericin B is that it is difficult to culture fungi before they cause disseminated disease and that mortality from disseminated fungal infections in granulocytopenic patients is high. The imidazoles (especially fluconazole) may have prophylactic efficacy in this regard, but the spectrum of activity of the currently available azoles is narrower than that of amphotericin B. Amphotericin B is the mainstay of therapy for disseminated *Candida* or *Aspergillus* infection in the neutropenic patient. The combined use of an imidazole and amphotericin B is controversial because of the theoretical antagonistic effects of these agents. The insolubility of amphotericin B has resulted in the marketing of several amphotericin B-lipid formulations. Lipid preparations have been shown to be less toxic than the amphotericin B deoxycholate complex. However, because of the high cost of the lipid preparations, at many centers their use is reserved for patients who fail to respond to standard amphotericin B. Since the side effects of the formulations differ, unnecessary switching from one to another is not recommended.

Other Therapeutic Modalities Another way to address the problems of the febrile neutropenic patient is to replenish the neutrophil population. Although granulocyte transfusions are efficacious in the treatment of refractory gram-negative bacteremia, they do not have a documented role in prophylaxis. Because of the expense, the risk of leukoagglutinin reactions (although this risk has probably been decreased by improved cell-separation procedures), and the risk of transmission ofCMV from unscreened donors, granulocyte transfusion is reserved for patients unresponsive to antibiotics. This modality is efficacious for documented gram-negative bacteremia refractory to antibiotics, particularly in situations where granulocyte numbers will be depressed for only a short period.

A variety of cytokines, including granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, enhance granulocyte recovery after chemotherapy and consequently shorten the period of maximal vulnerability to fatal infections. The role of these cytokines in routine practice is still a matter of some debate. Most authorities recommend their use only when neutropenia is both severe and prolonged. The cytokines themselves may have adverse effects, including fever, hypoxemia, and pleural effusions or serositis in other areas. Since there is little evidence that their routine administration lessens the risk of death and since they are still expensive, the cytokines have not become the standard of care in all centers. The role of other cytokines (such as macrophage colony-stimulating factor for monocytes or interferon-g) in preventing or treating infections in granulocytopenic patients is under investigation.

Once neutropenia has resolved, patients are not at high risk of infection. However, depending on what drugs they receive, patients who continue on chemotherapeutic protocols remain at high risk for certain diseases. Any patient receiving more than a maintenance dose of glucocorticoids (including many treatment regimens for diffuse lymphoma) should also receive prophylactic trimethoprim-sulfamethoxazole because of the risk of *P. carinii* infection; those withALLshould receive such prophylaxis for the duration of chemotherapy.

PREVENTION OF INFECTION IN CANCER PATIENTS

EFFECT OF THE ENVIRONMENT

Outbreaks of fatal *Aspergillus* infection have been associated with construction projects and materials in several hospitals. The association between spore counts and risk of infection suggests the need for a high-efficiency air-handling system in hospitals that care for large numbers of neutropenic patients. The use of laminar-flow rooms and prophylactic antibiotics has decreased the number of infectious episodes in severely neutropenic patients. However, because of the expense of such a program and the failure to show that it dramatically affects mortality, most centers do not routinely use laminar flow to care for neutropenic patients. Some centers use "reverse isolation," in which health care providers and visitors to a patient who is neutropenic wear gowns and gloves. Since most of the infections these patients develop are due to organisms that colonize the patients' own skin and bowel, the validity of such schemes is dubious, and limited clinical data do not support their use. Hand washing by all staff caring for neutropenic patients should be required to prevent the spread of resistant organisms.

The presence of large numbers of bacteria (particularly *P. aeruginosa*) in certain foods, especially fresh vegetables, has led some authorities to recommend a special "low-bacteria" diet. A diet consisting of cooked and canned food is satisfactory to most neutropenic patients and does not involve elaborate disinfection or sterilization protocols. However, there are no studies to support even this type of dietary restriction. Counseling of patients to avoid leftovers, deli foods, and unpasteurized dairy products is recommended.

PHYSICAL MEASURES

Although few studies address this issue, patients with cancer are predisposed to infections resulting from anatomic compromise (e.g., lymphedema resulting from node dissections after radical mastectomy). Surgeons who specialize in cancer surgery can provide specific guidelines for the care of such patients, and patients benefit from common-sense advice about how to prevent infections in vulnerable areas.

ANTIBIOTIC PROPHYLAXIS

There is no consensus on the use of prophylactic antibiotics in neutropenic patients. The incidence of infection is lower among patients who receive broad-spectrum antibiotic prophylaxis than among those who do not. Because of the prolongation of neutropenia associated with the use of trimethoprim-sulfamethoxazole, some clinicians use broad-spectrum agents such as quinolones (e.g., ciprofloxacin). Either regimen can be given orally, and both have the advantage of inactivity against anaerobic organisms; thus, neither is likely to disrupt the bowel flora and permit colonization with new aerobes or *Candida*. However, both regimens have adverse effects and can lead to the selection of resistant organisms in a hospital. For these reasons, many clinicians reserve their use for patients with the longest periods of neutropenia (e.g., bone marrow transplant recipients). The same issues apply to the use of antifungal agents. While agents such as fluconazole may prevent infections with susceptible organisms (e.g., *C. albicans*), they can cause a concomitant increase in infections due to resistant fungi (e.g., *C. krusei*). Thus, the decision to use antifungal prophylaxis may vary with the fungi endemic in a given hospital. Prophylaxis for *P. carinii* is mandatory for patients withALL and for all cancer patients receiving glucocorticoid-containing chemotherapy regimens.

VACCINATION OF CANCER PATIENTS

In general, patients undergoing chemotherapy respond less well to vaccines than normal hosts. Their greater need for vaccines thus leads to a dilemma in their management. Purified proteins and inactivated vaccines are almost never contraindicated and should be given to patients even during chemotherapy. For example, all adults should receive diphtheria-tetanus toxoid boosters at the indicated times as well as seasonal influenza vaccine. However, if possible, vaccination should not be undertaken concurrent with cytotoxic chemotherapy. If patients are expected to be receiving chemotherapy for several months and vaccination is indicated (for example, influenza vaccination in the fall), the vaccine should be given midcycle -- as far as possible from the antimetabolic agents that will prevent an immune response. The meningococcal and pneumococcal polysaccharide vaccines should be given to patients before splenectomy, if possible. The Advisory Committee on Immunization Practices recommends reimmunization every 5 years for the pneumococcal vaccine; although no official stand has been taken, this recommendation seems reasonable for the meningococcal vaccine as well. The *H. influenzae* type b conjugate vaccine should be administered to all splenectomized patients; there is no current recommendation for reimmunization, but immunity appears to be much longer-lasting than that induced by polysaccharide vaccines.

In general, live virus (or live bacterial) vaccines should not be given to patients during intensive chemotherapy because of the risk of disseminated infection. Recommendations on vaccination are summarized in Table 85-2.

86. MELANOMA AND OTHER SKIN CANCERS - *Arthur J. Sober*, *Howard K. Koh*, *Gregory P. Wittenberg*, *Carl V. Washington, Jr.*

Pigmented skin lesions are among the most common findings on physical examination. The challenge is to distinguish cutaneous melanomas, which may be lethal, from the remainder, which with rare exceptions are benign. Cutaneous neoplasms are depicted in Section IIB (Plates IIB-20,IIB-21,IIB-22,IIB-23,IIB-24,IIB-25,IIB-26, andIIB-27) of the Color Atlas; benign and malignant pigmented lesions are in Section IIC (Plates IIC-28,IIC-29,IIC-30,IIC-31,IIC-31, andIIC-33).

MELANOMA

Melanomas originate from melanocytes, pigment cells normally present in the epidermis and sometimes in the dermis. This tumor affects approximately 44,200 individuals per year in the United States, resulting in 7300 deaths. The tumor can affect adults of all ages, even teenagers; it has distinct clinical features that make it detectable at a time when cure by surgical excision is possible; and it is located on the skin surface, where it is visible. The incidence has increased dramatically; if the incidence continues to increase at the present rate, within a decade, lifetime risk of melanoma will exceed 1%.

The reason for the increase in melanoma incidence is thought to be increased recreational sun exposure, especially early in life. Individuals of similar ethnic background who immigrate after childhood to areas of high sun exposure (e.g., Israel and Australia) have lower melanoma rates than individuals of similar age who were either born in those countries or immigrated before age 10. The individuals most susceptible to development of melanoma are those with fair complexions, red or blond hair, blue eyes, and freckles and who tan poorly and sunburn easily. Most studies link increased melanoma risk to history of sunburn. Other factors associated with increased risk include a family history of melanoma (1 in 10 melanoma patients have an affected family member); the presence of a clinically atypical mole (dysplastic nevus), a giant congenital melanocytic nevus, or a small to medium-sized congenital melanocytic nevus (see below); the presence of a higher than average number of ordinary melanocytic nevi; and immunosuppression (Table 86-1). Individuals with 50 or more moles³2 mm in size have a 64-fold increased risk. About 30% of melanomas arise in a nevus. Melanoma is relatively rare in heavily pigmented peoples. Dark-skinned populations (such as those of India and Puerto Rico), blacks, and East Asians have rates 10 to 20 times lower than lighter-skinned whites. In keeping with the role of sun exposure, the incidence is inversely correlated with the latitude of residence; at any latitude, however, darker-skinned persons have a lower incidence.

CLINICAL CHARACTERISTICS

There are four types of cutaneous melanoma (Table 86-2). In three of these -- superficial spreading melanoma, lentigo maligna melanoma, and acral lentiginous melanoma -- the lesion has a period of superficial (so-called radial) growth during which it increases in size but does not penetrate deeply. During this period, the melanoma is most capable of being cured by surgical excision. The fourth type -- nodular melanoma -- does not have a recognizable radial growth phase and usually presents as a deeply invasive lesion, capable of early metastasis. When tumors begin to penetrate deeply

into the skin, they are in the so-called vertical growth phase. Melanomas with a radial growth phase are characterized by irregular and sometimes notched borders, variation in pigment pattern, and variation in color. An increase in size or change in color is noted by the patient in 70% of early lesions. Bleeding, ulceration, and pain are late signs and are of little help in early recognition. Nodular melanomas are dark brown-black to blue-black nodules. Melanomas are occasionally amelanotic, in which case the diagnosis is established histologically after biopsy of a new or changing skin growth. Lentigo maligna melanoma is usually confined to chronically sun-damaged sites (face, neck, back of hands) in older individuals. Acral lentiginous melanoma occurs on the palms, soles, nail beds, and mucous membranes. While this type occurs in whites, it is most frequent (along with nodular melanoma) in blacks and East Asians. Superficial spreading melanoma is most frequent in whites. Melanomas arising in dysplastic nevi (see below) are usually of this type. The back is the most common site for melanoma in men. In women, the back and the lower leg (knee to ankle) are frequent sites.

PROGNOSTIC FACTORS

The most important prognostic factor is the stage at the time of presentation [see the discussion of revised American Joint Cancer Commission (AJCC) stages, below]. Five-year survival for clinical stages I and II (primary tumor; no clinical evidence of disease elsewhere) is about 85%. For clinical stage III (clinically palpable regional nodes that contain tumor), the 5-year survival is about 50% when only one node is involved and about 15 to 20% when four or more nodes are involved. The 5-year survival for clinical stage IV (disseminated disease) is<5%. Fortunately, most melanomas are diagnosed in clinical stages I and II. Within these stages, the prognosis depends on the thickness of the primary tumor (Table 86-3). This system is based on the rationale that the likelihood of metastasis should correlate with tumor volume, with thickness being the best single index of tumor volume. Melanomas<0.76 mm thick are usually cured by surgical removal (with 5-year survival rates of 96 to 99%). Approximately 40% of primary melanomas now fall in a low-risk category (thickness<1 mm). In low-risk patients who develop metastases, the primary tumors often exhibit either microscopic features of anaplasia or a vertical growth phase. More than 50% of individuals with melanomas ³4 mm thick will develop metastatic disease and die of their melanoma (Table 86-3). These thick tumors are almost always raised above the plane of the skin. Certain anatomic sites affect the prognosis. The favorable sites appear to be the forearm and leg (excluding feet), while unfavorable sites include scalp, hands, feet, and mucous membranes. In general, women with stage I or II disease have a better survival than men, perhaps in part because of earlier diagnosis; women frequently have melanomas on the lower leg, where self-recognition is more likely and prognosis is better. Older individuals have poorer prognoses. This finding has been explained in part by a tendency toward later diagnosis (and thus thicker tumors) in men and by a higher proportion in men of acral melanomas (palmar-plantar), which have a poorer prognosis. Melanoma may recur after many years. About 10 to 15% of first-time recurrences develop more than 5 years after treatment of the original lesion. The time to recurrence varies inversely with tumor thickness. Other prognostic factors for stages I and II melanoma include the presence of an ulcer in the primary tumor, high mitotic rate, and the presence of microscopic tumor satellites (foci of tumor ³0.05 mm in diameter in the reticular dermis or subcutaneous fat, distinct from the main body of the tumor). The presence of microscopic satellites is also predictive of microscopic metastases to the

regional lymph nodes. An alternative prognostic scheme for clinical stages I and II melanoma, proposed by Clark, is based on the anatomic level of invasion in the skin. Level I is intraepidermal (in situ); level II penetrates the papillary dermis; level III spans the papillary dermis; level IV penetrates the reticular dermis; and level V penetrates into the subcutaneous fat. The 5-year survival for these stages averages 100, 95, 82, 71, and 49%, respectively.

NATURAL HISTORY

Melanomas may spread by the lymphatic channels or the bloodstream. The earliest metastases are often to regional lymph nodes. Surgical lymphadenectomy usually controls regional disease. Liver, lung, bone, and brain are common sites of hematogenous spread, but unusual sites, such as the anterior chamber of the eye, may also be involved. Once metastatic disease is established, the likelihood of cure is low.

MANAGEMENT

The entire cutaneous surface, including the scalp and mucous membranes, should be examined in each patient. Bright room illumination is important, and a 7´ to 10´ hand lens is helpful for evaluating variation in pigment pattern. A history of relevant risk factors should be elicited. Any suspicious lesions should be biopsied, evaluated by a specialist, or recorded by chart and/or photography for follow-up. Examination of the lymph nodes and palpation of the abdominal viscera are part of the staging examination for suspected melanoma. The patient should be advised to have other family members screened if either melanoma or clinically atypical moles (dysplastic nevi) are present. Melanoma prevention is based on protection from the sun. Routine use of a sunblock of SPF³15, use of protective clothing, and avoiding intense midday ultraviolet exposure should be recommended. The patient should be educated in the clinical features of melanoma and advised to report any growth or other change in a pigmented lesion. Patient education brochures are available from the American Cancer Society, the American Academy of Dermatology, the National Cancer Institute, and the Skin Cancer Foundation. Self-examination at 6- to 8-week intervals may enhance the likelihood of detecting change between follow-up visits. Routine follow-up visits for melanoma patients and patients with clinically atypical moles (dysplastic nevi) may facilitate early detection of new tumors.

Precursor Lesions Clinically atypical moles, also termed *dysplastic nevi*, occur in certain families affected by melanoma. In some families, melanomas occur nearly exclusively in the individuals with dysplastic nevi. These nevi appear to be transmitted as an autosomal dominant trait that involves chromosome 9p16. In other families, the nevi may not be present in all individuals with an increased risk of melanoma. The melanomas may arise in clinically atypical moles or in normal skin. Individuals with clinically atypical moles and two family members with melanoma have been reported to have a >50% lifetime risk for developing melanoma.Table 86-4 lists the features that are characteristic of clinically atypical moles and that differentiate them from benign acquired nevi. The number of clinically atypical moles may vary from one to several hundred. Clinically atypical moles usually differ from each other in appearance. The borders are often hazy and indistinct, and the pigment pattern is more highly varied than that in benign acquired nevi. Of the 90% of melanoma patients whose disease is

regarded as sporadic (i.e., who lack a family history of melanoma), about 40% have clinically atypical moles, as compared with an estimated 5 to 10% of the population at large. The observation that at least 20% of sporadic melanomas arise in association with a clinically atypical mole makes this nevus the most important precursor for melanoma.

Less frequent precursors include the giant congenital melanocytic nevus and the small congenital melanocytic nevus (although the latter relationship is disputed by some). Congenital melanocytic nevi are present at birth or appear in the neonatal period (tardive form). The giant melanocytic nevus, also called the bathing trunk, cape, or garment nevus, is a rare malformation that affects perhaps 1 in 30,000 to 1 in 100,000 individuals. These nevi are usually>20 cm in diameter and may cover more than half the body surface. Giant nevi often occur in association with multiple small congenital nevi. The borders are sharp, and hair may be present. The lesions are usually dark brown and may have darker and lighter areas. Pigment is haphazardly displayed. The surface is smooth to rugose or cerebriform and may vary from one portion of the lesion to another. A lifetime risk of melanoma development of 6% has been estimated. The risk is greatest before age 5 and next greatest between ages 5 and 10. Early detection of melanoma is difficult in these lesions because of the deep dermal or subcutaneous origin of melanoma in these lesions and because of the large and varied surface of the nevus. Prophylactic excision early in life can be accomplished by staged removal with coverage by split-thickness skin grafts. No uniform management guidelines for giant congenital nevi have been developed.

The small- to medium-sized congenital melanocytic nevus, which affects approximately 1% of persons, usually presents as a raised dark- to medium-brown lesion with a smooth or papillomatous surface. The border is sharp, and lesions may be oriented along lines of skin cleavage. Follicular hyper- and hypopigmentation may coexist in a salt-and-pepper configuration. The lesion may have an excess of coarse hairs. Melanoma may develop in these lesions but the risk is not quantitated. Considerations of body surface area suggest that the incidence of melanomas arising in small congenital melanocytic nevi is probably higher than would be expected by chance. The remnants of a nevus with histopathologic features of a congenital nevus have been observed in 2 to 6% of melanomas. The management of small- to medium-sized congenital melanocytic nevi remains controversial; prophylactic removal under local anesthesia in the early teen years is appropriate as melanomas arise later in these lesions.

Differential Diagnosis The aim of differential diagnosis is to distinguish benign pigmented lesions from melanoma and its precursors. If melanoma is a consideration, then biopsy is appropriate. Some benign look-alikes may be removed in the process of trying to detect authentic melanoma. Table 86-5 summarizes the distinguishing features of benign lesions that may be confused with melanoma. Early detection of melanoma may be facilitated by applying the "ABCD rules": A -- asymmetry, benign lesions are usually symmetric; B -- border irregularity, most nevi have clear-cut borders; C -- color variegation, benign lesions usually have uniform light or dark pigment; D -- diameter >6 mm (the size of a pencil eraser).

Biopsy Any pigmented cutaneous lesion that has changed in size or shape or has other

features suggestive of malignant melanoma should be biopsied. The recommended technique is an excisional biopsy, as that facilitates pathologic assessment of the lesion, permits accurate measurement of thickness if the lesion is melanoma, and constitutes treatment if the lesion is benign. Shave biopsy or curettage of a suspected melanoma is contraindicated. For large lesions or lesions on anatomic sites where excisional biopsy may not be feasible (such as the face, hands, or feet), an incisional biopsy through the most nodular or darkest area of the lesion is acceptable; this should include the vertical growth phase of the primary tumor, if present. Data from prospective studies do not indicate that an incisional biopsy facilitates the spread of melanoma.

Staging Once the diagnosis of malignant melanoma has been confirmed, the tumor must be staged to determine prognosis and treatment. The history should probe for evidence of metastatic disease, such as malaise, weight loss, headaches, visual difficulty, or bone pain. The physical examination should be directed especially to the skin, regional draining lymph nodes, central nervous system, liver, and spleen. In the absence of signs or symptoms of metastasis, few laboratory or radiologic tests are indicated for staging purposes. Aside from a chest radiograph, and possibly liver function tests, no other tests or scans are routinely indicated unless the history or physical examination suggests metastasis to a specific organ. Specifically, liver-spleen scans and computed tomography have a low yield and are not cost-effective. However, once signs of metastasis exist, favored sites of spread, such as the liver, lungs, bone, and brain, should be scanned. Appropriate evaluations place patients into four clinical stages (Table 86-3).

TREATMENT

Surgical Management For a newly diagnosed cutaneous melanoma, wide surgical excision of the lesion with a margin of normal skin is necessary to remove all malignant cells and minimize local recurrence. The appropriate width of the margin is a source of controversy. Based upon clinical studies, the following margins can be recommended for primary melanoma: in situ: 0.5 cm; invasive up to 1 mm thick: 1.0 cm; 1 to 4 mm thick: 2.0 cm; >4 mm thick: at least 2 cm. For lesions on the face, hands, and feet, strict adherence to these margins must give way to individual considerations about the constraints of surgery and minimization of morbidity. In all instances, however, inclusion of subcutaneous fat in the surgical specimen facilitates adequate thickness measurement and assessment of surgical margins by the pathologist.

Elective Regional Node Dissection Elective regional node dissection inAJCCstage II disease (without palpable adenopathy) has been advocated, based on the hypothesis that melanoma metastasizes in an orderly fashion from the skin to regional lymph nodes and finally to distant sites. If that is the case, surgical excision of nodal micrometastases could theoretically provide definitive treatment at a time of relatively low tumor burden and perhaps improve survival. The efficacy of this procedure remains controversial; while some retrospective series suggest a survival benefit, randomized studies examining this question showed no survival advantage for wide local excision followed by immediate elective regional node dissection compared with wide local excision followed by delayed dissection (only if nodes became palpable). Furthermore, the procedure has associated morbidity, and some lesions, especially those on the trunk, have ambiguous nodal draining sites, making it difficult to decide which area to dissect.

Results of biopsy of the first drainage node -- the so-called sentinel node -- predicts the likelihood of metastases in higher nodes. Sentinel nodes can be identified by injecting a blue dye or radioactive isotope around the primary tumor site. A negative biopsy result appears to obviate the need for elective regional nodal dissection. Patients with lesions <1 mm thick have an excellent prognosis and need no node dissection; at the other extreme, patients with lesions >4 mm thick have such a high risk for distant metastases that elective node dissection may not alter the ultimate clinical outcome. A subset of patients with AJCC stage II lesions of intermediate thickness may benefit from elective regional node dissection, but there is no consensus about which patients should undergo this procedure.

Adjuvant Therapy For patients who are free of disease but at high risk for metastases, adjuvant therapy that complements surgery is needed to destroy occult micrometastases, prolong disease-free survival, and improve the cure rate. Many strategies have been tried unsuccessfully. However, adjuvant interferon-a may improve disease-free and overall survival, particularly in patients with nodal metastases (stage III disease). High-dose interferon, 20 million units per square meter intravenously 5 days a week for 4 weeks followed by 10 million units per square meter subcutaneously three times a week for 11 months, has been effective in some, but not all, studies. In nearly half of patients, these doses of interferon are associated with severe toxicity, including flulike illness and decline in performance status. The toxicity reverses with lower doses and when therapy is stopped. If interferon is beneficial at all, it benefits only a small fraction of treated patients.

Treatment of Metastatic Disease Melanoma can metastasize to any organ, the brain being a particularly common site. Metastatic melanoma generally is incurable, with survival in patients with visceral metastases generally<1 year. Thus, the goal of treatment is usually palliation. Patients with soft-tissue and node metastases fare better than those with liver and brain metastases. Metastases limited to regional nodes (AJCCstage III disease) warrant a therapeutic lymph node dissection. Surgical excision of a single metastasis to the lung or to a surgically accessible brain site can prolong survival. Trials of stereotactic radiosurgery will determine its future role in the treatment of brain metastases. More often, however, patients have multiple brain metastases that require radiation therapy and glucocorticoids. Radiation therapy can provide local palliation for recurrent tumors or metastases. Patients who have advanced regional disease limited to a limb may benefit from hyperthermic limb perfusion with melphalan and tumor necrosis factor. Complete response rates >90% have been reported; responses are associated with significant palliation of symptoms.

A number of drugs and biologicals have minimal antitumor activity (15 to 20% partial response rates) in metastatic melanoma, including dacarbazine (DTIC); the nitrosoureas carmustine (BCNU), lomustine (CCNU), and semustine (methyl-CCNU); platinum analogues such as cisplatin and carboplatin; vinca alkyloids such as vincristine, vinblastine, and vindesine; the taxanes paclitaxel and docetaxel; interferon; and interleukin 2 (IL-2). Single-agent dacarbazine is considered the standard treatment. This agent has been given at a number of different doses and schedules; 250 mg/m$_2$intravenously every day for 5 days every 3 weeks is a standard schedule. Dacarbazine-based combination regimens are probably more effective. Interferon and IL-2 produce response rates similar to those seen with cytotoxic agents; however, at

active doses, they usually cause greater toxicity than chemotherapy.

Melanomas often express cell-surface antigens that may be recognized by host immune cells. A number of melanoma-associated antigens have been discovered. Melanoma antigens (MAGEs)-1, -2, and -3 (endogenous proteins controlled by genes on the X chromosome; there are up to 12 of these genes) and tyrosinase, an enzyme involved in melanin synthesis, are antigens that are processed into peptides and presented to T cells via HLA-A antigens on the tumor, particularly the HLA-A1 and -A2 alleles, which are expressed in about 85% of patients with melanoma. In addition, a melanoma antigen called MART is recognized in the context of class II MHC antigens. These melanoma-associated antigens alone or in combination may make it possible to develop vaccination strategies against melanoma. Such strategies include the use of purified proteins as immunogens and the use of genetically altered tumor cells to elicit a T cell response. Alternative experimental approaches include efforts to expand tumor-specific T cells (obtained either from the tumor as tumor-infiltrating lymphocytes or harvested from the peripheral blood after vaccination) in vitro and transfer them into patients in large numbers. In addition, monoclonal antibodies to tumor antigens are being tested, with some early indication of efficacy in around 15% of patients. All of these experimental approaches will need considerable further development before being applicable on a wide scale. However, once an approach is found that is active in metastatic disease, it may prove most useful as adjuvant therapy.

The absence of curative therapy for patients with metastatic melanoma underscores the importance of early detection and prevention as strategies to decrease melanoma mortality.

NONMELANOMA SKIN CANCER

Nonmelanoma skin cancer is the most common cancer in the United States, with an estimated annual incidence of more than 1,000,000 cases. Basal cell carcinomas (BCCs) account for 70 to 80% of nonmelanoma skin cancers. Squamous cell carcinomas (SCCs), while representing only about 20% of nonmelanoma skin cancers, are more significant because of their ability to metastasize; they account for most of the 2300 deaths annually. Incidence rates have risen dramatically over the past decade.

ETIOLOGY

The cause ofBCC andSCC is multifactorial. Cumulative exposure to sunlight, principally the ultraviolet B (UV-B) spectrum, is the most significant factor. Other factors associated with a higher incidence of skin cancer are male sex, older age, Celtic descent, a fair complexion, a tendency to sunburn easily, and an outdoor occupation. The incidence of these tumors increases with decreasing latitude. Most tumors develop on sun-exposed areas of the head and neck. Tumors are more common on the left side of the body in the United States but on the right side in England, presumably owing to asymmetric exposure during driving. As the earth's protective ozone shield continues to thin, further increases in the incidence of skin cancer can be anticipated. In certain geographic areas, exposure to arsenic in well water or from industrial sources may significantly increase the risk of BCC and SCC. Skin cancer in affected individuals may be seen with or without other cutaneous markers of chronic arsenism (e.g., arsenical keratoses).

Less common is exposure to the cyclic aromatic hydrocarbons in tar, soot, or shale. The risk of lip or oral SCC is increased with cigarette smoking. Human papillomaviruses and ultraviolet radiation may act as cocarcinogens.

Host factors associated with a high risk of skin cancer include immunosuppression induced by disease or drugs. Transplant recipients receiving chronic immunosuppressive therapy are particularly prone toSCC. The frequency of skin cancer is proportional to the duration of immunosuppression and the extent of sun exposure. Skin cancer is a not uncommon finding in patients infected with HIV, and it may be more aggressive in this setting. Other factors include ionizing radiation, thermal burns, certain scars, and chronic ulcerations. Several heritable conditions have been associated with skin cancer (e.g., albinism, xeroderma pigmentosum, andBCCnevus syndrome). Mutations in the tumor suppressor gene, *patched*, may lead to BCC.

CLINICAL PRESENTATION

Nonmelanoma skin cancers are often asymptomatic, but nonhealing ulceration, bleeding, or pain can occur.

Basal Cell Carcinoma BCC is a malignancy arising from epidermal basal cells. The most common type is *noduloulcerative BCC*, which begins as a small, pearly nodule, often with small telangiectatic vessels on its surface. The nodule grows slowly and may undergo central ulceration. Various amounts of melanin may be present in the tumor; tumors with a heavier accumulation are referred to as *pigmented BCC*. While clinically no more aggressive than the noduloulcerative variant, the latter may be mistaken for malignant melanoma. *Superficial BCC* consists of one or several erythematous, scaling plaques that slowly enlarge. Although they are more commonly found on the trunk and extremities, the head and neck can also be affected. The lesions may be confused with benign inflammatory dermatoses, especially nummular eczema and psoriasis. *Morpheaform (fibrosing) BCC* manifests itself as a solitary, flat or slightly depressed, indurated, whitish or yellowish plaque. Borders are typically indistinct, a feature associated with a greater potential for extensive subclinical spread.

Squamous Cell Carcinoma Primary cutaneousSCC is a malignant neoplasm of keratinizing epidermal cells. UnlikeBCC, which has a very low metastatic potential, SCC can metastasize and grow rapidly. The clinical features of SCC vary widely. Commonly, SCC appears as an ulcerated nodule or a superficial erosion on the skin or lower lip, but it may present as a verrucous papule or plaque. Unlike BCC, overlying telangiectasias are uncommon. The margins of this tumor may be ill-defined, and fixation to underlying structures may occur. Cutaneous SCC may develop anywhere on the body, but it usually arises on sun-damaged skin. A related neoplasm, keratoacanthoma, typically appears as a dome-shaped papule with a central keratotic crater, expands rapidly, and commonly regresses without therapy. This lesion can be difficult to differentiate from SCC.

SCChas several premalignant forms (actinic keratosis, actinic cheilitis, and some cutaneous horns) and in situ forms (e.g., Bowen's disease) that are confined to the epidermis. Actinic keratoses and cheilitis are hyperkeratotic papules and plaques that occur on sun-exposed areas. While the potential for malignant degeneration is low in

any individual lesion, the risk of SCC increases with larger numbers of lesions. Bowen's disease presents as a scaling, erythematous plaque, which may develop into invasive SCC in up to 20% of cases. Controversy exists regarding the association of Bowen's disease with internal malignancy; however, no significant relationship is noted when other predisposing factors (e.g., arsenic) are absent. Treatment of premalignant and in situ lesions reduces the subsequent risk of invasive disease.

NATURAL HISTORY

Basal Cell Carcinoma The natural history ofBCC is that of a slowly enlarging, locally invasive neoplasm. The degree of local destruction and risk of recurrence vary with the size, duration, and location of the tumor; the histologic subtype; the presence of recurrent disease; and various patient characteristics. Location on the central face (e.g., the nose, the nasolabial fold, or the periorbital or perioral area), the ears, or the scalp may portend a higher risk. Small nodular, pigmented, cystic, or superficial BCCs respond well to most treatments. Large nodular, noduloulcerative, and especially morpheaform BCCs may be more aggressive. The metastatic potential of BCC is about 0.0028 to 0.1%. Persons with either BCC orSCC have an increased risk of developing subsequent skin cancers.

Squamous Cell Carcinoma The natural history ofSCCdepends on both tumor and host characteristics. Tumors arising on actinically damaged skin have a lower metastatic potential than those on protected surfaces. The metastatic frequency of cutaneous SCC, 0.3 to 3.7%, is lower than that of mucosal SCC. Tumors occurring on the lower lip and ear have metastatic potential approaching 13 and 11%, respectively. The metastatic potential of SCC arising in burn scars, chronic ulcerations, or the genitalia is higher. The overall metastatic rate for recurrent tumors approaches 30%. Poorly differentiated, deep tumors with perineural or lymphatic invasion often behave aggressively. Multiple tumors with rapid growth and aggressive behavior can be a therapeutic challenge in immunosuppressed patients. Regional lymph nodes are the most common site of metastasis. In patients with metastatic disease, the 5-year survival rate may be low.

TREATMENT

Basal Cell Carcinoma The treatment modalities used forBCCinclude electrodesiccation and curettage (ED&C), excision, cryosurgery, radiation therapy, Mohs micrographic surgery (MMS), and others. The mode of therapy chosen depends on tumor characteristics, age, medical status, preferences of the patient, and other factors. ED&C remains the method most commonly employed by dermatologists. This method is selected for low-risk tumors (e.g., a small primary tumor of a less aggressive subtype in a favorable location). Excision, which offers the advantage of histologic control, is usually selected for more aggressive tumors or those in high-risk locations, or, in many instances, for esthetic reasons. Cryosurgery using liquid nitrogen may be used in certain low-risk tumors, but it requires specialized equipment (cryoprobes) to be effective for advanced neoplasms. Radiation therapy, while not employed as often as surgical modalities, offers an excellent chance for cure in many cases of BCC. It is useful in patients not considered surgical candidates and as a surgical adjunct in high-risk tumors. Younger patients may not be good candidates for radiation therapy because of

the risks of long-term carcinogenesis and radiodermatitis. MMS is a specialized type of surgical excision that permits the ultimate in histologic control and preservation of uninvolved tissue. It is preferred for lesions that are recurrent, in a high-risk location, or large and ill-defined, and where maximal tissue conservation is critical (e.g., the eyelids). Topical chemotherapy with 5-fluorouracil (5FU) cream has limited usefulness in the management of BCC and should be used only for treating superficial BCC. Intralesional 5FU is being investigated for BCC. Intralesional interferon is effective in certain primary tumors. Photodynamic therapy, which employs selective activation of a photoactive drug by visible light, may be useful in patients with numerous tumors. Lasers also have been used for the treatment of skin cancer.

Squamous Cell Carcinoma The therapy of cutaneousSCCshould be based on an analysis of risk factors influencing the biologic behavior of the tumor. These include the size, location, and degree of histologic differentiation of the tumor and the age and physical condition of the patient. Surgical excision,MMS, and radiation are standard methods of treatment. Cryosurgery andED&Chave been used successfully for small primary tumors. Metastases are treated with lymph node dissection, irradiation, or both. 13-*Cis*-retinoic acid (1 mg orally every day) plus interferon (3 million units subcutaneously or intramuscularly every day) may produce a partial response in most patients. Systemic chemotherapy combinations that include cisplatin may also be palliative in some patients.

PREVENTION

Since the vast majority of skin cancers are related to chronicUV-Bexposure, they are largely preventable by blocking sun exposure. Emphasis should be placed on preventive measures beginning early in life. Patients must understand that damage from UV-B begins early, despite the fact that cancers develop years later. Regular use of sunscreens and protective clothing should be encouraged. Avoidance of tanning salons and sun exposure during midday (10 A.M. to 2 P.M.) is recommended. Precancerous and in situ lesions should be treated early. Early detection of small tumors affords simpler treatment modalities with higher cure rates and lower morbidity. In patients with a history of skin cancer, long-term follow-up for the detection of recurrence, metastasis, and new skin cancers should be emphasized. Chemoprophylaxis using synthetic retinoids is useful in controlling new lesions in some patients with multiple tumors.

OTHER TYPES OF CUTANEOUS CANCER

Neoplasms of cutaneous adnexa, and sarcomas of fibrous, mesenchymal, fatty, and vascular tissues make up 1 to 2% of nonmelanoma skin cancers. The recent rapid rise in the incidence of Kaposi's sarcoma is attributed to HIV infection and immunosuppressive therapy. Human herpesvirus 8 appears to be the cause of sporadic and HIV-associated Kaposi's sarcoma. Current therapy is palliative and depends on the symptoms and sites of involvement. Treatment modalities include cryosurgery, vinblastine, excision, radiation, interferon, and systemic combination chemotherapy (Chap. 309).

ACKNOWLEDGEMENT
The authors wish to acknowledge Dr. Nhu-linh T. Tran, who was a co-author of

this chapter in the 14th edition.

87. HEAD AND NECK CANCER - *Everett E. Vokes*

Epithelial carcinomas of the head and neck arise from the mucosal surfaces in the head and neck area and typically are squamous cell in origin. This category includes tumors of the paranasal sinuses, the oral cavity, and the nasopharynx, oropharynx, hypopharynx, and larynx. Tumors of the salivary glands differ from the more common carcinomas of the head and neck in etiology, histopathology, clinical presentation, and therapy.**Thyroid malignancies are described in Chap. 330.*

INCIDENCE AND EPIDEMIOLOGY

The annual number of new cases of head and neck cancers in the United States is approximately 40,000, accounting for about 5% of adult malignancies. Head and neck cancers are more common in certain other countries, and the worldwide incidence exceeds half a million cases annually. In North America and Europe, the tumors usually arise from the oral cavity, oropharynx, or larynx, whereas nasopharyngeal cancer is more common in the Mediterranean countries and in the Far East.

ETIOLOGY AND GENETICS

Alcohol and tobacco use are the most common risk factors for head and neck cancer in the United States. Smokeless tobacco is an etiologic agent for oral cancers. Other potential carcinogens include marijuana and occupational exposures such as nickel refining, exposure to textile fibers, and woodworking.

Dietary factors may contribute. The incidence of head and neck cancer is highest in people with the lowest consumption of fruits and vegetables. Certain vitamins, including dietary carotenoids, may be protective; retinoids are being tested for prevention.

Some head and neck cancers may have a viral etiology. The DNA of human papilloma virus has been detected in the tissue of oral and tonsil cancers, and Epstein-Barr virus (EBV) infection is associated with nasopharyngeal cancer. Nasopharyngeal cancer occurs endemically in some countries of the Mediterranean and Far East, where EBV antibody titers can be measured to screen high-risk populations. Nasopharyngeal cancer has also been associated with other environmental factors, such as consumption of salted fish.

No specific risk factors or environmental carcinogens have been identified for salivary gland tumors.

HISTOPATHOLOGY, CARCINOGENESIS, AND MOLECULAR BIOLOGY

Squamous cell head and neck carcinomas can be divided into well-differentiated, moderately well-differentiated, and poorly differentiated categories. Patients with poorly differentiated tumors have a worse prognosis than those with well-differentiated tumors. For nasopharyngeal cancers, the less common differentiated squamous cell carcinoma is distinguished from nonkeratinizing and undifferentiated carcinoma (lymphoepithelioma) that contains infiltrating (bystander) lymphocytes.

Salivary gland tumors can arise from the major (parotid, submandibular, sublingual) or minor salivary glands (located in the submucosa of the upper aerodigestive tract). Most parotid tumors are benign, but half of submandibular and sublingual gland tumors and most minor salivary gland tumors are malignant. Malignant tumors include mucoepidermoid and adenoidcystic carcinomas and adenocarcinomas.

The mucosal surface of the entire pharynx is exposed to alcohol and tobacco-related carcinogens and is at risk for the development of a premalignant or malignant lesion, such as erythroplakia or leukoplakia (hyperplasia, dysplasia), that can progress to invasive carcinoma. Alternatively, multiple synchronous or metachronous cancers can develop. In fact, patients with early-stage head and neck cancer are at greater risk of dying of a second malignancy than of dying from a recurrence of the primary disease.

Second head and neck malignancies are not therapy-induced but, instead, reflect the exposure of the upper aerodigestive mucosa to the same carcinogens that caused the first cancer. These second primaries develop in the head and neck area, the lung, or the esophagus.

Chromosomal deletions and other alterations, most frequently involving chromosomes 3p, 9p, 17p, and 13q, have been identified in both premalignant and malignant head and neck lesions, as have mutations in tumor suppressor genes, commonly the *p53* gene. Amplification of oncogenes is less common, but overexpression of PRAD-1/bcl-1 (cyclin D1), bc1-2, transforming growth factor b, and the epidermal growth factor receptor have been described. The latter finding correlates positively with tumor size and poor outcome and is a target for experimental treatments.

Resected tumor specimens with histopathologically negative margins ("complete resection") can have histopathologically undetectable residual tumor cells with persistent *p53* mutations at the margins. Thus, a tumor-specific *p53* mutation can be detected in some phenotypically "normal" surgical margins, indicating residual disease. Patients with such submicroscopic marginal involvement may have a worse prognosis than patients with negative margins.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Most head and neck cancers occur after age 50, although these cancers can appear in younger patients, including those without known risk factors. The manifestations vary according to the stage and primary site of the tumor. Patients with nonspecific signs and symptoms in the head and neck area should be evaluated with a thorough otolaryngologic exam, particularly if symptoms persist longer than 2 to 4 weeks.

Cancer of the nasopharynx typically does not cause early symptoms. However, on occasion it may cause unilateral serous otitis media due to obstruction of the eustachian tube, unilateral or bilateral nasal obstruction, or epistaxis. Advanced nasopharyngeal carcinoma causes neuropathies of the cranial nerves.

Carcinomas of the oral cavity present as nonhealing ulcers, changes in the fit of dentures, or painful lesions. Tumors of the tongue base or oropharynx can cause decreased tongue mobility and alterations in speech. Cancers of the oropharynx or

hypopharynx rarely cause early symptoms, but they may cause sore throat and/or otalgia.

Hoarseness may be an early symptom of laryngeal cancer, and persistent hoarseness requires referral to an otorhinolaryngologist for indirect laryngoscopy and/or radiographic studies. If a head and neck lesion treated initially with antibiotics does not resolve in a short period, further workup is indicated; to simply continue the antibiotic treatment may be to lose the chance of early diagnosis of a malignancy.

Advanced head and neck cancers in any location can cause severe pain, otalgia, airway obstruction, cranial neuropathies, trismus, odynophagia, dysphagia, decreased tongue mobility, fistulas, skin involvement, and massive cervical lymphadenopathy, which may be unilateral or bilateral. Some patients have enlarged lymph nodes even though no primary lesion can be detected by endoscopy or biopsy; these patients are considered to have carcinoma of unknown primary. If the enlarged nodes are located in the upper neck and the tumor cells are of squamous cell histology, the malignancy probably arose from a mucosal surface in the head or neck. Tumor cells in supraclavicular lymph nodes may also arise from a primary site in the chest or abdomen.

The physical examination should include scrutiny of all visible mucosal surfaces and palpation of the floor of mouth and tongue and of the neck. In addition to tumors themselves, leukoplakia -- a white mucosal patch -- or erythroplakia -- a red mucosal patch -- may be observed; these "premalignant" lesions can represent hyperplasia, dysplasia, or carcinoma in situ. All visible lesions should be biopsied. Further examination should be performed by the otorhinolaryngologist. Additional staging procedures include computed tomography of the head and neck to identify the extent of the disease. Patients with lymph node involvement should have chest radiography and a bone scan to screen for distant metastases. The definitive staging procedure is an endoscopic examination under anesthesia, which may include laryngoscopy, esophagoscopy, and bronchoscopy; during this procedure, multiple biopsy samples are obtained to establish a primary diagnosis, define the extent of primary disease, and identify any additional premalignant lesions or second primaries.

Head and neck tumors are classified according to the TNM system of the American Joint Committee on Cancer. This classification varies according to the specific anatomic subsite (Tables 87-1 and87-2). Distant metastases are found in <10% of patients at initial diagnosis, but in autopsy series, microscopic involvement of the lungs, bones, or liver is more common, particularly in patients with advanced neck lymph node disease.

In patients with lymph node involvement and no visible primary, the diagnosis should be made by lymph node excision. If the results indicate squamous cell carcinoma, a panendoscopy should be performed, with biopsy of all suspicious-appearing areas and directed biopsies of common primary sites, such as the nasopharynx, tonsil, tongue base, and pyriform sinus.

TREATMENT

Generally, patients with head and neck cancer can be categorized into three clinical groups: those with localized disease, those with locally or regionally advanced disease,

and those with recurrent and/or metastatic disease. Comorbidities associated with tobacco and alcohol abuse can affect treatment outcome.

Localized Disease Approximately one-third of patients have localized disease; that is, T1 or T2 (stage I or stage II) lesions without detectable lymph node involvement or distant metastases. These lesions are treated with curative intent by surgery or radiation. The choice of modality differs according to institutional expertise. Generally, radiation therapy is preferred for laryngeal cancer to preserve voice function, and surgery is preferred for small lesions in the oral cavity to avoid the long-term complications of radiation, such as xerostomia and dental decay. Overall 5-year survival is 60 to 90%.

Locally or Regionally Advanced Disease Locally or regionally advanced disease -- that is, disease with a large primary tumor and/or lymph node metastases -- can also be treated with curative intent, but not with surgery or radiation therapy alone. Combined modality therapy including surgery, radiation therapy and chemotherapy is most successful. Concomitant chemotherapy and radiation therapy appears to be the most effective sequencing of treatment.

Induction Chemotherapy In this strategy, patients receive chemotherapy [usually cisplatin and fluorouracil (5FU)] before surgery and radiotherapy. Most patients who receive three cycles of this combination show tumor reduction, and the response is clinically "complete" in up to half of these patients. This "sequential" multimodality therapy does not cure more patients than surgery plus radiation therapy alone. Time to recurrence may be improved but survival is similar. However, induction chemotherapy allows for organ preservation in patients with laryngeal and hypopharyngeal cancer.

Concomitant Chemoradiotherapy With the concomitant strategy, chemotherapy and radiation therapy are given simultaneously rather than sequentially. Because most patients with head and neck cancer develop recurrent disease in the head and neck area, this approach is aimed at killing radiation-resistant cancer cells with chemotherapy. In addition, chemotherapy can enhance cell killing by radiation therapy. Toxicity (mucositis) is increased with concomitant chemoradiotherapy; however, meta-analysis of randomized trials documents an improvement in 5-year survival of 8% with concomitant5FU and radiation therapy. Results seem even better with 5FU and cisplatin plus radiation therapy. Five-year survival is 34 to 50%. The use of radiation therapy together with cisplatin has produced markedly improved survival in patients with advanced nasopharyngeal cancer. The success of concomitant chemoradiotherapy in patients with unresectable disease has led to the testing of a similar approach in patients with resectable disease in an effort to increase organ preservation.

Recurrent and/or Metastatic Disease Patients with recurrent and/or metastatic disease are, with few exceptions, treated with palliative intent. Some patients may require local or regional radiation therapy for pain control, but most are given chemotherapy. Response rates to chemotherapy average only 30 to 50%; the duration of response averages only 3 months, and the median survival time is 6 months. Therefore, chemotherapy provides transient symptomatic benefit. Drugs with single-agent activity in this setting include methotrexate,5FU, cisplatin, paclitaxel, and docetaxel. Combinations of cisplatin and 5FU, carboplatin and 5FU, and cisplatin and

paclitaxel are also used.

CHEMOPREVENTION

b-carotene and *cis*-retinoic acid can lead to the regression of leukoplakia. In addition, the use of *cis*-retinoic acid may reduce the incidence of second primaries.

TREATMENT COMPLICATIONS

Complications involved in the treatment of head and neck cancer are usually related to the extent of surgery. Several attempts have been made to limit the extent of surgery or to replace it with chemotherapy and radiation therapy. Acute complications of radiation include mucositis and dysphagia. Long-term complications include xerostomia, loss of taste, decreased tongue mobility, second malignancies, and dysphagia and neck fibrosis. The complications of chemotherapy vary with the regimen used but usually include myelosuppression, mucositis, nausea and vomiting, and nephrotoxicity (with cisplatin).

SALIVARY GLAND TUMORS

Most benign salivary gland tumors are treated with surgical excision, and patients with invasive salivary gland tumors are treated with surgery and radiation therapy. Neutron radiation may be particularly effective. These tumors may recur regionally; adenoidcystic carcinoma has a tendency to recur along the nerve tracks. Distant metastases may occur as late as 10 to 20 years after the initial diagnosis. For metastatic disease, therapy is given with palliative intent, usually chemotherapy with doxorubicin and/or cisplatin.

88. NEOPLASMS OF THE LUNG - *John D. Minna*

Each year, primary carcinoma of the lung affects 94,000 males and 78,000 females in the United States, 86% of whom die within 5 years of diagnosis, making it the leading cause of cancer death in both men and women and in all races. The incidence of lung cancer peaks between ages 55 and 65 years. Lung cancer accounts for 31% of all cancer deaths in men and 25% in women. The effects of smoking cessation efforts begun 25 years ago have been seen in a slowing of the rate of age-adjusted cancer death from lung cancer in males (~70 per 100,000 male population); but, unfortunately, the rate in females is still increasing (~35 per 100,000 female population). Only 15% of patients have local disease at diagnosis; 25% have disease spread to regional lymph nodes, and>55% have distant metastases. The 5-year survival rate of patients with local disease is 50%; it is 20% for patients with regional disease and 14% overall. The 5-year overall lung cancer survival rate has nearly doubled in the last 30 years. The improvement is due to advances in combined-modality treatment with surgery, radiotherapy, and chemotherapy. Thus, primary carcinoma of the lung is a major health problem with a generally grim prognosis. However, an orderly approach to diagnosis, staging, and treatment based on knowledge of the clinical behavior of lung cancer and involving multidisciplinary input allows choice and delivery of the best therapy for potential cure or optimal palliation of individual patients.

PATHOLOGY

The term *lung cancer* is used for tumors arising from the respiratory epithelium (bronchi, bronchioles, and alveoli). Mesotheliomas, lymphomas, and stromal tumors (sarcomas) are distinct from epithelial lung cancer. Four major cell types make up 88% of all primary lung neoplasms according to the World Health Organization classification (Table 88-1). These are *squamous* or *epidermoid carcinoma*, *small cell* (also called *oat cell*) *carcinoma*, *adenocarcinoma* (including bronchioloalveolar), and *large cell* (also called *large cell anaplastic*) *carcinoma*. The remainder include undifferentiated carcinomas, carcinoids, bronchial gland tumors (including adenoid cystic carcinomas and mucoepidermoid tumors), and rarer tumor types. The various cell types have different natural histories and responses to therapy, and thus a correct histologic diagnosis by an experienced pathologist is the first step to correct treatment. In the past 25 years, for unknown reasons, adenocarcinoma has replaced squamous cell carcinoma as the most frequent histologic subtype for all sexes and races combined (Table 88-1).

Major treatment decisions are made on the basis of whether a tumor is classified histologically as a small cell carcinoma or as one of the non-small cell varieties (epidermoid, adenocarcinoma, large cell carcinoma, bronchioloalveolar carcinoma, and mixed versions of these). Some of the distinctions are summarized in Tables 88-1 and88-2. At presentation, small cell carcinomas usually have already spread such that surgery is unlikely to be curative, and they are managed primarily by chemotherapy with or without radiotherapy. In contrast, non-small cell cancers that are found to be localized at the time of presentation may be cured with either surgery or radiotherapy. Non-small cell cancers do not respond as well to chemotherapy as small cell cancers.

Ninety percent of patients with lung cancer of all histologic types are current or former cigarette smokers. Of the annual 171,600 new cases of lung cancer, ~50% develop in

former smokers. With increased success in smoking cessation efforts, the number of former smokers will grow, and these individuals will be important candidates for early detection and chemoprevention efforts. By far the most common form of lung cancer arising in lifetime nonsmokers, in women, and in young patients (<45 years) is adenocarcinoma. However, in nonsmokers with adenocarcinoma involving the lung, the possibility of other primary sites should be considered. Epidermoid and small cell cancers usually present as central masses with endobronchial growth, while adenocarcinomas and large cell cancers tend to present as peripheral nodules or masses, frequently with pleural involvement. Epidermoid and large cell cancers cavitate in ~10 to 20% of cases. Bronchioloalveolar carcinoma, a form of adenocarcinoma arising from peripheral airways, can present as a single mass; as a diffuse, multinodular lesion; or as a fluffy infiltrate.

ETIOLOGY

Most lung cancers are caused by carcinogens and tumor promoters ingested via cigarette smoking. The prevalence of smoking in the United States is 28% for males and 25% for females, age 18 years or older; 38% of high school seniors smoke. The relative risk of developing lung cancer is increased about 13-fold by active smoking and about 1.5-fold by long-term passive exposure to cigarette smoke. Chronic obstructive pulmonary disease, which is also smoking-related, further increases the risk of developing lung cancer. The lung cancer death rate is related to the total amount (often expressed in "cigarette pack-years") of cigarettes smoked, such that the risk is increased 60- to 70-fold for a man smoking two packs a day for 20 years as compared with a nonsmoker. Conversely, the chance of developing lung cancer decreases with cessation of smoking but may never return to the nonsmoker level. The increase in lung cancer rate in women is also associated with a rise in cigarette smoking. Women have a higher relative risk per given exposure than men (~1.5 fold higher), and women with lung cancer are more likely to have never smoked than men. This gender difference is likely due to a higher susceptibility to tobacco carcinogens in women.

Efforts to get people to stop smoking are mandatory. However, smoking cessation is extremely difficult, because the smoking habit represents a powerful addiction to nicotine (Chap. 390). Preventing people from starting to smoke may be more effective, an effort that needs to be targeted to children.

Although human lung cancer is not thought of as a genetic disease, various molecular genetic studies have shown the acquisition by lung cancer cells of a number of genetic lesions, including activation of dominant oncogenes and inactivation of tumor suppressor or recessive oncogenes (Chaps. 81 and82). In fact, lung cancer cells may have to accumulate a large number (perhaps³10) of such lesions. For the dominant oncogenes, these include point mutations in the coding regions of the *ras* family of oncogenes (particularly in the K-*ras* gene in adenocarcinoma of the lung); amplification, rearrangement, and/or loss of transcriptional control of *myc* family oncogenes (c-, N-, and L-*myc*; changes in c-*myc* are found in non-small cell cancers, while changes in all *myc* family members are found in small cell lung cancer); and overexpression of *bcl-2*, *Her-2/neu*, and the telomerase gene (Table 88-2). Tumor mutations in *ras* genes are associated with a poor prognosis in non-small cell lung cancer, while tumor amplification of c-*myc* is associated with a poor prognosis in small cell lung cancer.

For the recessive oncogenes (*tumor suppressor genes*), cytogenetic and allelotyping analyses have shown allele loss involving chromosome regions 1p, 1q, 3p12-13, 3p14 (*FHIT* gene region), 3p21, 3p24-25, 4p, 4q, 5q, 8p, 9p (*p16/CDKN2*, *p15,p19ARF* gene cluster), 11p13, 11p15, 13q14 (retinoblastoma, *rb*, gene), 16q, and 17p13 (*p53* gene), as well as other sites. Several candidate recessive oncogenes on chromosome 3p appear to be involved in nearly all lung cancers and may be affected early in preneoplastic lesions. The *p53* and *rb* genes are both mutated in>90% of small cell lung cancers, while *p53* is mutated in >50% and *rb* in 20% of non-small cell lung cancers. *p16/CDKN2* is abnormal in 10% of small cell and >50% of non-small cell lung cancers. Rb and *p16/CDKN2* are part of the same G1-to-S cell cycle regulatory pathway. Either one or the other of these elements appears to be mutated or to have its expression turned off (e.g., by hypermethylation of the promoter) in the large majority of lung cancers. Histologically identifiable preneoplastic lesions found in the respiratory epithelium of lung cancer patients and smokers include hyperplasia, dysplasia (progressively severe), and carcinoma in situ. 3p allele loss (hyperplasia) followed by 9p (*p16/CDKN2*) allele loss (hyperplasia) are the earliest events; 17p (*p53*) abnormalities and then *ras* mutations usually are found only in carcinoma in situ and invasive cancer. Thus, molecular changes involving allele loss and microsatellite alteration can be found in the earliest preneoplastic lesions and potentially even before any histologic changes are noted. Clinical trials of early diagnosis are needed to prove the usefulness of these molecular markers in the identification of very early lung cancer and in the monitoring of treatment and chemoprevention.

The large number of lesions shows that lung cancer, like other common epithelial malignancies, is a multistep process that is likely to involve both carcinogens and tumor promoters. Prevention can be directed at both processes. Lung cancer cells produce many peptide hormones and express receptors for these hormones, which can act to stimulate tumor cell growth in an "autocrine" fashion. Highly carcinogenic derivatives of nicotine are formed in cigarette smoke. Lung cancer cells of all histologic types express receptors for nicotine. Nicotine can prevent apoptosis in lung cancer cell lines. Thus, nicotine itself could be directly involved in lung cancer pathogenesis.

While lung cancer does not have a clear pattern of Mendelian inheritance, several features suggest a potential for familial association. Inherited mutations in *rb* (patients with retinoblastomas living to adulthood) and *p53* (Li-Fraumeni syndrome) genes may develop lung cancer. First-degree relatives of lung cancer probands have a two- to threefold excess risk of lung cancer or other cancers, many of which are not smoking-related. Genetic epidemiologic studies have proposed an association between the P450 enzyme or chromosome fragility (*mutagen sensitivity*) genotypes and the development of lung cancer. The identification of persons at very high risk of developing lung cancer would be useful in early detection and prevention efforts.

CLINICAL MANIFESTATIONS

Lung cancer gives rise to signs and symptoms caused by local tumor growth, invasion or obstruction of adjacent structures, growth in regional nodes through lymphatic spread, growth in distant metastatic sites after hematogenous dissemination, and remote effects of tumor products (paraneoplastic syndrome). Peptide hormone secretion

by the tumor or immunologic cross-reaction between tumor and normal tissue antigens can produce a variety of signs and symptoms (Chap. 100).

Although 5 to 15% of patients with lung cancer are identified while they are asymptomatic, usually as a result of a routine chest radiograph, most patients present with some sign or symptom. Central or endobronchial growth of the primary tumor may cause cough, hemoptysis, wheeze and stridor, dyspnea, and postobstructive pneumonitis (fever and productive cough). Peripheral growth of the primary tumor may cause pain from pleural or chest wall involvement, cough, dyspnea on a restrictive basis, and symptoms of lung abscess resulting from tumor cavitation. Regional spread of tumor in the thorax (by contiguous growth or by metastasis to regional lymph nodes) may cause tracheal obstruction, esophageal compression with dysphagia, recurrent laryngeal nerve paralysis with hoarseness, phrenic nerve paralysis with elevation of the hemidiaphragm and dyspnea, and sympathetic nerve paralysis with Horner's syndrome (enophthalmos, ptosis, miosis, and ipsilateral loss of sweating). *Pancoast's* (or *superior sulcus tumor*) *syndrome* results from local extension of a tumor (usually epidermoid) growing in the apex of the lung with involvement of the eighth cervical and first and second thoracic nerves, with shoulder pain that characteristically radiates in the ulnar distribution of the arm, often with radiologic destruction of the first and second ribs. Often Horner's syndrome and Pancoast's syndrome coexist. Other problems of regional spread include *superior vena cava syndrome* from vascular obstruction; pericardial and cardiac extension with resultant tamponade, arrhythmia, or cardiac failure; lymphatic obstruction with resultant pleural effusion; and lymphangitic spread through the lungs with hypoxemia and dyspnea. In addition, bronchioloalveolar carcinoma can spread transbronchially, producing tumor growing along multiple alveolar surfaces with impairment of gas exchange, respiratory insufficiency, dyspnea, hypoxemia, and sputum production.

Extrathoracic metastatic disease is found at autopsy in >50% of patients with epidermoid carcinoma, 80% of patients with adenocarcinoma and large cell carcinoma, and >95% of patients with small cell cancer. Lung cancer metastases may occur in virtually every organ system. Common clinical problems related to metastatic lung cancer include brain metastases with neurologic deficits; bone metastases with pain and pathologic fractures; bone marrow invasion with cytopenias or leukoerythroblastosis; liver metastases causing biochemical liver dysfunction, biliary obstruction, and pain; lymph node metastases in the supraclavicular region and occasionally in the axilla and groin; and spinal cord compression syndromes from epidural or bone metastases. Adrenal metastases are common but rarely cause adrenal insufficiency.

Paraneoplastic syndromes are common in patients with lung cancer and may be the presenting finding or first sign of recurrence. In addition, paraneoplastic syndromes may mimic metastatic disease and, unless detected, lead to inappropriate palliative rather than curative treatment. Often the paraneoplastic syndrome may be relieved with successful treatment of the tumor. In some cases, the pathophysiology of the paraneoplastic syndrome is known, particularly when a hormone with biologic activity is secreted by a tumor (Chap. 100). However, in many cases the pathophysiology is unknown. Systemic symptoms of anorexia, cachexia, weight loss (seen in 30% of patients), fever, and suppressed immunity are paraneoplastic syndromes of unknown etiology. *Endocrine syndromes* are seen in 12% of patients; hypercalcemia and

hypophosphatemia resulting from the ectopic production by epidermoid tumors of parathyroid hormone (PTH) or PTH-related peptide production, hyponatremia with the syndrome of inappropriate secretion of antidiuretic hormone or possibly atrial natriuretic factor by small cell cancer, and ectopic secretion by small cell cancer of adrenocorticotropic hormone (ACTH). ACTH secretion usually results in additional electrolyte disturbances, especially hypokalemia, rather than the changes in body habitus that occur in Cushing's syndrome from a pituitary adenoma.

Skeletal-connective tissue syndromes include clubbing in 30% of cases (usually non-small cell carcinomas) and hypertrophic pulmonary osteoarthropathy in 1 to 10% of cases (usually adenocarcinomas) with periostitis and clubbing giving pain, tenderness, and swelling over the affected bones and a positive bone scan. *Neurologic-myopathic syndromes* are seen in only 1% of patients but are dramatic and include the myasthenic *Eaton-Lambert syndrome* and retinal blindness with small cell cancer, while peripheral neuropathies, subacute cerebellar degeneration, cortical degeneration, and polymyositis are seen with all lung cancer types. Many of these are caused by autoimmune responses such as the development of anti-voltage-gated calcium channel antibodies in the Eaton-Lambert syndrome (Chap. 101). Coagulation, thrombotic, or other hematologic manifestations occur in 1 to 8% of patients and include migratory venous thrombophlebitis (*Trousseau's syndrome*), nonbacterial thrombotic (marantic) endocarditis with arterial emboli, disseminated intravascular coagulation with hemorrhage, and anemia, granulocytosis, and leukoerythroblastosis. Cutaneous manifestations such as dermatomyositis and acanthosis nigricans are uncommon (£1%), as are the renal manifestations of nephrotic syndrome or glomerulonephritis (£1%).

DIAGNOSIS AND STAGING

EARLY DIAGNOSIS

The screening of asymptomatic persons at high risk (men older than 45 years who smoke³40 cigarettes per day) by means of sputum cytology and chest radiographs has not improved the survival rate. Although 90% of patients whose lung cancer is detected by screening are asymptomatic, no difference was found in the survival rates of the screened and nonscreened groups. Women have not been studied. The use of low dose spiral computed tomography (CT) lung scanning may be more sensitive, particularly for peripheral lesions. However, false positive rates are high (25% have abnormal tests, only 10% of which are cancers), and survival benefit for screening has not yet been shown (Chap. 80).

ESTABLISHING A TISSUE DIAGNOSIS OF LUNG CANCER

Once signs, symptoms, or screening studies suggest lung cancer, a tissue diagnosis must be established. Tumor tissue can be obtained by a bronchial or transbronchial biopsy during fiberoptic bronchoscopy; by node biopsy during mediastinoscopy; from the operative specimen at the time of definitive surgical resection; by percutaneous biopsy of an enlarged lymph node, soft tissue mass, lytic bone lesion, bone marrow, or pleural lesion; by fine-needle aspiration of thoracic or extrathoracic tumor masses usingCTguidance; or from an adequate cell block obtained from a malignant pleural

effusion. In most cases, the pathologist should be able to make a definite diagnosis of epithelial malignancy and make the crucial differentiation of small cell from non-small cell lung cancer.

STAGING PATIENTS WITH LUNG CANCER

Lung cancer staging consists of two parts: first, a determination of the location of tumor (anatomic staging) and, second, an assessment of a patient's ability to withstand various antitumor treatments (physiologic staging). In a patient with non-small cell lung cancer, *resectability* (whether the tumor can be entirely removed by a standard surgical procedure such as a lobectomy or pneumonectomy), which depends on the anatomic stage of the tumor, and *operability* (whether the patient can tolerate such a surgical procedure), which depends on the cardiopulmonary function of the patient, are determined.

Non-Small Cell Lung Cancer The TNM International Staging System should be used for cases of non-small cell lung cancer, particularly in preparing patients for curative attempts with surgery or radiotherapy (Table 88-3). The various T (tumor size), N (regional node involvement), and M (presence or absence of distant metastasis) factors are combined to form different stage groups. At presentation, approximately one-third of patients have disease localized enough for a curative attempt with surgery or radiotherapy (patients with stage I or II disease and some with stage IIIA disease), one-third have distant metastatic disease (stage IV disease), and one-third have local or regional disease that may or may not be amenable to a curative attempt (some patients with stage IIIA disease and others with stage IIIB disease) (see below). This staging system provides useful prognostic information.

Small Cell Lung Cancer A simple two-stage system is used. In this system, limited-stage disease (seen in about 30% of all patients with small cell lung cancer) is defined as disease confined to one hemithorax and regional lymph nodes (including mediastinal, contralateral hilar, and usually ipsilateral supraclavicular nodes), while extensive-stage disease (seen in about 70% of patients) is defined as disease exceeding those boundaries. Clinical studies such as physical examination, x-rays,CT and bone scans, and bone marrow examination are used in staging. In part, the definition of limited-stage disease relates to whether the known tumor can be encompassed within a tolerable radiation therapy port. Thus, contralateral supraclavicular nodes, recurrent laryngeal nerve involvement, and superior vena caval obstruction can all be part of limited-stage disease. However, cardiac tamponade, malignant pleural effusion, and bilateral pulmonary parenchymal involvement generally qualify disease as extensive-stage because the organs within a curative radiation therapy port cannot safely tolerate curative radiation doses.

GENERAL STAGING PROCEDURES (See Table 88-4)

All patients with lung cancer should have a complete history and physical examination, with evaluation of all other medical problems, determination of performance status and history of weight loss, and aCT scan of the chest and abdomen with contrast. Positron emission tomography (PET) scans are sensitive in detecting metastatic disease. While not done in every patient, fiberoptic bronchoscopy provides material for pathologic

examination, information on tumor size, location, degree of bronchial obstruction (i.e., assesses resectability), and recurrence.

Chest radiographs andCT scans are needed to evaluate tumor size and nodal involvement; old radiographs are useful for comparison. CT scans are of use in the preoperative staging of non-small cell lung cancer to detect mediastinal nodes and pleural extension and occult abdominal disease (e.g., of the liver and adrenal glands), as well as in the planning of curative radiation therapy to allow the design of fields to encompass all the known tumor while avoiding as much normal tissue as possible. However, mediastinal nodal involvement should be documented histologically if the findings will influence therapeutic decisions. Thus, sampling of lymph nodes via mediastinoscopy or thoracotomy to establish the presence or absence of N2 or N3 nodal involvement is crucial in considering a curative surgical approach for patients with non-small cell lung cancer with clinical stage I, II, or III disease. Likewise, unless the CT-detected abnormalities are unequivocal, histology of suspicious abdominal lesions should be confirmed by procedures such as fine-needle aspiration if the patient would otherwise be considered for curative treatment. In small cell lung cancer, CT scans are used in the planning of chest radiation treatment and in the assessment of the response to chemotherapy and radiation therapy. Surgery or radiotherapy can make interpretation of conventional chest x-rays difficult; after treatment, CT scans can provide good evidence of tumor recurrence.

If signs or symptoms suggest involvement by tumor, brainCT or bone scans are performed, as well as radiography of any suspicious bony lesions. Any accessible lesions suspicious for cancer should be biopsied if a histologic diagnosis would influence treatment.

In patients presenting with a mass lesion on chest x-ray orCT scan and no obvious contraindications to a curative approach after the initial evaluation, the mediastinum must be investigated. Approaches vary among centers and include performing chest CT scan and mediastinoscopy (for right-sided tumors) or lateral mediastinotomy (for left-sided lesions) on all patients and proceeding directly to thoracotomy for staging of the mediastinum. In patients presenting with disease that is confined to the chest but not resectable, and who thus are candidates for neoadjuvant chemotherapy plus surgery or for curative radiotherapy with or without chemotherapy, other tests are done as indicated to evaluate specific symptoms. In patients presenting with non-small cell cancer that is not curable, all the general staging procedures are done, plus fiberoptic bronchoscopy as indicated to evaluate hemoptysis, obstruction, or pneumonitis, as well as thoracentesis with cytologic examination (and chest tube drainage as indicated) if fluid is present. As a rule, a radiographic finding of an isolated lesion (such as an enlarged adrenal gland) should be confirmed as cancer by fine-needle aspiration before a curative attempt is rejected.

STAGING OF SMALL CELL LUNG CANCER

Pretreatment staging for patients with small cell lung cancer includes the initial general lung cancer evaluation with chest and abdominalCT scans (because of the high frequency of hepatic and adrenal involvement) as well as fiberoptic bronchoscopy with washings and biopsies to determine the tumor extent before therapy; brain CT scan

(10% of patients have metastases); bone marrow biopsy and aspiration (20 to 30% of patients have tumor in the bone marrow); and radionuclide scans (bone) if symptoms or other findings suggest disease involvement in these areas. Chest and abdominal CT scans are very useful to evaluate and follow tumor response to therapy, and chest CT scans are helpful in planning chest radiotherapy ports.

If signs or symptoms of spinal cord compression or leptomeningitis develop at any time in lung cancer patients with disease of any histologic type, a spinalCT scan or magnetic resonance imaging (MRI) scan and examination of the cerebrospinal fluid cytology are performed. If malignant cells are detected, radiation therapy to the site of compression and intrathecal chemotherapy (usually with methotrexate) are given. In addition, a brain CT or MRI scan is performed to search for brain metastases, which often are associated with spinal cord or leptomeningeal metastases.

DETERMINATION OF RESECTABILITY AND OPERABILITY

In patients with non-small cell lung cancer, the following are major contraindications to curative surgery or radiotherapy alone: extrathoracic metastases; superior vena cava syndrome; vocal cord and, in most cases, phrenic nerve paralysis; malignant pleural effusion; cardiac tamponade; tumor within 2 cm of the carina (not curable by surgery but potentially curable by radiotherapy); metastasis to the contralateral lung; bilateral endobronchial tumor (potentially curable by radiotherapy); metastasis to the supraclavicular lymph nodes; contralateral mediastinal node metastases (potentially curable by radiotherapy); and involvement of the main pulmonary artery. Most patients with small cell lung cancer have unresectable disease; however, if clinical findings suggest the potential for resection (most common with peripheral lesions), that option should be considered.

PHYSIOLOGIC STAGING

Patients with lung cancer often have cardiopulmonary and other problems related to chronic obstructive pulmonary disease as well as other medical problems. To improve their preoperative condition, correctable problems (e.g., anemia, electrolyte and fluid disorders, infections, and arrhythmias) should be addressed, smoking stopped, and appropriate chest therapy instituted. Since it is not always possible to predict whether a lobectomy or pneumonectomy will be required until the time of operation, a conservative approach is to restrict resectional surgery to patients who could potentially tolerate a pneumonectomy. In addition to nonambulatory performance status, a myocardial infarction within the past 3 months is a contraindication to thoracic surgery because 20% of patients will die of reinfarction, while an infarction in the past 6 months is a relative contraindication. Other major contraindications include uncontrolled major arrhythmias, a maximum breathing capacity <40% of the predicted value, an FEV_1(forced expiratory volume in 1 s) <1 L, CO_2retention (which is more serious than hypoxemia), and severe pulmonary hypertension. Recommending surgery when the FEV_1 is 1.1 to 2.4 L requires careful judgment, while an FEV_1>2.5 L usually permits a pneumonectomy. In patients with borderline pulmonary status or a question of pulmonary hypertension, split pulmonary function testing by ventilation-perfusion lung scans can define physiologic operability. The activity from quantitative scans is summed for each lung in the anterior and posterior views, and the ratio of the normal to total lung

activity is multiplied by the FEV_1. Pneumonectomy usually is physiologically tolerable if this predicted value is>1 L.

TREATMENT

The overall treatment approach to patients with lung cancer is shown inTable 88-5. Patients should be encouraged to stop smoking. Those who do fare better than those who continue to smoke.

Non-Small Cell Lung Cancer: Localized Disease

Surgery In patients with non-small cell lung cancer of stages IA, IB, IIA and IIB (Table 88-3) who can tolerate operation, the treatment of choice is pulmonary resection. In stage IIIA cases where the patient's age, cardiopulmonary function, and anatomy are favorable, resection also should be considered. If a complete resection is possible, the 5-year survival rate for N1 disease is about 50%, while it is about 20% for N2 disease. However, only 20% of cases of N2 disease are technically resectable, and most of these are discovered to be N2 only at thoracotomy. Surgery for N2 disease is the most controversial area in the surgical management of lung cancer. Patients with N2 disease can be divided into "minimal" disease (involvement of only one node with microscopic foci, usually discovered at thoracotomy or mediastinoscopy) and the more common "advanced," bulky disease, clinically obvious onCT scans and discovered preoperatively. Patients with contralateral or bilateral positive mediastinal (N3) nodes, extracapsular nodal involvement, or fixed nodes are not considered candidates for resection. Approaches that may make resection possible include chest wall resection for direct extension of tumor, tracheal sleeve pneumonectomy, and sleeve lobectomy for lesions near the carina. Neoadjuvant (preoperative) chemotherapy has response rates of 50 to 60% and causes unresectable disease to become resectable in many patients who respond (see below). Video-assisted thoracic surgery (VATS) via thoracoscopy is not usually used for curative lung cancer resection but may be useful for peripheral lesions in patients with poor lung function.

The extent of resection is a matter of surgical judgment based on findings at exploration. Conservative resection that encompasses all known tumor gives survival equal to that obtained with more extensive procedures. However, lobectomy is superior to wedge resection in reducing the rate of local recurrence. Thus, lobectomy is preferred to pneumonectomy and wedge resection. Wedge resection and segmentectomy (potentially byVATS) are reserved for patients with poor pulmonary reserve and small peripheral lesions. About 43% of all patients with lung cancer undergo thoracotomy. Of these, 76% have a definitive resection, 12% are explored only for disease extent, and 12% have a palliative procedure with known disease left behind. About 30% of patients treated with resection for cure survive for 5 years, and 15% survive for 10 years (Table 88-3). The 30-day hospital mortality rate after pulmonary resection is 3% for lobectomy and 6% for pneumonectomy. Thus, most patients thought to have a "curative" resection ultimately die of metastatic disease (usually within 5 years of surgery).

Management of occult and stage 0 carcinomas In the uncommon situation where malignant cells are identified in a sputum or bronchial washing specimen but the chest radiograph appears normal (TX tumor stage), the lesion must be localized. More than

90% can be localized by meticulous examination of the bronchial tree with a fiberoptic bronchoscope under general anesthesia and collection of a series of differential brushings and biopsies. Often, carcinoma in situ or multicentric lesions are found in these patients. Current recommendations are for the most conservative surgical resection, allowing removal of the cancer and conservation of lung parenchyma, even if the bronchial margins are positive for carcinoma in situ. The 5-year overall survival rate for these occult cancers is ~60%. Close follow-up of these patients is indicated because of the high incidence of second primary lung cancers (5% per patient per year). One approach to in situ or multicentric lesions uses systemically administered hematoporphyrin (which localizes to tumors and sensitizes them to light) followed by bronchoscopic phototherapy.

Solitary pulmonary nodule When a patient presents with an asymptomatic, solitary pulmonary nodule (defined as an x-ray density completely surrounded by normal aerated lung, with circumscribed margins, of any shape, usually 1 to 6 cm in greatest diameter), a decision to resect or follow the nodule must be made. Approximately 35% of all such lesions in adults are malignant, most being primary lung cancer, while <1% are malignant in nonsmokers under 35 years of age. A complete history, including a smoking history, physical examination, routine laboratory tests, chestCT scan, fiberoptic bronchoscopy, and old chest x-rays are obtained.PETscans are useful in detecting lung cancers >1.5 cm in diameter. If no diagnosis is immediately apparent, the following risk factors would all argue strongly in favor of proceeding with resection to establish a histologic diagnosis: a history of cigarette smoking; age 35 years or older; a relatively large lesion; lack of calcification; chest symptoms; associated atelectasis, pneumonitis, or adenopathy; and growth of the lesion revealed by comparison with old x-rays. At present, only two radiographic criteria are reliable predictors of the benign nature of a solitary pulmonary nodule: lack of growth over a period >2 years and certain characteristic patterns of calcification. Calcification alone does not exclude malignancy. However, a dense central nidus, multiple punctate foci, and "bull's eye" (granuloma) and "popcorn ball" (hamartoma) calcifications are all highly suggestive of a benign lesion.

When old x-rays are not available and the characteristic calcification patterns are absent, the following approach is reasonable: Nonsmoking patients younger than 35 years can be followed with serialCT every 3 months for 1 year and then yearly. If any significant growth is found, a histologic diagnosis is needed. For patients older than 35 years and all patients with a smoking history, a histologic diagnosis must be made. The sample for histologic diagnosis can be obtained either at the time of nodule resection or, if the patient is a poor operative risk, viaVATS or transthoracic fine-needle biopsy. Some institutions use preoperative fine-needle aspiration on all such lesions; however, all positive lesions have to be resected, and negative cytologic findings in most cases have to be confirmed by histology on a resected specimen. While much has been made of sparing patients an operation, the high probability of finding a malignancy (particularly in smokers older than 35 years) and the excellent chance for surgical cure when the tumor is small both suggest an aggressive approach to these lesions.

The application of low-dose spiralCTscanning to high-risk populations is under investigation. The test identifies a large number of asymptomatic pulmonary nodules that require evaluation. Approximately 23% of screened high-risk patients have an abnormality, and ~12% of the detected abnormalities are lung cancer. Criteria for

distinguishing cancers from nonmalignant lesions short of a lobectomy are being developed. Lesions >1 cm are usually resected; those£1 cm are followed for change at 3-month intervals. Although a number of early lung cancers are detected in this way, it is not yet clear that survival is improved.

Radiotherapy with curative intent Patients with stage III disease, as well as patients with stage I or II disease who refuse surgery or are not candidates for pulmonary resection, should be considered for radiation therapy with curative intent. The decision to administer high-dose radiotherapy is based on the extent of disease and the volume of the chest that requires irradiation. Patients with distant metastases, malignant pleural effusion, or cardiac involvement are generally not considered for curative radiation treatment. The median survival period for patients with unresectable non-small cell lung cancer localized to the chest who undergo primary radiotherapy with curative intent is<1 year. However, 6% of these patients are alive at 5 years and are cured by radiotherapy alone. In addition to being potentially curative, radiotherapy, by controlling the primary tumor, may increase the quality and length of life of noncured patients. Treatment usually involves midplane doses of 55 to 60 Gy, and the major concern is the amount of lung parenchyma and other organs in the thorax included in the treatment plan, including the spinal cord, heart, and esophagus. In patients with a major degree of underlying pulmonary disease, the treatment plan may have to be compromised because of the deleterious effect of radiation on pulmonary function. The risk of radiation pneumonitis is proportional to the radiation dose and the volume of lung in the field. The full clinical syndrome (dyspnea, fever, and radiographic infiltrate corresponding to the treatment port) occurs in 5% of cases. Acute radiation esophagitis occurs during treatment but usually is self-limited, while spinal cord injury should be avoided by careful treatment planning. Continuous hyperfractionated accelerated radiation therapy (CHART) involves delivery of 36 treatments of 1.5 Gy given 3 times a day for 12 consecutive days to a total dose of 54 Gy. The 2-year survival rate increased from 20 to 29% with CHART, although more esophagitis occurred. Brachytherapy (local radiotherapy delivered by placing radioactive "seeds" in a catheter in the tumor bed) provides a way to give a high local dose while sparing surrounding normal tissue.

Combined-modality therapy with curative intent After apparently complete resection, adjuvant radiation therapy has not been shown to improve survival. Meta-analysis of studies with post-operative radiation therapy found it to be deleterious to survival in patients with stage I and II disease.

Carcinomas of the superior pulmonary sulcus producing *Pancoast's syndrome* are usually treated with combined radiotherapy and surgery. Patients with these carcinomas should have the usual preoperative staging procedures, including mediastinoscopy andCT scans to determine tumor extent and a neurologic examination (and sometimes nerve conduction studies) to document neurologic findings. Sometimes a histologic diagnosis is not made, but the combination of tumor location and pain distribution permit a diagnostic accuracy for cancer of>90%. If mediastinoscopy is negative, two curative approaches may be used in treating a Pancoast's syndrome tumor. Preoperative irradiation [30 Gy in 10 treatments] is given to the area, followed by an en bloc resection of the tumor and involved chest wall 3 to 6 weeks later. The 3 year survival rate is 42% for epidermoid and 21% for adeno- and large cell carcinomas. The second approach involves radiotherapy alone in curative doses and standard fractionation, which leads to

survival rates similar to those from combined-modality therapy.

A meta-analysis of chemotherapy in non-small cell lung cancer used updated data on 9387 individual patients from 52 randomized trials, both published and unpublished, with the main outcome measure being survival. Regimens containing cisplatin were significantly more effective than no treatment. Trials in early-stage disease comparing surgery with surgery plus chemotherapy gave a hazard ratio of 0.87 (13% reduction in risk of death at 5 years) in favor of chemotherapy. Confidence intervals of these data are wide. However, adjuvant chemotherapy is, in general, not considered standard treatment.

The most impressive benefits were obtained when chemotherapy was added to radiotherapy for locally advanced disease (stage IIIB and some stage IIIA disease) and when chemotherapy was given preoperatively in a neoadjuvant fashion in stage IIIA disease. Preoperative neoadjuvant chemotherapy is widely used for stage IIIA disease. Preoperative combined modality therapy followed by surgical resection has given promising early results. Whether the surgery adds benefit after chemoradiotherapy has not been defined. Provided the risk/benefit ratio of using chemotherapy is discussed appropriately with patients, such therapy can be given in a noninvestigational setting. For stage IIIA disease, resection followed by postoperative radiation plus chemotherapy for N2 disease, neoadjuvant chemotherapy followed by surgical resection, or neoadjuvant chemoradiotherapy followed by resection are options. For stage IIIB and bulky IIIA disease, neoadjuvant chemotherapy (2 or 3 cycles of a cisplatin-based combination) followed by chest radiation therapy (60 Gy) has improved median survival time from 10 to 14 months and the 5-year survival rate from 7 to 17% compared to results with radiation therapy alone. Administration of radiation and chemotherapy concurrently is being tested; myelotoxicity and esophagitis are increased, but survival improvement is not yet proven. Randomized clinical trials also are needed to evaluate the usefulness of the new agents with activity against non-small cell lung cancer, including the taxanes (paclitaxel and docetaxel), vinorelbine, gemcitabine, and camptothecins (topotecan and CPT-11) in both adjuvant and neoadjuvant settings.

Disseminated Non-Small Cell Lung Cancer The 70% of patients who have unresectable non-small cell cancer have a poor prognosis. Patients with performance status scores of 0 (asymptomatic), 1 (symptomatic, fully ambulatory), 2 (in bed <50% of the time), 3 (in bed >50% of the time), and 4 (bedridden) have median survival times of 34, 25, 17, 8, and 4 weeks, respectively. Standard medical management, the judicious use of pain medications, the appropriate use of radiotherapy, and outpatient chemotherapy form the cornerstone of management. Patients whose primary tumor is causing symptoms such as bronchial obstruction with pneumonitis, hemoptysis, or upper airway or superior vena cava obstruction should have radiotherapy to the primary tumor. The case for prophylactic treatment of the asymptomatic patient is to prevent major symptoms from occurring in the thorax. However, if the patient can be followed closely, it may be appropriate to defer treatment until symptoms develop. Usually a course of 30 to 40 Gy over 2 to 4 weeks is given to the tumor. Radiation therapy provides relief of intrathoracic symptoms with the following frequencies: hemoptysis, 84%; superior vena cava syndrome, 80%; dyspnea, 60%; cough, 60%; atelectasis, 23%; and vocal cord paralysis, 6%. Cardiac tamponade (treated with pericardiocentesis and radiation therapy to the heart), painful bony metastases (with relief in 66%), brain or

spinal cord compression, and brachial plexus involvement may also be palliated with radiotherapy. Usually, with brain metastases and cord compression, dexamethasone (25 to 100 mg/d in four divided doses) is also given and then rapidly tapered to the lowest dosage that relieves symptoms.

Brain metastases often are isolated instances of relapse in patients with adenocarcinoma of the lung otherwise controlled by surgery or radiotherapy. However, there is no proven value for prophylactic cranial irradiation or forCT scans of the head in asymptomatic patients.

Pleural effusions are common and are usually treated with thoracentesis. If they recur and are symptomatic, chest tube drainage with a sclerosing agent such as intrapleural talc is used. First, the chest cavity is completely drained. Xylocaine 1% is instilled (15 mL), followed by 50 mL normal saline. Then, 10 g sterile talc is dissolved in 100 mL normal saline, and this solution is injected through the chest tube. The chest tube is clamped for 4 h if tolerated, and the patient is rotated onto different sides to distribute the sclerosing agent. The chest tube is removed 24 to 48 h later, after drainage has become slight (usually <100 mL/24 h).VATS has been used to drain and treat large malignant effusions. Symptomatic endobronchial lesions that recur after surgery or radiotherapy or that develop in patients with severely compromised pulmonary function are difficult to treat with conventional therapy. Neodynium-YAG (yttrium-aluminum-garnet) laser therapy administered through a flexible fiberoptic bronchoscope (usually under general anesthesia) can provide palliation in 80 to 90% of patients even when the tumor has relapsed after radiotherapy. Local radiotherapy delivered by brachytherapy, photodynamic therapy using a photosensitizing agent, and endobronchial stents are other measures that can relieve airway obstruction from tumor.

Chemotherapy The use of chemotherapy for non-small cell lung cancer requires careful judgment to balance potential benefits and toxicity. Modest survival benefits (of 1 to 2 months), symptom palliation, and improved quality of life may accrue from combination chemotherapy. Randomized trials in advanced disease comparing supportive care with supportive care plus chemotherapy gave a hazard ratio of 0.73 (27% reduction in risk of death at 1 year) in favor of including chemotherapy. Economic analysis has found chemotherapy to be cost-effective palliation. Combination chemotherapy produces an objective tumor response in ~30 to 40% of patients; the response is complete in <5%. Median survival for chemotherapy-treated patients is 9 to 10 months, and the 1-year survival rate is 40%. Thus, in patients with non-small cell lung cancer who desire chemotherapy, it is reasonable to give chemotherapy if the patient is ambulatory, has not received prior chemotherapy, and is able to understand and accept the risk/benefit ratio from such therapy. The chemotherapy should be one of the published standard regimens, such as paclitaxel plus carboplatin, paclitaxel plus cisplatin, or vinorelbine plus cisplatin. Improved antiemetics have made treatment tolerable on an outpatient basis. New drugs with proven activity in non-small cell lung cancer include docetaxel, irinotecan, and gemcitabine. All eligible patients should be encouraged to enter clinical studies that are designed to determine the benefits and toxicities of these new treatments.

Small Cell Lung Cancer Untreated patients with small cell lung cancer have a median survival period of 6 to 17 weeks, while patients treated with combination chemotherapy

have a median survival period of 40 to 70 weeks. Thus, chemotherapy with or without radiotherapy or surgery can prolong survival in patients with small cell lung cancer. The goal of treatment is to achieve a complete clinical regression of tumor documented by repeating the initial positive staging procedures, particularly fiberoptic bronchoscopy with washings and biopsy. The initial response, determined 6 to 12 weeks after the start of therapy, predicts both the median and long-term survivals and the potential for cure. Patients who achieve a complete clinical regression survive longer than patients with only partial regression, who in turn survive longer than patients with no response. Complete response is required for long-term (>3-year) survival.

After initial staging, patients are classified as having limited or extensive disease and as being physiologically able or not able to tolerate combination chemotherapy or chemoradiotherapy. The overall mortality rate from initial combination chemotherapy even in these selected patients is 1 to 5%, comparable with the operative mortality rate for pulmonary resection. Such therapy should be reserved for ambulatory patients with no prior chemotherapy or radiotherapy; no other major medical problems; and adequate heart, liver, renal, and bone marrow function. The arterial P_{O2} on room air should be >6.6 kPa (50 mmHg), and there should be no CO_2retention. For patients with limitations in any of these areas, the initial combined-modality therapy or chemotherapy must be modified to prevent undue toxicity. In all patients, these treatments must be coupled with supportive care for infectious, hemorrhagic, and other medical complications.

Chemotherapy The combination most widely used is etoposide plus cisplatin or carboplatin, given every 3 weeks on an outpatient basis for 4 to 6 cycles. Another active regimen is etopside, cisplatin, and paclitaxel. Increased dose intensity of chemotherapy adds toxicity without clear survival benefit. Appropriate supportive care (antiemetic therapy, administration of fluid and saline boluses with cisplatin, monitoring of blood counts and blood chemistries, monitoring for signs of bleeding or infection, and, as required, administration of erythropoietin and granulocyte colony-stimulating factor) and adjustment of chemotherapy doses on the basis of nadir granulocyte counts are essential. The initial combination chemotherapy may result in moderate to severe granulocytopenia (e.g., granulocyte counts <500 to 1500/uL) and thrombocytopenia (platelet counts <50,000 to 100,000/uL). After the initial 4 to 6 cycles of therapy, patients should be restaged to determine if they have entered a complete clinical remission, indicated by complete disappearance of all clinically evident lesions and paraneoplastic syndromes, or a partial remission, or have no response or tumor progression (seen in 10 to 20% of patients). Chemotherapy is then stopped in responding patients. More prolonged chemotherapy has not been shown to be of value. Patients whose tumors are progressing or not responding should be switched to a new, experimental chemotherapy regimen. Oral etoposide, as a single agent, has been shown to be of clinical benefit in the initial treatment of patients who are elderly or have a very poor performance status.

Radiotherapy High-dose (40 Gy) radiotherapy to the whole brain should be given to patients with documented brain metastases. Prophylactic cranial irradiation (PCI) may be given to patients with complete responses, since it significantly decreases the development of brain metastases (which occur in 60 to 80% of patients living³2 years who do not receive PCI), but survival benefit is small (5%). Because some studies indicate possible deficits in cognitive ability that could be related to PCI, the long-term quality of life after PCI needs to be further studied. The patient needs to be informed of

the risks and benefits. In the case of symptomatic, progressive lesions in the chest or at other critical sites, if radiotherapy has not yet been given to these areas, it may be administered in full doses (e.g., 40 Gy to the chest tumor mass).

Combined-modality therapy Most patients with limited-stage small cell lung cancer should receive combined-modality therapy with etoposide plus cisplatin (or other platinum-containing regimen) and concurrent chest radiotherapy. Acute and chronic toxicities are expected with chemoradiotherapy, particularly when the chemotherapy and radiotherapy are given concurrently. However, the addition of chest radiation therapy to chemotherapy reduces the local failure rate and improves survival. Patients should be selected (limited-stage disease, a performance status of 0 to 1, and initial good pulmonary function) such that radiotherapy can be given in full doses and in a manner that does not sacrifice too much lung function. Some studies show twice-daily radiation fractions produce less toxicity and improve survival compared to once-daily treatments, but large randomized trials are still needed.

For extensive-stage disease, initial chest radiotherapy usually is not advocated. However, for favorable patients (e.g., those with a performance status of 0 to 1, good pulmonary function, and only one site of extensive disease), the addition of chest radiotherapy to chemotherapy can be considered. For all patients, if chemotherapy is inadequate to relieve local tumor symptoms, a course of radiotherapy can be added.

About 20 to 30% of patients with limited-stage disease and 1 to 5% of patients with extensive-stage disease are cured. About 50% of patients with limited-stage and 30% of patients with extensive-stage disease enter complete remission, and 90 to 95% of all patients have complete or partial responses. These responses increase the median survival period to 10 to 12 months for patients with extensive-stage disease and to 14 to 18 months for patients with limited-stage disease, as compared with 2 to 4 months for untreated patients. In addition, most patients have relief of their tumor-related symptoms and improvement of performance status. However, the maintenance of good performance status in a patient receiving outpatient chemotherapy requires judgment and skill to avoid undue therapeutic toxicity. New treatments, such as new drug combinations, very intensive initial or "reinduction" therapy with autologous bone marrow infusion, and novel ways of combining chemotherapy, radiotherapy, and surgery, should be given only in the context of an approved clinical protocol.

Although surgical resection is not routinely recommended for small cell lung cancer, occasional patients meet the usual requirements for resectability (stage I or II disease with negative mediastinal nodes). Moreover, this histologic diagnosis is made in some patients only on review of the resected surgical specimen. Such patients have been reported to have high cure rates (>25%) if adjuvant chemotherapy is used.

LUNG CANCER PREVENTION

Deterring children from taking up smoking is likely to be the most effective lung cancer prevention. Smoking cessation programs are successful in 5 to 20% of volunteers; the poor efficacy is because of the nature of nicotine addiction. Early diagnosis strategies have the problem of high false-positive rates, which add to the expense and the failure of such strategies to result in improved survival.

Chemoprevention may be an approach to reduce lung cancer risk. Patients with head and neck cancer, who are at increased risk of developing lung cancer, experienced a decrease in second cancers when given 13-cis retinoic acid. However, the drug causes significant toxicity, and its activity is not yet confirmed. Vitamin E andb-carotene supplements actually increase the risk of lung cancer. Thus, currently no strategy for chemoprevention of lung cancer has been proven effective.

BENIGN LUNG NEOPLASMS

The benign neoplasms of the lung, representing <5% of all primary tumors, include bronchial adenomas and hamartomas (90% of such lesions) and a group of very uncommon neoplasms (chondromas, fibromas, lipomas, hemangiomas, leiomyomas, teratomas, pseudolymphomas, and endometriosis). The diagnostic and primary-treatment approach is basically the same for all these neoplasms. They can present as central masses causing airway obstruction, cough, hemoptysis, and pneumonitis. The masses may or may not be visible on radiographs but usually are accessible to fiberoptic bronchoscopy. Alternatively, they can present without symptoms as solitary pulmonary nodules and thus will be evaluated as part of a solitary pulmonary nodule workup. In all cases, the extent of surgery must be determined at operation, and a conservative procedure with appropriate reconstructions is usually performed.

BRONCHIAL ADENOMAS

Bronchial adenomas (80% are central) are slow-growing, endobronchial lesions; they represent 50% of all benign pulmonary neoplasms. About 80 to 90% are carcinoids, 10 to 15% are adenocystic tumors (or cylindromas), and 2 to 3% are mucoepidermoid tumors. Adenomas present in patients 15 to 60 years old (average age, 45) as endobronchial lesions and are often symptomatic for several years. Patients may have a chronic cough, recurrent hemoptysis, or obstruction with atelectasis, lobar collapse, or pneumonitis and abscess formation. Bronchial carcinoids, which usually follow a benign course, and small cell lung cancers, which are highly malignant, both express a neuroendocrine phenotype similar to the Kulchitsky cell. This cell is part of the amine precursor uptake and decarboxylation (APUD) system. Carcinoids, like small cell lung cancers, may secrete other hormones, such asACTH or arginine vasopressin, and can cause paraneoplastic syndromes that resolve on resection. In addition, bronchial carcinoid metastases (usually to the liver) may produce the carcinoid syndrome, with cutaneous flush, bronchoconstriction, diarrhea, and cardiac valvular lesions (Chap. 93), which small cell lung cancer does not. Occasionally, pathologists may have difficulty distinguishing carcinoids from small cell lung cancers. Carcinoid tumors that have an unusually aggressive histologic appearance (referred to as *atypical carcinoids*) metastasize in 70% of cases to regional nodes, liver, or bone, compared with only a 5% rate of metastasis for carcinoids with typical histology.

Bronchial adenomas of all types, because of their endobronchial and often central location, are usually visible by fiberoptic bronchoscopy; and tissue for histologic diagnosis is obtained in this manner. Because they are hypervascular, they can bleed profusely after bronchoscopic biopsy, and this problem should be anticipated. Bronchial adenomas must be dealt with as potentially malignant and thus require removal not only

for symptom relief but also because they can be locally invasive or recurrent, potentially can metastasize, and may produce paraneoplastic syndromes. Surgical excision is the primary treatment for all types of bronchial adenomas. The extent of surgery is determined at operation and should be as conservative as possible. Often bronchotomy with local excision, sleeve resection, segmental resection, or lobectomy is sufficient. Five-year survival rates after surgical resection are 95%, decreasing to 70% if regional nodes are involved. The treatment of metastatic pulmonary carcinoids is unclear because they can either be indolent or behave more like small cell lung carcinoma. Assessment of the tempo and histology of the disease in the individual patient is necessary to determine if and when chemotherapy or radiotherapy is indicated.

HAMARTOMAS

Pulmonary hamartomas have a peak incidence at age 60 and are more frequent in men than in women. Histologically, they contain normal pulmonary tissue components (smooth muscle and collagen) in a disorganized fashion. They are usually peripheral, clinically silent, and benign in their behavior. Unless the radiographic findings are pathognomonic for hamartoma, with "popcorn" calcification, the lesions usually have to be resected for diagnosis, particularly if the patient is a smoker.VATS may minimize the surgical complications.

METASTATIC PULMONARY TUMORS

The lung is a frequent site of metastases from primary cancers outside the lung. Usually such metastatic disease is considered incurable. However, two special situations should be borne in mind. The first is the development of a solitary pulmonary shadow on a chest x-ray in a patient known to have an extrathoracic neoplasm. This shadow may represent a metastasis or a new primary lung cancer. Because the natural history of lung cancer is often worse than that of other primary tumors, a single pulmonary nodule in a patient with a known extrathoracic tumor is approached as though the nodule is a primary lung cancer, particularly if the patient is older than 35 years and a smoker. If a vigorous search for other sites of active cancer proves negative, the nodule is surgically resected. Second, in some cases, multiple pulmonary nodules can be resected with curative intent. This tactic is usually recommended if, after careful staging, it is found that (1) the patient can tolerate the contemplated pulmonary resection, (2) the primary tumor has been definitively and successfully treated, and (3) all known metastatic disease can be encompassed by the projected pulmonary resection. The key is selection and screening of patients to exclude those with uncontrolled primary tumors and extrapulmonary metastases. Primary tumors whose pulmonary metastases have been successfully resected for cure include osteogenic and soft tissue sarcomas; colon, rectal, uterine, cervix, and corpus tumors; head and neck, breast, testis, and salivary gland cancer; melanoma; and bladder and kidney tumors. Five-year survival rates of 20 to 30% have been found in carefully selected patients, and dramatic results have been achieved in patients with osteogenic sarcomas, where resection of pulmonary metastases (sometimes requiring several thoracotomies) is becoming a standard curative treatment approach.

89. BREAST CANCER - *Marc E. Lippman*

Breast cancer is a malignant proliferation of epithelial cells lining the ducts or lobules of the breast. In the year 2000, about 185,000 cases of invasive breast cancer and 42,000 deaths occurred in the United States. Mortality from breast cancer has begun to decrease. Epithelial malignancies of the breast are the most common cause of cancer in women (excluding skin cancer), accounting for about one-third of all cancer in women. This chapter will not consider rare malignancies of the breast, including sarcomas and lymphomas. Human breast cancer is a clonal disease; a single transformed cell -- the end result of a series of somatic (acquired) or germline mutations -- is able to express full malignant potential. Thus, breast cancer may exist for a long period as either a noninvasive disease or an invasive but nonmetastatic disease.

GENETIC CONSIDERATIONS

Not more than 10% of human breast cancers can be linked directly to germline mutations. Several genes have been implicated in familial cases. The Li-Fraumeni syndrome is characterized by inherited mutations in the p53 tumor suppressor gene, which lead to an increased incidence of breast cancer, osteogenic sarcomas, and other malignancies.

Another putative tumor suppressor gene, *BRCA-1*, has been identified at the chromosomal locus 17q21; this gene encodes a zinc finger protein, and the product therefore may function as a transcriptional factor. The gene appears to be involved in gene repair. Women who inherit a mutated allele of this gene from either parent have an approximately 60 to 80% lifetime chance of developing breast cancer and about a 33% chance of developing ovarian cancer. Men who carry a mutant allele of the gene have an increased incidence of prostate cancer but usually not of breast cancer. A third gene, termed *BRCA-2*, which has been localized to chromosome 13q12, is associated with an increased incidence of breast cancer in men and women.

BRCA-1 and *BRCA-2* can now be sequenced readily and germline mutations detected; patients with these mutations can be counseled appropriately. All women with strong family histories for breast cancer should be referred to genetic screening programs whenever possible, particularly women of Ashkenazi Jewish descent who have a high likelihood of a specific *BRCA-1* mutation (deletion of adenine and guanine at position 185).

Even more important than the role these genes play in inherited forms of breast cancer may be their role in sporadic breast cancer. The p53 mutation is present in approximately 40% of human breast cancers as an acquired defect. Evidence for *BRCA-1* mutation in primary breast cancer has not been reported. However, decreased expression of *BRCA-1* mRNA and abnormal cellular location of the *BRCA-1* protein have been found in some breast cancers. Loss of heterozygosity of some genes suggests that tumor-suppressor activity may be inactivated in sporadic cases of human breast cancer. Finally, one dominant oncogene plays a role in about a quarter of human breast cancer cases. The product of this gene, a member of the epidermal growth factor receptor superfamily, is called *erbB2* (HER-2, neu) and is overexpressed in these breast cancers due to gene amplification; this overexpression can transform human breast

epithelium.

EPIDEMIOLOGY

Breast cancer is a hormone-dependent disease. Women without functioning ovaries who never receive estrogen replacement do not develop breast cancer. The female to male ratio is about 150 to 1. For most epithelial malignancies, a log-log plot of incidence versus age shows a straight-line increase with every year of life. A similar plot for breast cancer shows the same straight-line increase but with a decrease in slope beginning at the age of menopause. The three dates in a woman's life that have a major impact on breast cancer incidence are age at menarche, age at first full-term pregnancy, and age at menopause. Women who experience menarche at age 16 have only 50 to 60% of the breast cancer risk of a woman having menarche at age 12; the lower risk persists throughout life. Similarly, menopause occurring 10 years before the median age of menopause (52 years), whether natural or surgically induced, reduces lifetime breast cancer risk by about 35%. Women who have a first full-term pregnancy by age 18 have a reduced (30 to 40%) risk of breast cancer compared with nulliparous women. Thus, length of menstrual life -- particularly the fraction occurring before first full-term pregnancy -- is a substantial component of the total risk of breast cancer. This factor can account for 70 to 80% of the variation in breast cancer frequency in different countries.

International variation in incidence has provided some of the most important clues on hormonal carcinogenesis. A woman living to age 80 in North America has one chance in nine of developing invasive breast cancer. Asian women have one-fifth to one-tenth the risk of breast cancer of women in North America or Western Europe. Asian women have substantially lower concentrations of estrogens and progesterone. These differences cannot be explained on a genetic basis, because Asian women living in a western environment have sex steroid hormone concentrations and risk identical to that of their western counterparts. These women also differ markedly in height and weight from Asian women in Asia; height and weight are critical regulators of age of menarche and have substantial effects on plasma concentrations of estrogens.

The role of diet in breast cancer etiology is controversial. While there are associative links between total caloric and fat intake and breast cancer risk, the exact role of fat in the diet is unproven. However, there is a risk associated with moderate alcohol intake; the mechanism is unknown. Recommendations favoring abstinence from alcohol must be weighed against other social pressures and the possible cardioprotective effect of moderate alcohol intake.

The potential role of exogenous hormones in breast cancer is of extraordinary importance, because millions of American women regularly use oral contraceptives and postmenopausal hormone replacement therapy (HRT). The most credible meta-analyses of oral contraceptive use suggest that these agents cause little if any increased risk of breast cancer. By contrast, oral contraceptives offer a substantial protective effect against ovarian epithelial tumors and endometrial cancers. Far more controversial are the data surrounding HRT in hypogonadal and/or menopausal women. First, HRT with estrogens alone, usually in the form of equine conjugated estrogens, provides less than the physiologic equivalent of premenopausal estrogens but is

associated with an increased risk of endometrial cancer, a reduction in the symptoms of estrogen deprivation, a reduction in osteoporosis and resultant hip fractures, and a one-third reduction in deaths due to cardiovascular disease. Meta-analyses suggest a small increase in breast cancer incidence, particularly with high dosages and a long duration of treatment. For the average woman, the negative effect on the breast is probably outweighed by protective effects on bone and heart. Preliminary data suggest that there is a reduction in the risk of colon cancer as well.

The addition of progestogens toHRTregimens drastically reduces the risk of endometrial cancer. It is not clear whether the protective effects against cardiovascular and osteoporotic bone diseases are altered. However, progestogens are copromoters of breast cancer in model systems, and an increased risk of breast cancer is possible.

Whether a history of previous biopsy findings of atypical hyperplasia or in situ carcinoma or strong family histories of breast cancer alter the risk-to-benefit ratios forHRT is unknown. It is likely that the average woman benefits from HRT. The risks of HRT in patients with a positive family history and patients with a remote personal history of breast cancer are unknown.

In addition to the other factors, radiation may be a risk factor in younger women. Women who have been exposed before age 30 to radiation in the form of multiple fluoroscopies (200 to 300 cGy) or treatment for Hodgkin's disease (>3600 cGy) have a substantial increase in risk of breast cancer, whereas radiation exposure after age 30 appears to have a minimal carcinogenic effect on the breast.

EVALUATION OF BREAST MASSES IN MEN AND WOMEN

Because the breasts are a common site of potentially fatal malignancy in women and because they frequently provide clues to underlying systemic diseases in both men and women, examination of the breast is an essential part of the physical examination. Unfortunately, internists frequently do not examine the breast in men, and, in women, they are apt to refer this evaluation to gynecologists. Because of the association between early detection and improved outcome, it is the duty of every physician to distinguish breast abnormalities at the earliest possible stage and to institute a definite diagnostic workup. It is for this reason that all women should be trained in self-examination of the breasts. Although breast cancer in men is unusual, unilateral lesions should be evaluated in the same manner as in women, with the recognition that gynecomastia in men can sometimes begin unilaterally and is often asymmetric. Nevertheless, about as many suspicious breast lesions are now detected by screening mammography as by physical examination.

Virtually all breast cancer is diagnosed by biopsy of a nodule detected either on a mammogram or by palpation. Algorithms have been developed to enhance the likelihood of diagnosing breast cancer and reduce the frequency of unnecessary biopsy.

The Palpable Breast Mass Women should be strongly encouraged to examine their breasts monthly. The minimum benefit of this practice is the greater likelihood of detecting a mass at a smaller size, when it can be treated with more limited surgery. Breast examination by the physician should be performed in good light so as to see

retractions and other skin changes. The nipple and areolae should be inspected, and an attempt should be made to elicit nipple discharge. All regional lymph node groups should be examined, and any lesions should be measured. While lesions with certain features are more likely to be cancerous (hard, irregular, tethered or fixed, or painless lesions), physical examination alone cannot exclude malignancy. Furthermore, a negative mammogram in the presence of a persistent lump in the breast does not exclude malignancy.

In premenopausal women, lesions that are either equivocal or nonsuspicious on physical examination should be reexamined in 2 to 4 weeks, during the follicular phase of the menstrual cycle. Days 5 to 7 of the cycle are the best time for breast examination. A dominant mass in a postmenopausal woman or a dominant mass that persists through a menstrual cycle in a premenopausal woman should be aspirated by fine-needle biopsy or referred to a surgeon. If nonbloody fluid is aspirated and the lesion is thereby cured, the diagnosis (cyst) and therapy have been accomplished together. Solid lesions that are persistent, recurrent, complex or bloody cysts require mammography and biopsy, although in selected patients the so-called triple diagnostic techniques (palpation, mammography, aspiration) can be used to avoid biopsy (Figs. 89-1,89-2, and89-3). Ultrasound can be used in place of fine-needle aspiration to distinguish cysts from solid lesions. Not all solid masses are detected by ultrasound; thus, a palpable mass that is not visualized on ultrasound must be presumed to be solid.

Several points are essential in pursuing these management decision trees. First, risk factor analysis is not part of the decision structure. Second, fine-needle aspiration should be used only in centers that have proven skill in obtaining such specimens and analyzing them. Although the likelihood of cancer is low in the setting of a "triple negative" (benign-feeling lump, negative mammogram, and negative fine-needle aspiration), it is not zero, and the patient and physician must be aware of about a 1% risk of false negativity. Third, additional technologies such as magnetic resonance imaging, ultrasound, and sestamibi imaging cannot be used to exclude the need for biopsy, although in unusual circumstances they may provoke a biopsy.

The Abnormal Mammogram Screening mammography has reduced the lethality of breast cancer by promoting detection at an earlier stage. The procedure is justified on an annual basis for women over age 40.

Screening mammography should not be confused with diagnostic mammography, which is performed after a palpable abnormality has been detected. Diagnostic mammography is aimed at evaluating the rest of the breast before biopsy is performed, or occasionally is part of the triple test strategy to exclude immediate biopsy.

Subtle abnormalities that are first detected by screening mammography should be evaluated carefully by compression or magnified views. These abnormalities include clustered microcalcifications, densities (especially if spiculated), and new or enlarging architectural distortion. For some nonpalpable lesions ultrasound may be helpful either to identify cysts or to guide biopsy. If there is no palpable lesion and detailed mammographic studies are unequivocally benign, the patient should have routine follow-up appropriate to the patient's age.

If a nonpalpable mammographic lesion has a low index of suspicion, mammographic follow-up in 3 to 6 months is reasonable. Workup of indeterminate and suspicious lesions has been rendered more complex by the advent of stereotactic biopsies. Morrow and colleagues have suggested that these procedures are indicated for lesions that require biopsy but are likely to be benign -- that is, for cases in which the procedure probably will eliminate additional surgery. When a lesion is more probably malignant, open excisional biopsy should be performed with a needle localization technique. Others have proposed more widespread use of stereotactic core biopsies for nonpalpable lesions, on economic grounds and because diagnosis leads to earlier treatment planning. However, stereotactic diagnosis of a malignant lesion does not eliminate the need for definitive surgical procedures, particularly if breast conservation is attempted. For example after a breast biopsy with needle localization (i.e., local excision) of a stereotactically diagnosed malignancy, reexcision may still be necessary to achieve negative margins. To some extent, these issues are decided on the basis of referral pattern and the availability of the resources for stereotactic core biopsies. A reasonable approach is shown in Fig. 89-4.

Breast Masses in the Pregnant or Lactating Woman During pregnancy, the breast grows under the influence of estrogen, progesterone, prolactin, and human placental lactogen. Lactation is suppressed by progesterone, which blocks the effects of prolactin. After delivery, lactation is promoted by the fall in progesterone levels, which leaves the effects of prolactin unopposed. The development of a dominant mass during pregnancy or lactation should never be attributed to hormonal changes, and biopsy should never be performed under local anesthesia. Breast cancer develops in 1 in every 3000 to 4000 pregnancies. Stage for stage, breast cancer in pregnant patients is no different from premenopausal breast cancer in nonpregnant patients. However, pregnant women often have more advanced disease because a breast mass was ignored.

Benign Breast Masses Only about 1 in every 5 to 10 breast biopsies leads to a diagnosis of cancer, although the rate of positive biopsies varies in different countries. (These differences may be related to interpretation and availability of mammograms.) The vast majority of benign breast masses are due to "fibrocystic" disease, a descriptive term for small fluid-filled cysts and modest epithelial cell and fibrous tissues hyperplasia. However, fibrocystic disease is a histologic, not a clinical, diagnosis, and women who have had a biopsy with benign findings are at greater risk of developing breast cancer than those who have not had a biopsy. The subset of women with ductal or lobular cell proliferation (about 30% of patients), particularly the small fraction (3%) with atypical hyperplasia, have a fourfold greater risk of developing breast cancer than unbiopsied women, and the increase in the risk is about ninefold for women in this category who also have an affected first-degree relative. Thus, careful follow-up of these patients is required. By contrast, patients with a benign biopsy without atypical hyperplasia are at little risk and may be followed routinely.

SCREENING

Breast cancer is virtually unique among the epithelial tumors in adults in that screening (in the form of annual mammography) has been proven to improve survival. Meta-analysis examining outcomes from every randomized trial of mammography conclusively shows a 25 to 30% reduction in the chance of dying from breast cancer

with annual screening after age 50; the data for women between ages 40 and 50 are almost as positive. It seems prudent to recommend annual mammography for women past the age of 40. Although no randomized study of breast self-examination (BSE) has ever shown any improvement in survival, its major benefit appears to be identification of tumors appropriate for conservative local therapy. Better mammographic technology, including digitized mammography, routine use of magnified views, and greater skill in mammographic interpretation, combined with newer diagnostic techniques (magnetic resonance imaging, magnetic resonance spectroscopy, positron emission tomography, etc.) may make it possible to identify breast cancers yet more reliably and earlier.

STAGING

Correct staging of breast cancer patients is of extraordinary importance. Not only does it permit an accurate prognosis, but in many cases therapeutic decision-making is based largely on the TNM classification (Table 89-1). Comparison with historic series should be undertaken with caution, as the staging has changed in the past 10 years.

TREATMENT

Primary Breast Cancer A series of randomized clinical trials both in the United States and abroad have shown that breast-conserving treatments, consisting of the removal of the primary tumor by some form of lumpectomy with or without irradiating the breast, results in a survival that is as good as that after extensive procedures, such as mastectomy or modified radical mastectomy, with or without further irradiation. While breast conservation is associated with a possibility of recurrence in the breast, 10-year survival is at least as good as that after more radical surgery. Postoperative radiation to regional nodes following mastectomy is also associated with an improvement in survival. Since radiation therapy can also reduce the rate of local or regional recurrence, it should be strongly considered following mastectomy for women with high-risk primary tumors (i.e., T2 in size, positive margins, positive nodes). At present, approximately one-third of women in the United States are managed by lumpectomy.
Breast-conserving surgery is not suitable for all patients; it is not generally suitable for tumors >5 cm (or for smaller tumors if the breast is small), for tumors involving the nipple areola complex, for tumors with extensive intraductal disease involving multiple quadrants of the breast, for women with a history of collagen-vascular disease, and for women who either do not have the motivation for breast conservation or do not have convenient access to radiation therapy. However, these groups probably do not account for more than one-third of patients. Thus, a great many women who undergo mastectomy could safely avoid this procedure.

An extensive intraductal component is a predictor of recurrence in the breast, and so are several clinical variables. Both axillary lymph node involvement and involvement of vascular or lymphatic channels by metastatic tumor in the breast are associated with a higher risk of relapse in the breast but are not contraindications to breast-conserving treatment. When these patients are excluded, and when lumpectomy with negative tumor margins is achieved, breast conservation is associated with a recurrence rate in the breast of less than 10%. The survival of patients who have recurrence in the breast is somewhat worse than that of women who do not. Thus, recurrence in the breast is a negative prognostic variable for long-term survival. However, recurrence in the breast is

not the *cause* of distant metastasis. If recurrence in the breast caused metastatic disease, then women treated with lumpectomy, who have a higher rate of recurrence in the breast, should have poorer survival. Most patients should consult with a radiation oncologist before making a final decision concerning local therapy. However, a multimodality clinic approach in which the surgeon, radiation oncologist, medical oncologist, and other caregivers cooperate to evaluate the patient and develop a treatment is usually considered a major advantage by patients.

Adjuvant Therapy One of the significant advances in the treatment of solid tumors of adults has been the improved survival resulting from the use of systemic therapy after local management of breast cancer. More than one-third of the women who would otherwise die of metastatic breast cancer remain disease-free when treated with the appropriate systemic regimen.

PROGNOSTIC VARIABLES The most important prognostic variables are provided by *tumor staging*. The size of the tumor and the status of the axillary lymph nodes provide reasonably accurate information on the likelihood of tumor relapse. The relation of pathologic stage to 5-year survival is shown inTable 89-2. For most women, the need for adjuvant therapy can be readily defined on this basis alone. In the absence of lymph node involvement, involvement of microvessels (either capillaries or lymphatic channels) in tumors is nearly equivalent to lymph node involvement. The greatest controversy concerns women with intermediate prognoses. *There is no justification for adjuvant chemotherapy in women with tumors<1 cm in size whose axillary lymph nodes are negative*.

Other prognostic variables have been sought and some appear to influence disease-free and overall survival. What is less clear is whether they add to the information from pathologic staging.

Estrogen and progesterone receptor status are of prognostic significance. Tumors that lack either or both of these receptors are more likely to recur than tumors that have them.

Several *measures of tumor growth rate* correlate with early relapse. S-phase analysis using flow cytometry is the most accurate measure, and the indirect S-phase assessments using antigens associated with the cell cycle, such as PCNA (Ki67), are also valuable. Several studies suggest that tumors with a high proportion (more than the median) of cells in the S phase pose a greater risk of relapse and that chemotherapy offers the greatest survival benefit for these tumors. For this reason, some clinicians use S-phase assessment as a deciding factor for instituting adjuvant therapy when other pathologic features are unclear. Assessment of DNA content in the form of ploidy is of modest value, with nondiploid tumors having a somewhat worse prognosis.

Histologic classification of the tumor has also been used as a prognostic factor. Tumors with a poor nuclear grade have a higher risk of recurrence than tumors with a good nuclear grade. Semiquantitative measures such as the Elston score improve the reproducibility of this measurement.

Molecular changes in the tumor are also useful. Tumors that overexpress erbB2

(HER-2/neu) or have a mutated p53 gene have a worse prognosis. Particular interest has centered on erbB2 overexpression as measured by histochemistry. Tumors that overexpress erbB2 are more likely to respond to higher doses of doxorubicin-containing regimens. For this reason, erbB2 expression is usually worth measuring as a means of deciding on therapy.

To grow, a tumor must generate a neovasculature (Chap. 83). The presence of more microvessels in a tumor is associated with a worse prognosis.

Other variables that have also been used to evaluate prognosis include proteins associated with invasiveness, such as type IV collagenase, cathepsin D, plasminogen activator, plasminogen activator receptor, and the metastasis suppressor gene, nm23. None of these has been widely accepted as a prognostic variable for therapeutic decision-making. One problem in interpreting these prognostic variables is that most of them have not been examined in a study using a large cohort of patients.

ADJUVANT REGIMENS Selection of appropriate adjuvant chemotherapy or hormone therapy regimens is a highly controversial issue in some situations. Meta-analyses have helped to define broad limits for therapy but do not help in choosing optimal regimens or in choosing a regimen for certain subgroups of patients. A summary of recommendations is shown in Table 89-3. In general, premenopausal women for whom any form of adjuvant systemic therapy is indicated should receive chemotherapy for 6 months. The antiestrogen (tamoxifen) improves survival in premenopausal patients with positive estrogen receptor values and should be added following completion of chemotherapy. Prophylactic castration may also be associated with a substantial survival benefit (primarily in estrogen receptor-positive patients) but is not widely used in this country.

Data on postmenopausal women are also controversial. The impact of adjuvant chemotherapy is less clear-cut than in premenopausal patients, although some survival advantage has been shown. The first decision is whether chemotherapy or tamoxifen should be used. While adjuvant tamoxifen improves survival regardless of axillary lymph node status, the improvement in survival is modest for patients in whom multiple lymph nodes are involved. For this reason, it has been usual to give chemotherapy to postmenopausal patients who have no medical contraindications and who have more than one positive lymph node; tamoxifen is commonly given simultaneously or subsequently. For postmenopausal women for whom systemic therapy is warranted but who have a more favorable prognosis, tamoxifen may be used as a single agent.

Most comparisons of adjuvant chemotherapy regimens show little difference among them, although slight advantages for doxorubicin-containing regimens are usually seen.

One approach -- so-called neoadjuvant chemotherapy -- involves the administration of adjuvant therapy before definitive surgery and radiation therapy. Because the objective response rates of patients with breast cancer to systemic therapy in this setting exceed 75%, many patients will be "downstaged" and may become candidates for breast-conserving therapy. At least one large randomized study has failed to show any difference in survival using this approach.

Other adjuvant treatments under investigation include the use of new drugs, such as paclitaxel, and therapy based on alternative kinetic and biologic models. In such approaches, high doses of single agents are used separately in relatively dose-intensive cycling regimens. One large randomized trial for node-positive patients suggests that patients treated with doxorubicin-cyclophosphamide for four cycles followed by four cycles of paclitaxel have a substantial additional gain in survival as compared with women receiving doxorubicin-cyclophosphamide alone. Very high dose therapy with stem cell transplantation in the adjuvant setting has not proved superior.

Systemic Therapy of Metastatic Disease Nearly half of patients treated for apparently localized breast cancer develop metastatic disease. Although some of these patients can be salvaged by combinations of systemic and local therapy, most eventually succumb. Soft tissue, bony, and visceral (lung and liver) metastases each account for approximately one-third of sites of initial relapses. However, by the time of death, most patients will have bony involvement. Recurrences can appear at any time after primary therapy. Half of all initial cancer recurrences occur more than 5 years following initial therapy.

Because this diagnosis of metastatic disease alters the outlook for the patient so drastically, it should not be made without biopsy. Every oncologist has seen patients with tuberculosis, gallstones, primary hyperparathyroidism, or other nonmalignant diseases misdiagnosed and treated as though they had metastatic breast cancer. This is a catastrophic mistake and justifies biopsy for every patient at the time of initial suspicion of metastatic disease.

The choice of therapy requires consideration of local therapy needs, the overall medical condition of the patient, and the hormone receptor status of the tumor, as well as the exercise of clinical judgment. Because therapy of systemic disease is palliative, the potential toxicities of therapies should be balanced against the response rates. Several variables influence the response to systemic therapy. For example, the presence of estrogen and progesterone receptors is a strong indication for endocrine therapy, since the response rates for tumors that express both receptors may approach 70%. On the other hand, patients with short disease-free intervals, rapidly progressive visceral disease, lymphangitic pulmonary disease, or intracranial disease are unlikely to respond to endocrine therapy.

In many cases, systemic therapy can be withheld while the patient is managed with appropriate local therapy. Radiation therapy and occasionally surgery are effective at relieving the symptoms of metastatic disease, particularly when bony sites are involved. Many patients with bone-only or bone-dominant disease have a relatively indolent course. Under such circumstances, systemic chemotherapy has a modest effect, whereas radiation therapy may be effective for long periods. Other systemic treatments, such as strontium 89 and/or bisphosphonates, may provide a palliative benefit without inducing objective responses. Since the goal of therapy is to maintain well-being for as long as possible, emphasis should be placed on avoiding the most hazardous complications of metastatic disease, including pathologic fracture of the axial skeleton and spinal cord compression. New back pain in patients with cancer should be explored aggressively on an emergent basis; to wait for neurologic symptoms is a potentially catastrophic error. Metastatic involvement of endocrine organs can cause profound

dysfunction, including adrenal insufficiency and hypopituitarism. Similarly, obstruction of the biliary tree or other impaired organ function may be better managed with a local therapy than with a systemic approach.

Endocrine Therapy Normal breast tissue is estrogen-dependent. Both primary and metastatic breast cancer may retain this phenotype. The best means of ascertaining whether a breast cancer is hormone-dependent is through analysis of estrogen and progesterone receptor levels on the tumor. Tumors that are positive for the estrogen receptor and negative for the progesterone receptor have a response rate of approximately 30%. Tumors that have both receptors have a response rate approaching 70%. If neither receptor is present, the objective response rates are less than 10%. Receptor analyses provide information as to the correct ordering of endocrine therapies. Because of their lack of toxicity and because some patients whose receptor analyses are reported as negative respond to endocrine therapy, an endocrine treatment should be attempted in every patient with metastatic breast cancer. Potential endocrine therapies are summarized in Table 89-4. The choice of endocrine therapy is usually determined by toxicity profile and availability. In most patients, the initial endocrine therapy is the antiestrogen tamoxifen. Newer antiestrogens that are free of agonistic effects are in clinical trial. Cases in which tumors shrink in response to tamoxifen withdrawal (as well as withdrawal of pharmacologic doses of estrogens) have been reported. Endogenous estrogen formation may be blocked by aromatase inhibitors or analogues of luteinizing hormone-releasing hormone (LHRH). Additive endocrine therapies, including treatment with progestogens, estrogens, and androgens, may also be tried in patients who respond to initial endocrine therapy; the mechanism of action of these latter therapies is unknown. However, patients who respond to one endocrine therapy have at least a 50% chance of responding to a second endocrine therapy. It is not uncommon for patients to respond to two or three sequential endocrine therapies; however, combination endocrine therapies do not appear to be superior to individual agents, and combinations of chemotherapy with endocrine therapy are not useful. The median survival of patients with metastatic disease is approximately 2 years, and many patients, particularly older persons and those with hormone-dependent disease, may respond to endocrine therapy for 3 to 5 years or longer.

Chemotherapy Unlike many other epithelial malignancies, breast cancer responds to several chemotherapeutic agents, including anthracyclines, alkylating agents, taxanes, and antimetabolites. Multiple combinations of these agents have been found to improve response rates somewhat, but they have had little impact on duration of response or survival. As previously mentioned, median survival from diagnosis of metastatic disease is approximately 2 years. The choice among multidrug combinations frequently depends on whether adjuvant chemotherapy was administered and, if so, what type. While patients treated with adjuvant regimens such as cyclophosphamide, methotrexate, and fluorouracil (CMF regimens) may subsequently respond to the same combination in the metastatic disease setting, most oncologists use drugs to which the patients have not been previously exposed. Once patients have progressed after combination drug therapy, it is most common to treat them with single agents. Given the significant toxicity of most drugs, the use of a single effective agent will minimize toxicity by sparing the patient exposure to drugs that would be of little value. Unfortunately, no form of in vitro drug sensitivity testing to select the drugs most efficacious for a given patient has been demonstrated to be useful.

Most oncologists use either an anthracycline or paclitaxel following failure with the initial regimen. However, the choice has to be balanced with individual needs.

The use of a humanized antibody to *erbB2* (herceptin) combined with paclitaxel can improve response rate and survival for women whose metastatic tumors overexpress *erbB2*. The magnitude of the survival extension is modest in patients with metastatic disease. Application to adjuvant therapy may prove even more beneficial.

High-Dose Chemotherapy including Autologous Bone Marrow Transplantation
Autologous bone marrow transplantation combined with high doses of single agents can produce improvement even in heavily pretreated patients. However, such responses are rarely, if ever, durable and are unlikely to substantially alter the clinical course for most patients with advanced metastatic disease. Randomized trials have not been encouraging, and these approaches cannot be recommended as part of clinical care outside of research settings.

Stage III Breast Cancer Between 10 and 25% of patients have so-called locally advanced or stage III breast cancer at diagnosis. Many of these cancers are technically operable, whereas others, particularly cancers with chest wall involvement, inflammatory breast cancers, or cancers with large matted axillary lymph nodes, cannot be managed with surgery initially. Although no randomized trials have proved the efficacy of induction chemotherapy, this approach has gained widespread use. More than 90% of patients with locally advanced breast cancer show a partial or better response to multidrug chemotherapy regimens that include an anthracycline. Early administration of this treatment reduces the bulk of the disease and frequently makes the patient a suitable candidate for salvage surgery and/or radiation therapy. These patients should be managed in multimodality clinics, if possible, to coordinate surgery, radiation therapy, and systemic chemotherapy. Such approaches produce long-term disease-free survival in about 30 to 50% of patients.

Breast Cancer Prevention Women who have one breast cancer are at risk of developing a contralateral breast cancer at a rate of approximately 0.5% per year. When adjuvant tamoxifen is administered to these patients, the rate of development of contralateral breast cancers is reduced. In other tissues of the body, tamoxifen has estrogen-like effects that are beneficial: preservation of bone mineral density and long-term lowering of cholesterol. However, tamoxifen has estrogen-like effects on the uterus, leading to an increased risk of uterine cancer (0.75% incidence after 5 years on tamoxifen). The Breast Cancer Prevention Trial (BCPT) revealed a >40% reduction in breast cancer amongst women with a risk of at least 1.66% taking the drug for 5 years. Raloxifene has shown similar breast cancer prevention potency but may have different effects on bone and heart. The two are being compared in a prospective randomized prevention trial (the STAR trial).

Noninvasive Breast Cancer Breast cancer develops as a series of molecular changes in the epithelial cells that lead to ever more malignant behavior. Increased use of mammography and better mammographic diagnosis have led to more frequent diagnosis of noninvasive breast cancer. These lesions fall into two groups: ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (lobular neoplasia). The

management of both entities is controversial.

Ductal Carcinoma in Situ Proliferation of cytologically malignant breast epithelial cells within the ducts is termedDCIS. Significant disagreement can occur in differentiating atypical hyperplasia from DCIS. At least one-third of the cases of untreated DCIS progress within 5 years to invasive breast cancer. For many years, the standard treatment for this disease was mastectomy. However, since treatment of this condition by lumpectomy and radiation therapy gives survival that is as good as the survival for invasive breast cancer by mastectomy, it appears paradoxical to recommend more aggressive therapy for a "less" malignant disease. In one randomized trial, the combination of wide excision plus irradiation for DCIS caused a substantial reduction in the local recurrence rate as compared with wide excision alone with negative margins, though survival is identical in the two arms. No studies have compared either of these regimens to mastectomy. Addition of tamoxifen to any DCIS surgical/radiation therapy regimen will further improve outcome.

Several prognostic features may help to identify patients at high risk for local recurrence after either lumpectomy alone or lumpectomy with radiation therapy. These include extensive disease; age less than 40; and cytologic features such as necrosis, poor nuclear grade, and comedo subtype with overexpression of erbB2. Some data suggest that adequate excision with careful determination of pathologically clear margins is associated with a low recurrence rates. When such surgery is combined with radiation therapy, recurrence (which is usually in the same quadrant) occurs with a frequency of £10%. Given the fact that half of these recurrences will be invasive, about 5% of the initial cohort will eventually develop invasive breast cancer. A reasonable expectation of mortality for these patients is about 1%, a figure that approximates the mortality rate for DCISmanaged by mastectomy. Although this train of reasoning has not formally been proved valid, it is reasonable at present to recommend that patients who desire breast preservation, and in whom DCIS appears to be reasonably localized, be managed by adequate surgery with meticulous pathologic evaluation, followed by breast irradiation and tamoxifen. For patients with localized DCIS, there is no need for axillary lymph node dissection. More controversial is the question of what management is optimal when there is any degree of invasion. Because of a significant likelihood (10 to 15%) of axillary lymph node involvement even when the primary lesion shows only microscopic invasion, it is prudent to do at least a level 1 and 2 axillary lymph node dissection for all patients with any degree of invasion, although in centers familiar with the technique, sentinel node biopsy may be substituted. Further management is dictated by the presence of nodal spread.

Lobular Neoplasia Proliferation of cytologically malignant cells within the lobules is termed *lobular neoplasia*. Approximately 30% of patients who have had adequate local excision of the lesion develop breast cancer (usually infiltrating ductal cell carcinoma) over the next 15 to 20 years. Ipsilateral and contralateral disease are equally common. Therefore, lobular neoplasia may be a premalignant lesion that suggests an elevated risk of subsequent breast cancer, rather than a form of malignancy itself, and aggressive local management seems unreasonable. Most patients should be treated with tamoxifen for 5 years and followed with careful annual mammography and semiannual physical examinations. Additional molecular analysis of these lesions may make it possible to discriminate between patients who are at risk of further progression

and who require additional therapy and those in whom simple follow-up is adequate.

Male Breast Cancer Breast cancer is about 1/150th as frequent in men as in women. It usually presents as a unilateral lump in the breast and is frequently not diagnosed promptly. Given the small amount of soft tissue and the unexpected nature of the problem, locally advanced presentations are somewhat more common. When male breast cancer is matched to female breast cancer by age and stage, its overall prognosis is identical. Although gynecomastia may initially be unilateral or asymmetric, any unilateral mass in a man over the age of 40 should receive a careful workup all the way through biopsy. On the other hand, bilateral symmetric breast development rarely represents breast cancer and is almost invariably due to endocrine disease or a drug effect. It should be kept in mind, nevertheless, that the risk of cancer is much greater in men with gynecomastia; in such men, gross asymmetry of the breasts should arouse suspicion of cancer. Male breast cancer is best managed by mastectomy and axillary lymph node dissection (modified radical mastectomy). Patients with locally advanced disease or positive nodes should also be treated with irradiation. Approximately 90% of male breast cancers contain estrogen receptors, and approximately 60% of cases with metastatic disease respond to endocrine therapy. There are no randomized studies exploring adjuvant therapy for male breast cancer. Two historic experiences suggest that the disease responds well to adjuvant systemic therapy, and, if not medically contraindicated, the same criteria for the use of adjuvant therapy in women should be applied to men.

The sites of relapse and spectrum of response to chemotherapeutic drugs are virtually identical for breast cancers in the two sexes.

FOLLOW-UP OF BREAST CANCER PATIENTS

Despite the availability of sophisticated and expensive imaging techniques and a wide range of serum tumor marker tests, no studies document that survival is influenced by early diagnosis of relapse. Surveillance guidelines are given in Table 89-5.

90. GASTROINTESTINAL TRACT CANCER - *Robert J. Mayer*

The gastrointestinal tract is the second most common noncutaneous site for cancer and the second major cause of cancer-related mortality in the United States.

ESOPHAGEAL CANCER

INCIDENCE AND ETIOLOGY

Cancer of the esophagus is a relatively uncommon but extremely lethal malignancy. The diagnosis was made in 12,300 Americans in 2000 and led to 12,100 deaths. Worldwide, the incidence of esophageal cancer varies strikingly. It occurs frequently within a geographic region extending from the southern shore of the Caspian Sea on the west to northern China on the east and encompassing parts of Iran, Central Asia, Afghanistan, Siberia, and Mongolia. High-incidence "pockets" of the disease are also present in such disparate locations as Finland, Iceland, Curacao, southeastern Africa, and northwestern France. In North America and western Europe, the disease is far more common in blacks than whites, is more common in males than females, appears most often after age 50, and seems to be associated with a lower socioeconomic status.

A variety of causative factors have been implicated in the development of the disease (Table 90-1). In the United States, esophageal cancer cases are either squamous cell carcinomas or adenocarcinomas. The etiology of squamous cell esophageal cancer is related to excess alcohol consumption and/or cigarette smoking. The relative risk increases with the amount of tobacco smoked or alcohol consumed, with these factors acting synergistically. The consumption of whiskey is linked to a higher incidence than the consumption of wine or beer. Squamous cell esophageal carcinoma has also been associated with the ingestion of nitrites, smoked opiates, and fungal toxins in pickled vegetables, as well as mucosal damage caused by such physical insults as long-term exposure to extremely hot tea, the ingestion of lye, radiation-induced strictures, and chronic achalasia. The presence of an esophageal web in association with glossitis and iron deficiency (i.e., Plummer-Vinson or Paterson-Kelly syndrome) and congenital hyperkeratosis and pitting of the palms and soles (i.e., tylosis palmaris et plantaris) have each been linked with squamous cell esophageal cancer, as have dietary deficiencies of molybdenum, zinc, and vitamin A.

For unclear reasons, the incidence of squamous cell esophageal cancer has decreased in both the black and white population in the United States over the past 20 years, while the rate of adenocarcinoma has risen dramatically, particularly in white males. Adenocarcinomas arise in the distal esophagus in the presence of chronic gastric reflux and gastric metaplasia of the epithelium (Barrett's esophagus), which is more common in obese persons. Adenocarcinomas arise within dysplastic columnar epithelium in the distal esophagus. Even before frank neoplasia is detectable, aneuploidy and p53 mutations are found in the dysplastic epithelium. These adenocarcinomas behave clinically like gastric adenocarcinoma and now account for >50% of esophageal cancers.

CLINICAL FEATURES

About 15% of esophageal cancers occur in the upper third of the esophagus (cervical esophagus), 40% in the middle third, and 45% in the lower third. Squamous cell carcinomas and adenocarcinomas of the esophagus cannot be distinguished radiographically or endoscopically.

Progressive dysphagia and weight loss of short duration are the initial symptoms in the vast majority of patients. Dysphagia initially occurs with solid foods and gradually progresses to include semisolids and liquids. By the time these symptoms develop, the disease is usually incurable, since difficulty in swallowing does not occur until ³60% of the esophageal circumference is infiltrated with cancer. Dysphagia may be associated with pain on swallowing (odynophagia), pain radiating to the chest and/or back, regurgitation or vomiting, and aspiration pneumonia. The disease most commonly spreads to adjacent and supraclavicular lymph nodes, liver, lungs, and pleura. Tracheoesophageal fistulas may develop as the disease advances, leading to severe suffering. As with other squamous cell carcinomas, hypercalcemia may occur in the absence of osseous metastases, probably from parathormone-related peptide secreted by tumor cells (Chap. 100).

DIAGNOSIS

Attempts at endoscopic and cytologic screening for carcinoma in patients with Barrett's esophagus, while effective as a means of detecting high-grade dysplasia, have not yet been shown to improve the prognosis in individuals found to have a carcinoma. Routine contrast radiographs effectively identify esophageal lesions large enough to cause symptoms. In contrast to benign esophageal leiomyomas, which result in esophageal narrowing with preservation of a normal mucosal pattern, esophageal carcinomas characteristically cause ragged, ulcerating changes in the mucosa in association with deeper infiltration, producing a picture resembling achalasia. Smaller, potentially resectable tumors are often poorly visualized despite technically adequate esophagograms. Because of this, esophagoscopy should be performed in all patients suspected of having an esophageal abnormality, to visualize the tumor and to obtain histopathologic confirmation of the diagnosis. Because the population of persons at risk for squamous cell carcinoma of the esophagus (i.e., smokers and drinkers) also has a high rate of cancers of the lung and the head and neck region, endoscopic inspection of the larynx, trachea, and bronchi should also be done. A thorough examination of the fundus of the stomach (by retroflexing the endoscope) is imperative as well. Endoscopic biopsies of esophageal tumors fail to recover malignant tissue in one-third of cases because the biopsy forceps cannot penetrate deeply enough through normal mucosa pushed in front of the carcinoma. Cytologic examination of tumor brushings frequently complements standard biopsies and should be performed routinely. The extent of tumor spread to the mediastinum and paraaortic lymph nodes should also be assessed by computed tomography (CT) scans of the chest and abdomen and by endoscopic ultrasound.

TREATMENT

The prognosis for patients with esophageal carcinoma is poor. Fewer than 5% of patients are alive 5 years after the diagnosis; thus, management focuses on symptom control. Surgical resection of all gross tumor (i.e., total resection) is feasible in only

40%of cases, with residual tumor cells frequently present at the resection margins. Such esophagectomies have been associated with a postoperative mortality rate of ~10% due to anastomotic fistulas, subphrenic abscesses, and respiratory complications. About 20% of patients who survive a total resection live 5 years. The outcome of primary radiation therapy (5500 to 6000 cGy) for squamous cell carcinomas is similar to that of radical surgery, sparing patients perioperative morbidity but often resulting in less satisfactory palliation of obstructive symptoms. The evaluation of chemotherapeutic agents in patients with esophageal carcinoma has been hampered by ambiguity in the definition of "response" (i.e., benefit) and the debilitated physical condition of many treated individuals. Nonetheless, significant reductions in the size of measurable tumor masses have been reported in 15 to 25% of patients given single-agent treatment and in 30 to 60% of patients treated with drug combinations that include cisplatin. Combination chemotherapy and radiation therapy as the initial therapeutic approach, either alone or followed by an attempt at operative resection, may be of benefit. When administered along with radiation therapy, chemotherapy produces a better survival outcome than radiation therapy alone. The use of preoperative chemotherapy and radiation therapy followed by esophageal resection appears to prolong survival as compared with historic controls, but randomized trials have produced inconsistent results.

For the incurable, surgically unresectable patient with esophageal cancer, dysphagia, malnutrition, and the management of tracheoesophageal fistulas loom as major issues. Approaches to palliation include repeated endoscopic dilatation, the surgical placement of a gastrostomy or jejunostomy for hydration and feeding, and endoscopic placement of an expansive metal stent to bypass the tumor. Endoscopic fulguration of the obstructing tumor with lasers appears to be the most promising of these techniques.

TUMORS OF THE STOMACH

GASTRIC ADENOCARCINOMA

Incidence and Epidemiology For unclear reasons, the incidence and mortality rates for gastric cancer have decreased markedly during the past 60 years. The mortality rate from gastric cancer in the United States has dropped in men from 28 to 5.0 per 100,000 population, while in women, the rate has decreased from 27 to 2.3 per 100,000. Nonetheless, 21,500 new cases of stomach cancer were diagnosed in the United States and 13,000 Americans died of the disease in 2000. Gastric cancer incidence has decreased worldwide but remains high in Japan, China, Chile, and Ireland.

The risk of gastric cancer is greater among lower socioeconomic classes. Migrants from high- to low-incidence nations maintain their susceptibility to gastric cancer, while the risk for their offspring approximates that of the new homeland. These findings suggest that an environmental exposure, probably beginning early in life, is related to the development of gastric cancer, with dietary carcinogens considered the most likely factor(s).

Pathology About 85% of stomach cancers are adenocarcinomas, with 15% due to lymphomas and leiomyosarcomas. Gastric adenocarcinomas may be subdivided into two categories: a *diffuse type* in which cell cohesion is absent, so that individual cells infiltrate and thicken the stomach wall without forming a discrete mass; and an *intestinal*

type characterized by cohesive neoplastic cells that form glandlike tubular structures. The diffuse carcinomas occur more often in younger patients, develop throughout the stomach (including the cardia), result in a loss of distensibility of the gastric wall (so-called linitis plastica or "leather bottle" appearance), and carry a poorer prognosis. Intestinal-type lesions are frequently ulcerative, more commonly appear in the antrum and lesser curvature of the stomach, and are often preceded by a prolonged precancerous process. While the incidence of diffuse carcinomas is similar in most populations, the intestinal type tends to predominate in the high-risk geographic regions and is less likely to be found in areas where the frequency of gastric cancer is declining. Thus, different etiologic factor(s) may be involved in these two subtypes. In the United States, the distal stomach is the site of origin of ~30% of gastric cancers, ~20% arise in the midportion of the stomach, and ~37% originate in the proximal third of the stomach. The remaining 13% involve the entire stomach.

Etiology The long-term ingestion of high concentrations of nitrates in dried, smoked, and salted foods appears to be associated with a higher risk. The nitrates are thought to be converted to carcinogenic nitrites by bacteria (Table 90-2). Such bacteria may be introduced exogenously through the ingestion of partially decayed foods, which are consumed in abundance worldwide by the lower socioeconomic classes. Bacteria such as *Helicobacter pylori* may also contribute to this effect by causing chronic gastritis, loss of gastric acidity, and bacterial growth in the stomach. Loss of acidity may occur when acid-producing cells of the gastric antrum have been removed surgically to control benign peptic ulcer disease or when achlorhydria, atrophic gastritis, and even pernicious anemia develop in the elderly. Serial endoscopic examinations of the stomach in patients with atrophic gastritis have documented replacement of the usual gastric mucosa by intestinal-type cells. This process of intestinal metaplasia may lead to cellular atypia and eventual neoplasia. Since the declining incidence of gastric cancer in the United States primarily reflects a decline in distal, ulcerating, intestinal-type lesions, it is conceivable that better food preservation and the availability of refrigeration to all socioeconomic classes have decreased the dietary ingestion of exogenous bacteria.

Several additional etiologic factors have been associated with gastric carcinoma. Gastric ulcers and adenomatous polyps have occasionally been so linked, but data regarding a cause-and-effect relationship are unconvincing. The inadequate clinical distinction between benign gastric ulcers and small ulcerating carcinomas may, in part, account for this presumed association. The presence of extreme hypertrophy of gastric rugal folds (i.e., Menetrier's disease), giving the impression of polypoid lesions, has been associated with a striking frequency of malignant transformation; such hypertrophy, however, does not represent the presence of true adenomatous polyps. Individuals with blood group A have a higher incidence of gastric cancer than persons with blood group O; this observation may be related to differences in the mucous secretion leading to altered mucosal protection from carcinogens. Duodenal ulcers are not associated with gastric cancer.

Clinical Features Gastric cancers, when superficial and surgically curable, usually produce no symptoms. As the tumor becomes more extensive, patients may complain of an insidious upper abdominal discomfort varying in intensity from a vague, postprandial fullness to a severe, steady pain. Anorexia, often with slight nausea, is very common but is not the usual presenting complaint. Weight loss may eventually be

observed, and nausea and vomiting are particularly prominent with tumors of the pylorus; dysphagia may be the major symptom caused by lesions of the cardia. There are no early physical signs. A palpable abdominal mass indicates long-standing growth and predicts regional extension.

Gastric carcinomas spread by direct extension through the gastric wall to the perigastric tissues, occasionally adhering to adjacent organs such as the pancreas, colon, or liver. The disease also spreads via lymphatics or by seeding of peritoneal surfaces. Metastases to intraabdominal and supraclavicular lymph nodes occur frequently, as do metastatic nodules to the ovary (Krukenberg's tumor), periumbilical region ("Sister Mary Joseph node") or peritoneal cul-de-sac (Blumer's shelf palpable on rectal or vaginal examination); malignant ascites may also develop. The liver is the most common site for hematogenous spread of tumor.

The presence of iron-deficiency anemia in men and of occult blood in the stool in both sexes mandate a search for an occult gastrointestinal tract lesion. A careful assessment is of particular importance in patients with atrophic gastritis or pernicious anemia. Unusual clinical features associated with gastric adenocarcinomas include migratory thrombophlebitis, microangiopathic hemolytic anemia, and acanthosis nigricans.

Diagnosis A double-contrast radiographic examination is the simplest diagnostic procedure for the evaluation of a patient with epigastric complaints. The use of double-contrast techniques helps to detect small lesions by improving mucosal detail. The stomach should be distended at some time during every radiographic examination, since decreased distensibility may be the only indication of a diffuse infiltrative carcinoma. Although gastric ulcers can be detected fairly early, distinguishing benign from malignant lesions is difficult. The anatomic location of an ulcer is not in itself an indication of the presence or absence of a cancer.

Gastric ulcers that appear benign by radiography present special problems. Some physicians believe that gastroscopy is not mandatory if the radiographic features are typically benign, if complete healing can be visualized by x-ray within 6 weeks, and if a follow-up contrast radiograph obtained several months later shows a normal appearance. However, we recommend gastroscopic biopsy and brush cytology for all patients with a gastric ulcer in order to exclude a malignancy. Malignant gastric ulcers must be recognized before they penetrate into surrounding tissues, because the rate of cure of early lesions limited to the mucosa or submucosa is>80%. Since gastric carcinomas are difficult to distinguish clinically or radiographically from gastric lymphomas, endoscopic biopsies should be made as deep as possible, due to the submucosal location of lymphoid tumors.

The staging system for gastric carcinoma is shown in Table 90-3.

TREATMENT

Complete surgical removal of the tumor with resection of adjacent lymph nodes offers the only chance for cure. However, this is possible in fewer than a third of patients. A subtotal gastrectomy is the treatment of choice for patients with distal carcinomas, while total or near-total gastrectomies are required for more proximal tumors. The inclusion of

extended lymph node dissection to these procedures appears to confer an added risk for complications without enhancing survival. The prognosis following complete surgical resection depends on the degree of tumor penetration into the stomach wall and is adversely influenced by regional lymph node involvement, vascular invasion, and abnormal DNA content (i.e., aneuploidy), characteristics found in the vast majority of American patients. As a result, the probability of survival after 5 years for the 25 to 30% of patients able to undergo complete resection is ~20% for distal tumors and<10% for proximal tumors, with recurrences continuing to occur for at least 8 years after surgery. In the absence of ascites or extensive hepatic or peritoneal metastases, however, even patients whose disease is believed to be incurable by surgery should be offered an attempt at resection of the primary lesion, since reduction of tumor bulk is the best form of palliation and may enhance the probability of benefit from chemotherapy and/or radiation therapy.

Gastric adenocarcinoma is a relatively radioresistant tumor, and adequate control of the primary tumor requires doses of external beam irradiation that exceed the tolerance of surrounding structures, such as bowel mucosa and spinal cord. As a result, the major role of radiation therapy in patients has been palliation of pain. Radiation therapy alone after a complete resection does not prolong survival. In the setting of surgically unresectable disease limited to the epigastrium, patients treated with 3500 to 4000 cGy did not live longer than similar patients not receiving radiotherapy; however, survival was prolonged slightly when 5-fluorouracil (5-FU) was given in combination with radiation therapy. In this clinical setting, the 5-FU may well be functioning as a radiosensitizer.

The administration of combinations of cytotoxic drugs to patients with advanced gastric carcinoma has been associated with partial responses in 30 to 50% of cases, providing significant benefit to individuals who respond to treatment. Such drug combinations have generally included5-FU and doxorubicin together with mitomycin-C, cisplatin, or high doses of methotrexate. Despite this encouraging response rate, complete remissions are uncommon, the partial responses are transient, and the overall influence of multidrug therapy on survival has been a source of debate. The use of prophylactic (i.e., adjuvant) chemotherapy following the complete resection of a gastric cancer has not improved survival. However, postoperative chemotherapy combined with radiation therapy has been shown to reduce the recurrence rate and prolong survival.

PRIMARY GASTRIC LYMPHOMA

Primary lymphoma of the stomach is relatively uncommon, accounting for<15% of gastric malignancies and about 2% of all lymphomas. The stomach is, however, the most frequent extranodal site for lymphoma, and gastric lymphoma has increased in frequency during the past 25 years. The disease is difficult to distinguish clinically from gastric adenocarcinoma; both tumors are most often detected during the sixth decade of life; present with epigastric pain, early satiety, and generalized fatigue; and are usually characterized by ulcerations with a ragged, thickened mucosal pattern demonstrated by contrast radiographs. The diagnosis of lymphoma of the stomach may occasionally be made through cytologic brushings of the gastric mucosa but usually it requires a biopsy at gastroscopy or laparotomy. Failure of gastroscopic biopsies to detect lymphoma in a given case should not be interpreted as being conclusive, since superficial biopsies may

miss the deeper lymphoid infiltrate. The macroscopic pathology of gastric lymphoma may also mimic adenocarcinoma, consisting of either a bulky ulcerated lesion localized in the corpus or antrum or a diffuse process spreading throughout the entire gastric submucosa and even extending into the duodenum. Microscopically, the vast majority of gastric lymphoid tumors are non-Hodgkin's lymphomas of B cell origin; Hodgkin's disease involving the stomach is extremely uncommon. Histologically, these tumors may range from well-differentiated, superficial processes [mucosa-associated lymphoid tissue (MALT)] to high-grade, large cell lymphomas. Infection with *H. pylori*, the same bacterium associated with the development of gastric adenocarcinoma, appears to increase the risk for gastric lymphoma in general andMALTlymphomas in particular. Gastric lymphomas spread initially to regional lymph nodes (often to Waldeyer's ring) and may then disseminate. Gastric lymphomas are staged like other lymphomas (Chap. 112).

TREATMENT

Primary gastric lymphoma is a far more treatable disease than adenocarcinoma of the stomach, a fact that underscores the need for making the correct diagnosis. Antibiotic treatment to eradicate *H. pylori* infection has led to regression of about 75% of gastricMALTlymphomas and should be considered before surgery, radiation therapy, or chemotherapy are undertaken in patients having such tumors. Responding patients should undergo periodic endoscopic surveillance because it remains unclear whether the neoplastic clone is eliminated or merely suppressed. Subtotal gastrectomy, usually followed by combination chemotherapy, has led to 5-year survival rates of 40 to 60% in patients with localized high-grade lymphomas. The need for a major surgical procedure is not clear, particularly in patients with preoperative radiographic evidence of nodal involvement, for whom chemotherapy alone is effective therapy. A role for radiation therapy is not defined because most recurrences develop at sites distant from the epigastrium. If widespread disease is discovered at the time of laparotomy, combination chemotherapy should be used.

GASTRIC (NONLYMPHOID) SARCOMA

Leiomyosarcomas are the most common of this group of gastric malignancies and make up 1 to 3% of gastric neoplasms. They most frequently involve the anterior and posterior walls of the gastric fundus and often ulcerate and bleed. Even those lesions that appear benign on histologic examination may behave in a malignant fashion. Leiomyosarcomas rarely invade adjacent viscera and characteristically do not metastasize to lymph nodes, but they may spread to the liver and lungs. The treatment of choice is surgical resection. Combination chemotherapy should be reserved for patients with metastatic disease.

COLORECTAL CANCER

INCIDENCE

Cancer of the large bowel is second only to lung cancer as a cause of cancer death in the United States. Approximately 130,200 new cases occurred in 2000, and 56,300 deaths were due to colorectal cancer. The incidence rate has declined slightly during the past 15 years and the mortality rate has decreased in recent years, particularly in

females. Colorectal cancer generally occurs in individuals³50 years.

POLYPS AND MOLECULAR PATHOGENESIS

Most colorectal cancers, regardless of etiology, arise from adenomatous polyps. A polyp is a grossly visible protrusion from the mucosal surface and may be classified pathologically as a nonneoplastic hamartoma (*juvenile polyp*), a hyperplastic mucosal proliferation (*hyperplastic polyp*), or an adenomatous polyp. Only adenomas are clearly premalignant, and only a minority of such lesions ever develop into cancer. Population-screening studies and autopsy surveys have revealed that adenomatous polyps may be found in the colons of>30% of middle-aged or elderly people; however<1% of polyps ever become malignant. Most polyps produce no symptoms and remain clinically undetected. Occult blood in the stool may be found in<5% of patients with such lesions.

A number of molecular changes have been described in DNA obtained from adenomatous polyps, dysplastic lesions, and polyps containing microscopic foci of tumor cells (carcinoma in situ), which are thought to represent a multistep process in the evolution of normal colonic mucosa to life-threatening invasive carcinoma. These developmental steps towards carcinogenesis include point mutations in the K-*ras* protooncogene; hypomethylation of DNA, leading to gene activation; loss of DNA ("allelic loss") at the site of a tumor suppressor gene [the adenomatous polyposis coli (*APC*) gene] located on the long arm of chromosome 5 (5q21); allelic loss at the site of a tumor suppressor gene located on chromosome 18q [the deleted in colorectal cancer (*DCC*) gene]; and allelic loss at chromosome 17p, associated with mutations in the *p53* tumor suppressor gene (Chap. 81). Thus, the altered proliferative pattern of the colonic mucosa, which results in progression to a polyp and then to carcinoma, may involve the mutational activation of an oncogene followed by and coupled with the loss of genes that normally suppress tumorigenesis. While the present model includes five such molecular alterations, others are likely involved in the carcinogenic process. It remains uncertain whether the genetic aberrations always occur in a defined order. Based on this model, however, it is believed that neoplasia develops only in those polyps in which all of these mutational events take place.

Clinically, the probability of an adenomatous polyp becoming a cancer depends on the gross appearance of the lesion, its histologic features, and its size. Adenomatous polyps may be pedunculated (stalked) or sessile (flat-based). Cancers develop more frequently in sessile polyps. Histologically, adenomatous polyps may be tubular, villous (i.e., papillary), or tubulovillous. Villous adenomas, most of which are sessile, become malignant more than three times as often as tubular adenomas. The likelihood that any polypoid lesion in the large bowel contains invasive cancer is related to the size of the polyp, being negligible (<2%) in lesions<1.5 cm, intermediate (2 to 10%) in lesions 1.5 to 2.5 cm in size, and substantial (10%) in lesions >2.5 cm.

Following the detection of an adenomatous polyp, the entire large bowel should be visualized endoscopically or radiographically, since synchronous lesions are present in about one-third of cases. Colonoscopy should then be repeated periodically, even in the absence of a previously documented malignancy, since such patients have a 30 to 50% probability of developing another adenoma and are at a higher-than-average risk for

developing a colorectal carcinoma. Adenomatous polyps are thought to require >5 years of growth before becoming clinically significant; colonoscopy need not be carried out more frequently than every 3 years.

ETIOLOGY AND RISK FACTORS

Risk factors for the development of colorectal cancer are listed in Table 90-4.

Diet The etiology for most cases of large-bowel cancer appears to be related to environmental factors. The disease occurs more often in upper socioeconomic populations who live in urban areas. Mortality from colorectal cancer is directly correlated with per capita consumption of calories, meat protein, and dietary fat and oil as well as elevations in the serum cholesterol concentration and mortality from coronary artery disease. Geographic variations in incidence are unrelated to genetic differences, since migrant groups tend to assume the large-bowel cancer incidence rates of their adopted countries. Furthermore, population groups such as Mormons and Seventh Day Adventists, whose lifestyle and dietary habits differ somewhat from those of their neighbors, have significantly lower than expected incidence and mortality rates for colorectal cancer. Colorectal cancer has increased in Japan since that nation has adopted a more "western" diet. At least two hypotheses have been proposed to explain the relationship to diet, neither of which is fully satisfactory.

Animal Fats One hypothesis is that the ingestion of animal fats leads to an increased proportion of anaerobes in the gut microflora, resulting in the conversion of normal bile acids into carcinogens. This provocative hypothesis is supported by several reports of increased amounts of fecal anaerobes in the stools of patients with colorectal cancer. Diets high in animal (but not vegetable) fats are also associated with high serum cholesterol, which is also associated with enhanced risk for the development of colorectal adenomas and carcinomas.

Fiber The observation that South African Bantus ingest a diet far higher in roughage, produce more frequent, bulkier stools, and have a lower incidence of large-bowel cancer than Americans and Europeans led to the proposal that the higher rate of colorectal cancer in western society results from low intake of dietary fiber. This theory suggests that dietary fiber accelerates intestinal transit time, thereby reducing the exposure of colonic mucosa to potential carcinogens and diluting these carcinogens because of enhanced fecal bulk. This theory has been largely discredited. Although an enhanced fiber intake increases fecal bulk, higher fiber intake has not been documented to consistently shorten stool transit time. In addition, despite the generally higher fiber intake in low-incidence countries, the environmental differences between developing and industrialized nations are myriad and include such other important dietary variables as meat and fat consumption. Furthermore, a diet low in fiber may lead to chronic constipation and diverticulosis. If a low-fiber diet were a significant risk factor in colorectal cancer, individuals with diverticulosis should be at higher risk for developing colorectal tumors; this is not the case. Finally, addition of fiber to the diet does not protect against the development of adenomatous polyps or colorectal cancer.

Thus, the weight of epidemiologic evidence implicates diet as being the major etiologic factor for colorectal cancer, particularly diets high in calories and animal fat.

HEREDITARY FACTORS AND SYNDROMES

As many as 25% of patients with colorectal cancer have a family history of the disease, suggesting a hereditary predisposition. Inherited large-bowel cancers can be divided into two main groups: the well-studied but uncommon polyposis syndromes and the more common nonpolyposis syndromes (Table 90-5).

Polyposis Coli Polyposis coli (familial polyposis of the colon) is a rare condition characterized by the appearance of thousands of adenomatous polyps throughout the large bowel. It is transmitted as an autosomal dominant trait; the occasional patients with no family history probably developed the condition due to a spontaneous mutation. Polyposis coli is associated with a deletion in the long arm of chromosome 5 (including the *APC* gene) in both neoplastic (somatic mutation) and normal (germline mutation) cells. The loss of this genetic material (i.e., allelic loss) results in the absence of tumor suppressor genes whose protein products would normally inhibit neoplastic growth. The presence of soft tissue and bony tumors, congenital hypertrophy of the retinal pigment epithelium, mesenteric desmoid tumors, and of ampullary cancers in addition to the colonic polyps characterizes a subset of polyposis coli known as *Gardner's syndrome*. The appearance of malignant tumors of the central nervous system accompanying polyposis coli defines *Turcot's syndrome*. The colonic polyps in all these conditions are rarely present before puberty but are generally evident in affected individuals by age 25. If the polyposis is not treated surgically, colorectal cancer will develop in almost all patients before age 40. Polyposis coli results from a defect in the colonic mucosa leading to an abnormal proliferative pattern and an impaired DNA repair following exposure to radiation or ultraviolet light. Once the multiple polyps that constitute polyposis coli are detected, patients should undergo a total colectomy. The ileoanal anastomotic technique allows removal of the entire bowel while retaining the anal sphincter; this appears to be the best treatment. Medical therapy with nonsteroidal anti-inflammatory drugs such as sulindac and cyclooxygenase-2 inhibitors such as celecoxib decreases the number and size of polyps in patients with polyposis coli; however, this effect on polyps is only temporary. Colectomy remains the primary therapy. The offspring of patients with polyposis coli, who often are prepubertal when the diagnosis is made in the parent, have a 50% risk for the development of this premalignant disorder and should be carefully screened by annual flexible sigmoidoscopy until age 35. Proctosigmoidoscopy is a sufficient screening procedure because polyps tend to be evenly distributed from cecum to anus, making more invasive and expensive techniques such as colonoscopy or barium enema unnecessary. Testing for occult blood in the stool is an inadequate screening maneuver. An alternative method for identifying carriers is testing DNA from peripheral blood mononuclear cells for the presence of a mutated *APC* gene. The detection of such a germline mutation can lead to a definitive diagnosis before the development of polyps.

Hereditary Nonpolyposis Colon Cancer Hereditary nonpolyposis colon cancer (HNPCC), also known as Lynch syndrome, is another autosomal dominant trait. It is characterized by the presence of three or more relatives with histologically documented colorectal cancer, one of whom is a first-degree relative of the other two; one or more cases of colorectal cancer diagnosed before age 50 in the family; and colorectal cancer involving at least two generations. In contrast to polyposis coli, HNPCC is associated

with an unusually high frequency of cancer arising in the proximal large bowel. The median age for the appearance of an adenocarcinoma is<50 years, 10 to 15 years younger than the median age for the general population. Despite having a poorly differentiated histologic appearance, the proximal colon tumors in HNPCC have a better prognosis than sporadic tumors from patients of similar age. Families with HNPCC often include individuals with multiple primary cancers; the association of colorectal cancer with either ovarian or endometrial carcinomas is especially strong in women. It has been recommended that members of such families undergo biennial colonoscopy beginning at age 25 years, with intermittent pelvic ultrasonography and endometrial biopsy offered for potentially afflicted women; such a screening strategy has not yet been validated. HNPCC is associated with germline mutations of several genes, particularly *hMSH2* on chromosome 2 and *hMLH1* on chromosome 3. These mutations lead to errors in DNA replication and are thought to result in DNA instability because of defective repair of DNA mismatches, resulting in abnormal cell growth and tumor development. Testing tumor cells for "microsatellite instability" (sequence changes reflecting defective mismatch repair) in patients under age 50 with colorectal cancer and a positive family history for colorectal or endometrial cancer may identify probands with HNPCC.

INFLAMMATORY BOWEL DISEASE (See alsoChap. 287)

Large-bowel cancer is increased in incidence in patients with long-standing inflammatory bowel disease. Cancers develop more commonly in patients with ulcerative colitis than in those with granulomatous colitis, but this impression may result in part from the occasional difficulty of differentiating these two conditions. The risk of colorectal cancer in a patient with inflammatory bowel disease is relatively small during the initial 10 years of the disease, but then it appears to increase at a rate of ~0.5 to 1% per year. Cancer may develop in 8 to 30% of patients after 25 years. The risk is higher in younger patients with pancolitis.

Cancer surveillance in patients with inflammatory bowel disease is unsatisfactory. Symptoms such as bloody diarrhea, abdominal cramping, and obstruction, which may signal the appearance of a tumor, are similar to the complaints caused by a flare-up of the underlying disease. In patients with a history of inflammatory bowel disease lasting 15 years or more who continue to experience exacerbations, the surgical removal of the colon can significantly reduce the risk for cancer and also eliminate the target organ for the underlying chronic gastrointestinal disorder. The value of such surveillance techniques as colonoscopy with mucosal biopsies and brushings for less symptomatic individuals with chronic inflammatory bowel disease is uncertain. The lack of uniformity regarding the pathologic criteria that characterize dysplasia and the absence of data that such surveillance reduces the development of lethal cancers have made this costly practice an area of controversy.

OTHER HIGH-RISK CONDITIONS

***Streptococcus bovis* Bacteremia** For unknown reasons, individuals who develop endocarditis or septicemia from this fecal bacteria have a high incidence of occult colorectal tumors and, possibly, upper gastrointestinal cancers as well. Endoscopic or radiographic screening appears advisable.

Ureterosigmoidostomy There is a 5 to 10% incidence of colon cancer 15 to 30 years after ureterosigmoidostomy to correct congenital extrophy of the bladder. Neoplasms characteristically are found at a site distal to the ureteral implant where colonic mucosa is chronically exposed to both urine and feces.

Tobacco Use Cigarette smoking is linked to the development of colorectal adenomas, particularly after more than 35 years of tobacco use. No biologic explanation for this association has yet been proposed.

PRIMARY PREVENTION

Several orally administered compounds have been assessed as possible inhibitors of colon cancer. The most effective class of these chemopreventive agents is aspirin and other nonsteroidal anti-inflammatory drugs, which are thought to suppress cell proliferation by inhibiting prostaglandin synthesis. Regular aspirin use reduces the risk for colonic adenomas and carcinomas as well as for death from large-bowel cancer; this inhibiting effect on colonic carcinogenesis appears to increase with the duration of drug use. Oral folic acid supplements and oral calcium supplements have been found to reduce the risk of adenomatous polyps and colorectal cancers in case-control studies. While antioxidant vitamins such as ascorbic acid, tocopherols, and b-carotene are present in diets rich in fruits and vegetables, which have been associated with lower rates of colorectal cancer, they have been found to be ineffective at reducing the incidence of subsequent adenomas in patients who had undergone the removal of a colonic adenoma. Estrogen replacement therapy has been associated with a reduction in the risk of colorectal cancer in women, conceivably by an effect on bile acid synthesis and composition. The otherwise unexplained reduction in colorectal cancer mortality in women may be a result of the widespread use of estrogen replacement in postmenopausal individuals.

SCREENING

The rationale for colorectal cancer screening programs is that the earlier detection of localized, superficial cancers in asymptomatic individuals will increase the surgical cure rate. Such screening programs are important for individuals having a family history of the disease in first-degree relatives. The relative risk for developing colorectal cancer increases to 1.75 in such people and may be even higher if the relative was afflicted before age 60. The use of proctosigmoidoscopy as a screening tool was based on the observation that 60% of early lesions are located in the rectosigmoid. For unexplained reasons, however, the proportion of large-bowel cancers arising in the rectum has been decreasing during the past several decades, with a corresponding increase in the proportion of cancers in the more proximal descending colon. As such, the potential for rigid proctosigmoidoscopy to detect a sufficient number of occult neoplasms to make the procedure cost-effective has been questioned. Flexible, fiberoptic sigmoidoscopes permit trained operators to visualize the colon for up to 60 cm, which enhances the capability for cancer detection. However, this technique still leaves the proximal half of the large bowel unscreened.

Most programs directed at the early detection of colorectal cancers have focused on digital rectal examinations and fecal occult blood testing. The digital examination should

be part of any routine physical evaluation in adults older than age 40, serving as a screening test for prostate cancer in men, a component of the pelvic examination in women, and an inexpensive maneuver for the detection of masses in the rectum. The development of the Hemoccult test has greatly facilitated the detection of occult fecal blood. Unfortunately, even when performed optimally, the Hemoccult test has major limitations as a screening technique. About 50% of patients with documented colorectal cancers have a negative fecal Hemoccult test, consistent with the intermittent bleeding pattern of these tumors. When random cohorts of asymptomatic persons have been tested, 2 to 4% have Hemoccult-positive stools. Colorectal cancers have been found in<10% of these "test-positive" cases, with benign polyps being detected in an additional 20 to 30%. Thus, a colorectal neoplasm will not be found in most asymptomatic individuals with occult blood in their stool. Nonetheless, persons found to have Hemoccult-positive stool routinely undergo further medical evaluation, including sigmoidoscopy, barium enema, and/or colonoscopy -- procedures that are not only uncomfortable and expensive but also associated with a small risk for significant complications. The added cost of these studies would appear justifiable if the small number of patients found to have occult neoplasms because of Hemoccult screening could be shown to have an improved prognosis and prolonged survival. Prospectively controlled trials addressing this issue have been performed. One of these studies, conducted at the University of Minnesota and involving >46,000 participants, reported a statistically significant reduction in mortality from colorectal cancer for individuals undergoing annual screening. However, this benefit only emerged after >13 years of follow-up and was extremely expensive to achieve, since all positive tests (most of which were false-positive) were followed by colonoscopy. Moreover, these colonoscopic examinations may have represented "chance selection" for more effective endoscopic screening and may also have provided the opportunity for cancer prevention through the removal of potentially premalignant adenomatous polyps.

Screening techniques for large-bowel cancer in asymptomatic persons remain unsatisfactory. Recommendations from governmental and private agencies are conflicting. Compliance with any screening strategy within the general population is poor. At present, the American Cancer Society suggests annual digital rectal examinations beginning at age 40, annual fecal Hemoccult screening beginning at age 50, and sigmoidoscopy (preferably flexible) every 3 to 5 years beginning at age 50 for asymptomatic individuals having no colorectal cancer risk factors. The use of colonscopy or double-contrast barium enemas for screening have not yet been systematically examined. Nonetheless, the American Cancer Society has proposed such a "total colon examination" every 10 years as an alternative to Hemoccult testing with periodic flexible sigmoidoscopy. More effective techniques for screening are needed, perhaps taking advantage of the molecular changes that have been described in these tumors. Analysis of stool for specific *ras* protooncogene mutations is being tested.

CLINICAL FEATURES

Presenting Symptoms Symptoms vary with the anatomic location of the tumor. Since stool is relatively liquid as it passes through the ileocecal valve into the right colon, cancers arising in the cecum and ascending colon may become quite large, without resulting in any obstructive symptoms or noticeable alterations in bowel habits. Lesions

of the right colon commonly ulcerate, leading to chronic, insidious blood loss without a change in the appearance of the stool. Consequently, patients with tumors of the ascending colon often present with symptoms such as fatigue, palpitations, and even angina pectoris and are found to have a hypochromic, microcytic anemia indicative of iron deficiency. Since the cancer may bleed intermittently, a random fecal occult blood test may be negative. As a result, the unexplained presence of iron-deficiency anemia in any adult (with the possible exception of a premenopausal, multiparous woman) mandates a thorough endoscopic and/or radiographic visualization of the entire large bowel (Fig. 90-1).

Since stool becomes more concentrated as it passes into the transverse and descending colon, tumors arising there tend to impede the passage of stool, resulting in the development of abdominal cramping, occasional obstruction, and even perforation. Radiographs of the abdomen often reveal characteristic annular, constricting lesions ("apple-core" or "napkin-ring") (Fig. 90-2).

Cancers arising in the rectosigmoid are often associated with hematochezia, tenesmus, and narrowing of the caliber of stool; anemia is an infrequent finding. While these symptoms may lead patients and their physicians to suspect the presence of hemorrhoids, the development of rectal bleeding and/or altered bowel habits demands a prompt digital rectal examination and proctosigmoidoscopy.

Staging, Prognostic Factors, and Patterns of Spread The prognosis for individuals having colorectal cancer is related to the depth of tumor penetration into the bowel wall and the presence of both regional lymph node involvement and distant metastases. These variables are incorporated into the staging system introduced by Dukes and applied to a TNM classification method, in which T represents the depth of tumor penetration, N the presence of lymph node involvement, and M the presence or absence of distant metastases (Table 90-6). Superficial lesions that do not penetrate into the muscularis or involve regional lymph nodes are designated as *stage A* (T1N0M0) disease; tumors that penetrate more deeply but have not spread to lymph nodes are *stage B* disease [subclassified as *stage* B_1(T2N0M0) if lesions are restricted to the muscularis and as *stage* B_2(T3N0M0) if lesions involve or penetrate the serosa]; regional lymph node involvement defines *stage C* (TxN1M0) disease; and metastatic spread to sites such as liver, lung, or bone indicates *stage D* (TxNxM1) disease. Unless gross evidence of metastatic disease is present, disease stage cannot be determined accurately before surgical resection and pathologic analysis of the operative specimens. It is not clear whether the detection of nodal metastases by special immunohistochemical molecular techniques has the same prognostic implications as disease detected by routine light microscopy.

Most recurrences after a surgical resection of a large-bowel cancer occur within the first 4 years, making 5-year survival a fairly reliable indicator of cure. The likelihood for 5-year survival in patients with colorectal cancer is stage-related (Table 90-6). That likelihood has improved during the past several decades when similar surgical stages have been compared. The most plausible explanation for this improvement appears to be more thorough intraoperative and pathologic staging. In particular, more exacting attention to pathologic detail has revealed that the prognosis following the resection of a colorectal cancer is not related merely to the presence or absence of regional lymph

node involvement but may be more precisely assessed by the number of involved lymph nodes (one to four lymph nodes versus five or more lymph nodes). Other predictors of a poor prognosis after a total surgical resection include tumor penetration through the bowel wall into pericolic fat, poorly differentiated histology, perforation and/or tumor adherence to adjacent organs (increasing the risk for an anatomically adjacent recurrence), and venous invasion by tumor (Table 90-7). Regardless of the clinicopathologic stage, a preoperative elevation of the plasma carcinoembryonic antigen (CEA) level predicts eventual tumor recurrence. The presence of aneuploidy and specific chromosomal deletions, such as allelic loss in chromosome 18q (involving the *DCC* gene) in tumor cells, appears to predict a higher risk for metastatic spread, particularly in patients with stage B_2(T3N0M0) disease. Conversely, the detection of microsatellite instability in tumor tissue has been associated with a more favorable outcome. In contrast to most other cancers, the prognosis in colorectal cancer is not influenced by the size of the primary lesion when adjusted for nodal involvement and histologic differentiation.

Cancers of the large bowel generally spread to regional lymph nodes or to the liver via the portal venous circulation. The liver represents the most frequent visceral site of metastatic dissemination; it is the initial site of distant spread in one-third of recurring colorectal cancers and is involved in more than two-thirds of such patients at the time of death. In general, colorectal cancer rarely metastasizes to the lungs, supraclavicular lymph nodes, bone, or brain without prior spread to the liver. A major exception to this rule occurs in patients having primary tumors in the distal rectum, from which tumor cells may spread through the paravertebral venous plexus, escaping the portal venous system and thereby reaching the lungs or supraclavicular lymph nodes without hepatic involvement. The median survival after the detection of distant metastases is 6 to 9 months (hepatomegaly, abnormal liver chemistries) to 24 to 30 months (small liver nodule initially identified by elevatedCEAlevel and subsequentCTscan).

TREATMENT

Total resection of tumor is the optimal treatment when a malignant lesion is detected endoscopically or radiographically in the large bowel. An evaluation for the presence of metastatic disease, including a thorough physical examination, chest radiograph, biochemical assessment of liver function, and measurement of the plasmaCEAlevel, should be performed before surgery. When possible, a colonoscopy of the entire large bowel should be performed to identify synchronous neoplasms and/or polyps. The detection of metastases should not preclude surgery in patients with tumor-related symptoms such as gastrointestinal bleeding or obstruction, but it often prompts the use of a less radical operative procedure. At the time of laparotomy, the entire peritoneal cavity should be examined, with thorough inspection of the liver, pelvis, and hemidiaphragm and careful palpation of the full length of the large bowel. Following recovery from a complete resection, patients should be observed carefully for 5 years by semiannual physical examinations and yearly blood chemistry measurements. If a complete colonoscopy was not performed preoperatively, it should be carried out within the first several postoperative months. Some authorities favor measuring plasma CEA levels at 3-month intervals because of the sensitivity of this test as a marker for otherwise undetectable tumor recurrence. Subsequent endoscopic or radiographic surveillance of the large bowel, probably at triennial intervals, is indicated, since patients

who have been cured of one colorectal cancer have a 3 to 5% probability of developing an additional bowel cancer during their lifetime and a>15% risk for the development of adenomatous polyps. Anastomotic ("suture-line") recurrences are infrequent in colorectal cancer patients provided the surgical resection margins were adequate and free of tumor. PeriodicCTscreening, chest radiographs, or more frequent colonoscopic examinations do not affect prognosis and add unnecessary costs to postoperative surveillance.

Radiation therapy to the pelvis is recommended for patients with rectal cancer because it reduces the 30 to 40% probability of regional recurrences following complete surgical resection of stage B or C tumors, especially if they have penetrated through the serosa. This alarmingly high rate of local disease recurrence is believed to be due to the fact that the contained anatomic space within the pelvis limits the extent of the resection and because the rich lymphatic network of the pelvic side wall immediately adjacent to the rectum facilitates the early spread of malignant cells into surgically inaccessible tissue. Radiation therapy, either pre- or postoperatively, reduces the likelihood of pelvic recurrences but does not appear to prolong survival. Preoperative radiotherapy is indicated for patients with large, potentially unresectable rectal cancers; such lesions may shrink enough to permit subsequent surgical removal. Radiation therapy is not effective in the primary treatment of colon cancer.

Chemotherapy in patients with advanced colorectal cancer has proven to be of only marginal benefit.5-FU is the most effective single agent for this disease. Partial responses are obtained in 15 to 20% of patients. The probability of tumor response appears to be somewhat greater for patients with liver metastases when chemotherapy is infused directly into the hepatic artery, but intraarterial treatment is costly and toxic and does not appear to prolong survival. The concomitant administration of folinic acid (leucovorin) improves the efficacy of 5-FU in patients with advanced colorectal cancer, presumably by enhancing the binding of 5-FU to its target enzyme, thymidylate synthase. A threefold improvement in the partial response rate is noted when folinic acid is combined with 5-FU; however, the effect on survival is marginal, and the optimal dose schedule remains to be defined.

Irinotecan (CPT-11), a topoisomerase 1 inhibitor, prolongs survival when compared to supportive care in patients whose disease has progressed on5-FU. Furthermore, the addition of irinotecan to 5-FU and leucovorin improves response rates and survival of patients with metastatic disease. Oxaliplatin, a platinum analogue, also improves the response rate when added to 5-FU and leucovorin as initial treatment of patients with metastatic disease.

Patients with solitary hepatic metastases without clinical or radiographic evidence of additional tumor involvement should be considered for partial liver resection, because such procedures are associated with 5-year survival rates of 25 to 30% when performed on selected individuals by experienced surgeons.

The administration of5-FU and leucovorin for 6 months after resection of tumor in patients with stage C disease leads to a 40% decrease in recurrence rates and 30% improvement in survival. Patients with stage B_2tumors do not benefit from adjuvant therapy. In rectal cancer, the delivery of postoperative (and probably preoperative)

combined modality therapy (5-FU plus radiation therapy) reduces the risk of recurrence and increases the chance of cure for patients with stages B_2 and C tumors. The 5-FU acts as a radiosensitizer when delivered together with radiation therapy.

TUMORS OF THE SMALL INTESTINE

Small-bowel tumors comprise <5% of gastrointestinal neoplasms. Because of their rarity, a correct diagnosis is often delayed. Abdominal symptoms are usually vague and poorly defined, and conventional radiographic studies of the upper and lower intestinal tract often appear normal. Small-bowel tumors should be considered in the differential diagnosis in the following situations: (1) recurrent, unexplained episodes of crampy abdominal pain; (2) intermittent bouts of intestinal obstruction, especially in the absence of inflammatory bowel disease or prior abdominal surgery; (3) intussusception in the adult; and (4) evidence of chronic intestinal bleeding in the presence of negative conventional contrast radiographs. A careful small-bowel barium study is the diagnostic procedure of choice; the diagnostic accuracy may be improved by infusing barium through a nasogastric tube placed into the duodenum (enteroclysis).

BENIGN TUMORS

The histology of benign small-bowel tumors is difficult to predict on clinical and radiologic grounds alone. The symptomatology of benign tumors is not distinctive, with pain, obstruction, and hemorrhage being the most frequent symptoms. These tumors are usually discovered during the fifth and sixth decades of life, more often in the distal rather than the proximal small intestine. The most common benign tumors are adenomas, leiomyomas, lipomas, and angiomas.

Adenomas These tumors include those of the islet cells and Brunner's glands as well as polypoid adenomas. *Islet cell adenomas* are occasionally located outside the pancreas; the associated syndromes are discussed inChap. 93. *Brunner's gland adenomas* are not truly neoplastic but represent a hypertrophy or hyperplasia of submucosal duodenal glands. These appear as small nodules in the duodenal mucosa that secrete a highly viscous alkaline mucus. Most often, this is an incidental radiographic finding not associated with any specific clinical disorder.

Polypoid Adenomas About 25% of benign small-bowel tumors are polypoid adenomas (Table 90-5). They may present as single polypoid lesions or, less commonly, as papillary villous adenomas. As in the colon, the sessile or papillary form of the tumor is sometimes associated with a coexisting carcinoma. Occasionally, patients with Gardner's syndrome develop premalignant adenomas in the small bowel; such lesions are generally in the duodenum. Multiple polypoid tumors may occur throughout the small bowel (and occasionally the stomach and colorectum) in the Peutz-Jeghers syndrome. The polyps are usually hamartomas (juvenile polyps) having a low potential for malignant degeneration. Mucocutaneous melanin deposits as well as tumors of the ovary, breast, pancreas, and endometrium are also associated with this autosomal dominant condition.

Leiomyomas These neoplasms arise from smooth-muscle components of the intestine and are usually intramural, affecting the overlying mucosa. Ulceration of the mucosa

may cause gastrointestinal hemorrhage of varying severity. Cramping, intermittent abdominal pain is frequently encountered.

Lipomas These tumors occur with greatest frequency in the distal ileum and at the ileocecal valve. They have a characteristic radiolucent appearance, are usually intramural and asymptomatic, but on occasion cause bleeding.

Angiomas While not true neoplasms, these lesions are important because they frequently cause intestinal bleeding. They may take the form of telangiectasia or hemangiomas. Multiple intestinal telangiectasias occur in a nonhereditary form confined to the gastrointestinal tract or as part of the hereditary Osler-Rendu-Weber syndrome. Vascular tumors may also take the form of isolated hemangiomas, most commonly in the jejunum. Angiography, especially during bleeding, is the best procedure for evaluating these lesions.

MALIGNANT TUMORS

While rare, small-bowel malignancies occur in patients with long-standing regional enteritis and celiac sprue as well as in individuals with AIDS. Malignant tumors of the small bowel are frequently associated with fever, weight loss, anorexia, bleeding, and a palpable abdominal mass. After ampullary carcinomas (many of which arise from biliary or pancreatic ducts), the most frequently occurring small-bowel malignancies are adenocarcinomas, lymphomas, carcinoid tumors, and leiomyosarcomas.

Adenocarcinomas The most common primary cancers of the small bowel are adenocarcinomas, accounting for ~50% of malignant tumors. These cancers occur most often in the distal duodenum and proximal jejunum, where they tend to ulcerate and cause hemorrhage or obstruction. Radiologically, they may be confused with chronic duodenal ulcer disease or with Crohn's disease if the patient has long-standing regional enteritis. The diagnosis is best made by endoscopy and biopsy under direct vision. Surgical resection is the treatment of choice.

Lymphomas Lymphoma in the small bowel may be primary or secondary. A diagnosis of a primary intestinal lymphoma requires histologic confirmation in a clinical setting in which palpable adenopathy and hepatosplenomegaly are absent and no evidence of lymphoma is seen on chest radiograph,CT scan, or peripheral blood smear or on bone marrow aspiration and biopsy. Symptoms referable to the small bowel are present, usually accompanied by an anatomically discernible lesion. Secondary lymphoma of the small bowel consists of involvement of the intestine by a lymphoid malignancy extending from involved retroperitoneal or mesenteric lymph nodes (Chap. 112).

Primary intestinal lymphoma accounts for ~20% of malignancies of the small bowel. These neoplasms are non-Hodgkin's lymphomas; they usually have a diffuse, large cell histology and are of T cell origin. Intestinal lymphoma involves the ileum, jejunum, and duodenum, in decreasing frequency, a pattern that mirrors the relative amount of normal lymphoid cells in these anatomic areas. The risk of small-bowel lymphoma is increased in patients with a prior history of malabsorptive conditions (e.g., celiac sprue), regional enteritis, and depressed immune function due to congenital immunodeficiency syndromes, prior organ transplantation, autoimmune disorders, or AIDS.

The development of localized or nodular masses that narrow the lumen results in periumbilical pain (made worse by eating) as well as weight loss, vomiting, and occasional intestinal obstruction. The diagnosis of small-bowel lymphoma may be suspected from the appearance on contrast radiographs of patterns such as infiltration and thickening of mucosal folds, mucosal nodules, areas of irregular ulceration, or stasis of contrast material. The diagnosis can be confirmed by surgical exploration and resection of involved segments. Intestinal lymphoma can occasionally be diagnosed by peroral intestinal mucosal biopsy, but since the disease mainly involves the lamina propria, full-thickness surgical biopsies are usually required.

Resection of the tumor constitutes the initial treatment modality. While postoperative radiation therapy has been given to some patients following a total resection, most authorities favor short-term (three cycles) systemic treatment with combination chemotherapy. The frequent presence of widespread intraabdominal disease at the time of diagnosis and the occasional multicentricity of the tumor often make a total resection impossible. The probability of sustained remission or cure is ~75% in patients with localized disease but is ~25% in individuals with unresectable lymphoma. In patients whose tumors are not resected, chemotherapy may lead to bowel perforation.

A unique form of small-bowel lymphoma, diffusely involving the entire intestine, was first described in oriental Jews and Arabs and is referred to as *immunoproliferative small intestinal disease* (IPSID), *Mediterranean lymphoma,* or*a-heavy chain disease*. This is a B cell tumor. The typical presentation includes chronic diarrhea and steatorrhea associated with vomiting and abdominal cramps; clubbing of the digits may be observed. A curious feature in many patients with IPSID is the presence in the blood and intestinal secretions of an abnormal IgA that contains a shortenedα-heavy chain and is devoid of light chains. It is suspected that the abnormal α chains are produced by plasma cells infiltrating the small bowel. The clinical course of patients with IPSID is generally one of exacerbations and remissions, with death frequently resulting from either progressive malnutrition and wasting or the development of an aggressive lymphoma. The use of oral antibiotics such as tetracycline appears to be beneficial in the early phases of the disorder, suggesting a possible infectious etiology. Combination chemotherapy has been administered during later stages of the disease, with variable results. Results are better when antibiotics and chemotherapy are combined.

Carcinoid Tumors Carcinoid tumors arise from argentaffin cells of the crypts of Lieberkuhn and are found from the distal duodenum to the ascending colon, areas embryologically derived from the midgut. More than 50% of intestinal carcinoids are found in the distal ileum, with most congregating close to the ileocecal valve. Most intestinal carcinoids are asymptomatic and of low malignant potential, but invasion and metastases may occur, leading to the carcinoid syndrome (Chap. 93).

Leiomyosarcomas Leiomyosarcomas often are >5 cm in diameter and may be palpable on abdominal examination. Bleeding, obstruction, and perforation are common.

CANCERS OF THE ANUS

Cancers of the anus account for 1 to 2% of the malignant tumors of the large bowel.

Most such lesions arise in the anal canal, the anatomic area extending from the anorectal ring to a zone approximately halfway between the pectinate (or dentate) line and the anal verge. Carcinomas arising proximal to the pectinate line (i.e., in the transitional zone between the glandular mucosa of the rectum and the squamous epithelium of the distal anus) are known as basaloid, cuboidal, or cloacogenic tumors; about one-third of anal cancers have this histologic pattern. Malignancies arising distal to the pectinate line have a squamous cell histology, ulcerate more frequently, and constitute ~55% of anal cancers. The prognosis for patients with basaloid and squamous cell cancers of the anus is identical when corrected for tumor size and the presence or absence of nodal spread.

The development of anal cancer is associated with infection by human papillomavirus, the same organism etiologically linked to cervical cancer. The virus is sexually transmitted. The infection may lead to anal warts (condyloma accuminata) which may progress to anal intraepithelial neoplasia and on to squamous cell carcinoma. The risk for anal cancer is increased among homosexual males, presumably related to anal intercourse. Anal cancer risk is increased in both men and women with AIDS, possibly because their immunosuppressed state permits more severe papillomavirus infection. Anal cancers occur most commonly in middle-aged persons and are more frequent in women than men. At diagnosis, patients may experience bleeding, pain, sensation of a perianal mass, and pruritus.

Radical surgery (abdominal-perineal resection with lymph node sampling and a permanent colostomy) used to be the treatment of choice for this tumor type. The 5-year survival rate after such a procedure was 55 to 70% in the absence of spread to regional lymph nodes;<20% if nodal involvement was present. An alternative therapeutic approach combining external beam radiation therapy with concomitant chemotherapy has resulted in biopsy-proven disappearance of all tumor in>80% of patients whose initial lesion was <3 cm in size. Tumor has recurred in <10% of these patients, and ~70% of patients with anal cancers can be cured with nonoperative treatment. Surgery should be reserved for the minority of individuals who are found to have residual tumor after being managed initially with radiation therapy combined with chemotherapy.

91. TUMORS OF THE LIVER AND BILIARY TRACT - *Jules L. Dienstag*, *Kurt J. Isselbacher*

BENIGN LIVER TUMORS

HEPATOCELLULAR ADENOMAS

Hepatocellular adenomas are benign tumors of the liver found predominantly in women in their third and fourth decades. Their preponderance in women suggests a hormonal influence in their pathogenesis, and oral contraceptives are thought to play an etiologic role. The risk of liver adenomas is increased among those who take anabolic steroids and exogenous androgens. Multiple hepatic adenomas have been associated with glycogen storage disease type I.

Hepatic adenomas occur predominantly in the right lobe of the liver, may be multiple, and are often quite large (>10 cm). Microscopically, they consist of normal or slightly atypical hepatocytes. These cells contain increased glycogen, making them appear paler and larger than normal. Clinical features include pain and the presence of a palpable mass or features of intratumor hemorrhage (pain and circulatory collapse). The diagnosis is usually made by a combination of techniques: sonography, computed tomography (CT), magnetic resonance imaging (MRI), selective hepatic arteriography, and radionuclide scans. The angiographic appearance is typically hypervascular but often also includes hypovascular regions. Technetium 99m scans usually show a defect, because phagocytosing Kupffer cells are absent. Like hepatocellular carcinomas, adenomas have a T_1-intense MRI appearance. The risk of malignant change is small; the risk is higher for large (>10 cm) and multiple adenomas.

Management involves imaging surveillance for small tumors. If the lesion is large (8 to 10 cm), near the surface, and resectable, surgical removal is appropriate. A patient with liver adenoma should stop taking oral contraceptives. Surgical resection may be required for tumors that do not shrink after oral contraceptives are stopped. Pregnancy increases the risk of hemorrhage and should be avoided in women with large adenomas. Patients with multiple large adenomas (e.g., those with glycogen-storage disease) may benefit from liver transplantation.

FOCAL NODULAR HYPERPLASIA

Focal nodular hyperplasia is a benign tumor often identified incidentally on imaging studies or at laparoscopy done for other reasons. Like hepatic adenomas, it occurs predominantly in women; however, oral contraceptives are not implicated, and hemorrhage and necrosis are rare. The risk of hemorrhage, however, appears to be higher in women taking oral contraceptives. Typically, the lesion is a solid tumor, often in the right lobe, with a fibrous core and stellate projections. The fibrous projections contain atypical hepatocytes, biliary epithelium, Kupffer cells, and inflammatory cells. A technetium scan will usually show a hot spot because of the presence of Kupffer cells. The lesion appears vascular on angiography, and septations may be detectable by angiography, helicalCT scan, and, most reliably, byMRI, but only rarely by ultrasound. Surgery is indicated only for symptomatic lesions.

HEMANGIOMA AND OTHER BENIGN TUMORS

Hemangiomas are the most common benign liver tumors, occurring predominantly in women and usually detected incidentally. The prevalence in the general population is in the range of 0.5 to 7.0%. These asymptomatic vascular lesions can be identified byMRI, contrast-enhancedCT, labeled red blood cell nuclide scans, or hepatic angiography. They do not need to be removed unless they are large and are producing a mass effect. Hemorrhage is rare, and malignant change does not occur.

Nodular regenerative hyperplasia consists of multiple hepatic nodules resulting from periportal hepatocyte regeneration with surrounding atrophy. It may be associated with an underlying condition such as malignancy or connective tissue disease. Portal hypertension (in the absence of cirrhosis) is the most common clinical manifestation. Other less common benign hepatic lesions include *bile duct adenomas* and *cystadenomas*.

CARCINOMAS OF THE LIVER

HEPATOCELLULAR CARCINOMA

Epidemiology and Etiology Primary hepatocellular carcinoma is one of the most common tumors in the world. It is especially prevalent in regions of Asia and sub-Saharan Africa, where the annual incidence is up to 500 cases per 100,000 population. In the United States and western Europe, it is much less common; however, the annual incidence in the United States has increased from 1.4/100,000 in the period 1976 to 1980 to 2.4/100,000 in 1991 to 1995. Hepatocellular carcinoma is up to four times more common in men than in women and usually arises in a cirrhotic liver. The incidence peaks in the fifth to sixth decades of life in western countries but one to two decades earlier in regions of Asia and Africa with a high prevalence of liver carcinoma.

The principal reason for the high incidence of hepatocellular carcinoma in parts of Asia and Africa is the frequency of chronic infection with *hepatitis B virus* (HBV) and *hepatitis C virus* (HCV). These chronic infections frequently lead to cirrhosis, which itself is an important risk factor for hepatocellular carcinoma (the risk of liver cancer in a cirrhotic liver is ~3% per year); 60 to 90% of these tumors occur in patients with macronodular cirrhosis. Studies in regions of Asia where hepatocellular carcinoma and HBV infection are prevalent have shown that the incidence of this cancer is about 100-fold higher in individuals with evidence of HBV infection than in noninfected controls. In China, the lifetime risk of developing hepatocellular carcinoma in patients with chronic hepatitis B approaches 40%. In patients with HBV infection and hepatocellular carcinoma, HBV DNA may be integrated into host genomic DNA, both in the tumor cells and in adjacent, uninvolved hepatocytes. In addition, modifications of cellular gene expression occur by insertional mutagenesis, chromosomal rearrangements, or the transcriptional transactivating activity of the X and the pre-S2 regions of the HBV genome.

HCValso leads to hepatocellular carcinoma. HCV genetic material does not become integrated into host genomic DNA. Therefore, the mechanism of HCV carcinogenesis is unclear. In Europe and Japan, HCV appears to be substantially more prevalent than HBVin cases of hepatocellular carcinoma. Both HBV and HCV can be demonstrated in

some patients, but the clinical course of liver malignancy in these patients does not appear to differ from that when only one virus is implicated. One distinction in high-prevalence areas between hepatocellular carcinoma associated with HBV infection and with HCV infection is in the timing of onset. In Asia, HBV is acquired at birth via perinatal transmission, whereas HCV infection is acquired primarily during adulthood from transfused blood and injections. Correspondingly, the onset of liver carcinoma occurs one to two decades earlier in those with lifelong hepatitis B than in persons with adult-acquired hepatitis C. Retrospective analysis indicates that hepatocellular carcinoma occurs on average approximately 30 years after HCV infection and almost exclusively in patients with cirrhosis. The annual incidence of hepatocellular carcinoma in cirrhotic patients with chronic hepatitis C is 1.5 to 4%.

Any agent or factor that contributes to chronic, low-grade liver cell damage and mitosis makes hepatocyte DNA more susceptible to genetic alterations. Thus, as indicated above, *chronic liver disease* of any type is a risk factor and predisposes to the development of liver cell carcinoma. These conditions include alcoholic liver disease,a_1-antitrypsin deficiency, hemochromatosis, and tyrosinemia. In Africa and southern China, *aflatoxin* $B_1$is an important public health hazard. This mycotoxin appears to induce a very specific mutation at codon 249 in the tumor suppressor gene p53.

The loss, inactivation, or mutation of the p53 gene has been implicated in tumorigenesis and is the most common genetic derangement present in human cancers. ThusHBV and aflatoxin B_1 have been implicated in the pathogenesis of hepatocellular carcinoma in regions of Africa and southern China where both agents are prevalent.

In view of the male predominance of liver cancer, hormonal factors may also play a role. Hepatocellular tumors may occur with long-term androgenic steroid administration, with exposure to thorium dioxide or vinyl chloride (see below), and possibly with exposure to estrogens in the form of oral contraceptives.

Clinical and Laboratory Features Cancers of the liver initially may escape clinical recognition because they occur in patients with underlying cirrhosis, and the symptoms and signs may suggest progression of the underlying disease. The most common presenting features are abdominal *pain* with detection of an abdominal mass in the right upper quadrant. There may be a *friction rub* or *bruit* over the liver. Blood-tinged ascites occurs in about 20% of cases. Jaundice is rare, unless there is significant deterioration of liver function or mechanical obstruction of the bile ducts. Serum elevations of alkaline phosphatase and a fetoprotein (AFP) are common (see below). An abnormal type of prothrombin, des-g-carboxy prothrombin, is made and correlates with AFP elevations.

A small percentage of patients with hepatocellular carcinoma have a *paraneoplastic syndrome*; erythrocytosis may result from erythropoietin-like activity produced by the tumor; hypercalcemia may result from secretion of a parathyroid-like hormone. Other manifestations may include hypercholesterolemia, hypoglycemia, acquired porphyria, dysfibrinogenemia, and cryofibrinogenemia.

Imaging procedures to detect liver tumors include ultrasound,CT,MRI, hepatic artery angiography (Chap. 282), and technetium scans. Ultrasound is frequently used to

screen high-risk populations and should be the first test if hepatocellular carcinoma is suspected; it is less costly than scans, is relatively sensitive, and can detect most tumors >3 cm. Helical CT and MRI scans are being used with increasing frequency and have higher sensitivities.

AFPlevels >500 ug/L are found in about 70 to 80% of patients with hepatocellular carcinoma. Lower levels may be found in patients with large metastases from gastric or colonic tumors and in some patients with acute or chronic hepatitis. High levels of serum AFP (>500 to 1000 ug/L) in an adult with liver disease and without an obvious gastrointestinal tumor strongly suggest hepatocellular carcinoma. A rising level suggests progression of the tumor or recurrence after hepatic resection or therapeutic approaches such as chemotherapy or chemoembolization (see below).

Percutaneous *liver biopsy* can be diagnostic if the sample is taken from an area localized by ultrasound orCT. Because these tumors tend to be vascular, percutaneous biopsies should be done with caution. Cytologic examination of ascitic fluid is invariably negative for tumor cells. Occasionally, *laparoscopy* or *minilaparotomy*, to permit liver biopsy under direct vision, may be used. This approach has the additional advantage of sometimes identifying patients who have a localized resectable tumor suitable for partial hepatectomy.

TREATMENT

Staging of hepatocellular carcinoma is based on tumor size (< or > 50% of the liver), ascites (absent or present), bilirubin (<or > 3), and albumin (< or >3) to establish Okuda stages I, II, and III. The Okuda system predicts clinical course better than the American Joint Cancer Commission TNM system. The natural history of each stage without treatment is: stage I, 8 months; stage II, 2 months; stage III, less than 1 month.

The course of *clinically apparent* disease is rapid; if untreated, most patients die within 3 to 6 months of diagnosis. When hepatocellular carcinoma is detected very early by serial screening ofAFP and ultrasound, survival is 1 to 2 years after resection. In selected cases, therapy may prolong life. *Surgical resection* offers the only chance for cure; however, few patients have a resectable tumor at the time of presentation, because of underlying cirrhosis, involvement of both hepatic lobes, or distant metastases (common sites are lung, brain, bone, and adrenal), and the 5-year survival is low. In patients at high risk for the development of hepatocellular carcinoma, screening programs have been initiated to identify small tumors when they are still resectable. Because 20 to 30% of patients with early hepatocellular carcinoma do not have elevated levels of circulating AFP, ultrasonographic screening is recommended as well as AFP determination. In a study in the Far East, persons positive for hepatitis B surface antigen, with or without liver disease, were screened serially; a number of patients with small, subclinical tumors were identified, and surgical resection undertaken. Follow-up observation revealed a 5-year survival rate in this group of 70% and a 10-year survival rate of 50%. These Asian patients, however, were unusual in that they had minimal or no liver disease and their tumors tended to be unifocal or encapsulated. The findings are in contrast to a study in a large population of Italian patients with cirrhosis, associated in most cases with chronicHBVand/orHCVinfections; screening every 3 to 12 months permitted the detection of a 3% annual incidence of

cancer in this cohort but in most cases failed to achieve the goal of early detection of surgically treatable disease. No randomized study has yet shown survival benefit for screening patients at high risk of developing hepatocellular carcinoma.

Liver transplantation may be considered as a therapeutic option; tumor recurrence or metastases are the major problems. Patients who have a single lesion£5 cm or three or fewer lesions£3 cm have survival after liver transplantation that is the same as survival after transplantation for nonmalignant liver disease (Chap. 301). Other approaches include (1) hepatic artery embolization and chemotherapy (chemoembolization), (2) alcohol or radio-frequency ablation via ultrasound-guided percutaneous injection, and (3) ultrasound-guided cryoablation.

Treatment options for unresectable disease are limited. Randomized trials have not shown a survival advantage after chemoembolization. The liver cannot tolerate high doses of radiation. The disease is not responsive to chemotherapy, including newer agents such as gemcytabine. Investigative immunotherapy and gene therapy techniques have not yet been successful. Based on the presence of hormone receptors on the tumor, tamoxifen has been tested, but without success, and octreotide has had some modest activity. In patients with resectable tumors, polyprenoic acid (a retinoic acid formulation) and intraarterial ^{131}I-labeled lipiodol have been reported to reduce the rate of recurrence.

Prevention is the preferred strategy. Hepatitis B vaccine can prevent infection and its sequelae, and a reduction in hepatocellular carcinoma has been seen in Taiwan with the introduction of universal vaccination of children. Interferon treatment reduces the incidence of hepatic failure, death, and liver cancer in patients infected withHBV. Treatment with interferon may lower the risk of development of liver cancer in patients with hepatitis C-related cirrhosis (Chap. 297), but additional studies are needed.

OTHER MALIGNANT LIVER TUMORS

Fibrolamellar carcinoma differs from the typical hepatocellular carcinoma in that it tends to occur in young adults without underlying cirrhosis. This tumor is nonencapsulated but well circumscribed and contains fibrous lamellae; it grows slowly and is associated with a longer survival if treated. Surgical resection has resulted in 5-year survivals >50%; if the lesion is nonresectable, liver transplantation is an option, and the outcome far exceeds that observed in the nonfibrolamellar variety of liver cancer. *Hepatoblastoma* is a tumor of infancy that typically is associated with very high serumAFPlevels. The lesions are usually solitary, may be resectable, and have a better 5-year survival than that of hepatocellular carcinoma. *Angiosarcoma* consists of vascular spaces lined by malignant endothelial cells. Etiologic factors include prior exposure to thorium dioxide (Thorotrast), polyvinyl chloride, arsenic, and androgenic anabolic steroids. *Epithelioid hemangioendothelioma* is of borderline malignancy; most cases are benign, but bone and lung metastases occur. This tumor occurs in early adulthood, presents with right upper quadrant pain, is heterogeneous on sonography, hypodense onCT, and without neovascularity on angiography. Immunohistochemical staining reveals expression of factor VIII antigen. In the absence of extrahepatic metastases, these lesions can be treated by surgical resection or liver transplantation.

METASTATIC TUMORS

Metastatic tumors of the liver are common, ranking second only to cirrhosis as a cause of fatal liver disease. In the United States, the incidence of metastatic carcinoma is at least 20 times greater than that of primary carcinoma. At autopsy, hepatic metastases occur in 30 to 50% of patients dying from malignant disease.

Pathogenesis The liver is uniquely vulnerable to invasion by tumor cells. Its size, high rate of blood flow, double perfusion by the hepatic artery and portal vein, and its Kupffer cell filtration function combine to make it the next most common site of metastases after the lymph nodes. In addition, local tissue factors or endothelial membrane characteristics appear to enhance metastatic implants. Virtually all types of neoplasms except those primary in the brain may metastasize to the liver. The most common primary tumors are those of the gastrointestinal tract, lung, and breast, as well as melanomas. Less common are metastases from tumors of the thyroid, prostate, and skin.

Clinical Features Most patients with metastases to the liver present with symptoms referable only to the primary tumor, and the asymptomatic hepatic involvement is discovered in the course of clinical evaluation. Sometimes hepatic involvement is reflected by nonspecific symptoms of weakness, weight loss, fever, sweating, and loss of appetite. Rarely, features indicating active hepatic disease, especially abdominal pain, hepatomegaly, or ascites, are present. Patients with widespread metastatic liver involvement usually have suggestive clinical signs of cancer and hepatic enlargement. Some have localized induration or tenderness, and, occasionally, a friction rub may be found over tender areas of the liver.

Results of liver biochemical tests are often abnormal, but the elevations in marker levels are often only mild and nonspecific. These signs reflect the effects of fever and wasting as well as those of the infiltrating neoplastic process itself. An increase in serum alkaline phosphatase is the most common and frequently the only abnormality. Hypoalbuminemia, anemia, and occasionally a mild elevation of aminotransferase levels may also be found with more widespread disease. Substantially elevated serum levels of carcinoembryonic antigen are usually found when the metastases are from primary malignancies in the gastrointestinal tract, breast, or lung.

Diagnosis Evidence of metastatic invasion of the liver should be sought actively in any patient with a primary malignancy, especially of the lung, gastrointestinal tract, or breast, before resection of the primary lesion. An elevated level of alkaline phosphatase or a mass apparent on ultrasound,CT, orMRIexamination of the liver may provide a presumptive diagnosis. Blind percutaneous needle biopsy of the liver will result in a positive diagnosis of metastatic disease in only 60 to 80% of cases with hepatomegaly and elevated alkaline phosphatase levels. Serial sectioning of specimens, two or three repeated biopsies, or cytologic examination of biopsy smears may increase the diagnostic yield by 10 to 15%. The yield is increased when biopsies are directed by ultrasound or CT or obtained during laparoscopy.

TREATMENT

Most metastatic carcinomas respond poorly to all forms of treatment, which is usually only palliative. Rarely a single, large metastasis can be removed surgically. Systemic chemotherapy may slow tumor growth and reduce symptoms, but it does not alter the prognosis. Chemoembolization, intrahepatic chemotherapy, and alcohol or radio-frequency ablation may provide palliation.

CHOLANGIOCARCINOMA

Benign tumors of the extrahepatic bile ducts are extremely rare causes of mechanical biliary obstruction. Most of these are papillomas, adenomas, or cystadenomas and present with obstructive jaundice or hemobilia. Adenocarcinoma of the extrahepatic ducts is more common. There is a slight male preponderance (60%), and the incidence peaks in the fifth to seventh decades. Apparent predisposing factors include (1) some chronic hepatobiliary parasitic infestations, (2) congenital anomalies with ectactic ducts, (3) sclerosing cholangitis and chronic ulcerative colitis, and (4) occupational exposure to possible biliary tract carcinogens (employment in rubber or automotive plants). Cholelithiasis is not clearly a predisposing factor for cholangiocarcinoma. The lesions of cholangiocarcinoma may be diffuse or nodular. Nodular lesions often arise at the bifurcation of the common bile duct (Klatskin tumors) and are usually associated with a *collapsed gallbladder*, a finding that mandates cholangiography to view proximal hepatic ducts.

Patients with cholangiocarcinoma usually present with biliary obstruction, painless jaundice, pruritus, weight loss, and acholic stools. A deep-seated, vaguely localized right upper quadrant pain may be noted. Hepatomegaly and a palpable, distended gallbladder (unless the lesion is high in the duct) are frequent accompanying signs. Fever is unusual unless associated with ascending cholangitis. Because the obstructing process is gradual, the cholangiocarcinoma is often far advanced by the time it presents clinically. The diagnosis is most frequently made by cholangiography following ultrasound demonstration of dilated intrahepatic bile ducts. Any focal strictures of the bile ducts should be considered malignant until proved otherwise. Endoscopic cholangiography permits obtaining specimens for cytology (sensitivity ~60%) and insertion of stents for biliary drainage. Survival of 1 to 2 years is possible in some cases. Perhaps 20% of patients have surgically resectable tumors, but 5-year survival is only 10 to 30%. The high recurrence rate limits the value of liver transplantation. Photodynamic therapy (intravenous hematoporphyrin with cholangioscopically delivered light) has been used with promising early results.

CARCINOMA OF THE PAPILLA OF VATER

The ampulla of Vater may be involved by extension of tumor arising elsewhere in the duodenum or may itself be the site of origin of a sarcoma, carcinoid tumor, or adenocarcinoma. Papillary adenocarcinomas are associated with slow growth and a more favorable clinical prognosis than diffuse, infiltrative cancers of the ampulla, which are more frequently widely invasive. The presenting clinical manifestation is usually obstructive jaundice. Endoscopic retrograde cannulation of the pancreatic duct is the preferred diagnostic technique when ampullary carcinoma is suspected, because it allows for direct endoscopic inspection and biopsy of the ampulla and for pancreatography to exclude a pancreatic malignancy. Cancer of the papilla is usually

treated by wide surgical excision. Lymph node or other metastases are present at the time of surgery in approximately 20% of cases, and the 5-year survival rate following surgical therapy in this group is only 5 to 10%. In the absence of metastases, radical pancreaticoduodenectomy (the Whipple procedure) is associated with 5-year survival rates as high as 40%.

CANCER OF THE GALLBLADDER

Most cancers of the gallbladder develop in conjunction with stones rather than polyps. In patients with gallstones, the risk for developing gallbladder cancer, while increased, is still quite low. In one study, gallbladder cancer developed in only 5 of 2583 patients with gallstones followed for a median of 13 years. In the United States, adenocarcinomas make up the vast majority of the estimated 6500 new cases of gallbladder cancer diagnosed each year. The female/male ratio is 4:1, and the mean age at diagnosis is approximately 70 years. The clinical presentation is most often one of unremitting right upper quadrant pain associated with weight loss, jaundice, and a palpable right upper quadrant mass. Cholangitis may supervene. The preoperative diagnosis of the condition has been facilitated by ultrasound andCT. CT is also useful in guiding fine-needle aspiration and biopsy.

Once symptoms have appeared, spread of the tumor outside the gallbladder by direct extension or by lymphatic or hematogenous routes is almost invariable. Over 75% of gallbladder carcinomas are unresectable at the time of surgery, the exceptions being tumors discovered incidentally at laparotomy. If the tumor is found by the pathologist, no additional therapy is required. If the tumor is noted by the surgeon on routine cholecystectomy, a second operation is generally performed to resect the adjacent liver, bile duct, and local lymph nodes. Incidental resectable gallbladder tumors have a 50% 5-year survival. The 1-year mortality rate for unresectable disease is about 95%, and <5% of patients survive 5 years. Radical operative resection does not appear to improve survival. Trials of radiation and chemotherapy in patients with gallbladder cancer have been disappointing.

92. PANCREATIC CANCER - *Robert J. Mayer*

INCIDENCE AND ETIOLOGY

The incidence of pancreatic carcinoma in the United States has increased significantly as the median life expectancy of the American population has lengthened. The tumor results in the death of >98% of afflicted patients. 28,200 individuals died of pancreatic cancer in 2000, making it the fifth most common cause of cancer-related mortality. The disease is more common in males than in females and in blacks than in whites. It rarely develops before the age of 50.

Little is known about the causes of pancreatic cancer. Cigarette smoking is the most consistent risk factor, with the disease being two to three times more common in heavy smokers than in nonsmokers. Whether this association is due to a direct carcinogenic effect of tobacco metabolites on the pancreas or an as yet undefined exposure that occurs more frequently in cigarette smokers is uncertain. Patients with chronic pancreatitis are at increased risk of pancreatic cancer, as are persons with long-standing diabetes mellitus. Obesity is a risk factor for pancreatic cancer; risk is directly related to increased calorie intake. Alcohol abuse or cholelithiasis are not risk factors for pancreatic cancer. Nor is pancreatic cancer associated with coffee consumption. Mutations in K-*ras* genes have been found in >85% of specimens of human pancreatic cancer. Pancreatic cancer has been associated with mutation of the *p16*$_{INK4}$gene located on chromosome 9p21, a gene also implicated in the pathogenesis of malignant melanoma.

CLINICAL FEATURES

More than 90% of pancreatic cancers are ductal adenocarcinomas, with islet cell tumors constituting the remaining 5 to 10%. Pancreatic cancers occur twice as frequently in the pancreatic head (70% of cases) as in the body (20%) or tail (10%) of the gland.

With the exception of jaundice, the initial symptoms associated with pancreatic cancer are often insidious and are usually present for >2 months before the cancer is diagnosed (Table 92-1). Pain and weight loss are present in>75% of patients. The pain typically has a gnawing, visceral quality, occasionally radiating from the epigastrium to the back. Pain is often a more severe problem in lesions arising in the body or tail of the gland, as such tumors may become quite large before being detected. Characteristically, the pain improves somewhat when the patient bends forward. The development of significant pain suggests retroperitoneal invasion and infiltration of the splanchnic nerves, indicating that the primary lesion is advanced and is not surgically resectable. Rarely, such pain may be transient and associated with hyperamylasemia, indicative of acute pancreatitis caused by ductal obstruction by tumor. The weight loss observed in most patients is primarily the result of anorexia, although in the initial period of the disease, subclinical malabsorption may also be a contributing factor.

Jaundice due to biliary obstruction is found in >80% of patients having tumors in the pancreatic head and is typically accompanied by dark urine, a claylike appearance of stool, and pruritus. In contrast to the "painless jaundice" sometimes observed in patients having carcinomas of the bile ducts, duodenum, or periampullary regions, most icteric

individuals with ductal carcinomas of the pancreatic head will complain of significant abdominal discomfort. Although the gallbladder is usually enlarged in patients with carcinoma of the head of the pancreas, it is palpable in <50% (Courvoisier's sign). However, the presence of an enlarged gallbladder in a jaundiced patient without biliary colic should suggest malignant obstruction of the extrahepatic biliary tree.

Glucose intolerance, presumably a direct consequence of the tumor, often develops within 2 years of the clinical diagnosis. Other initial manifestations include venous thrombosis and migratory thrombophlebitis (Trousseau's syndrome), gastrointestinal hemorrhage from varices due to compression of the portal venous system by tumor, and splenomegaly caused by cancerous encasement of the splenic vein.

DIAGNOSTIC PROCEDURES (Fig. 92-1)

Despite the availability of serologic tests for tumor-associated antigens, such as the carcinoembryonic antigen (CEA) and CA 19-9, and noninvasive imaging techniques, such as computed tomography (CT) and ultrasonography, the early diagnosis of a potentially resectable pancreatic carcinoma remains extremely difficult. The nonspecificity of the initial symptoms and the poor sensitivity of both serologic assays and noninvasive techniques have frustrated the development of effective screening procedures. When the disease is clinically suspected in a patient having vague, persistent abdominal complaints, ultrasound should be performed to visualize the gallbladder and the pancreas, as well as upper gastrointestinal contrast radiographs to rule out a hiatal hernia or a peptic ulcer. If these studies fail to provide an explanation for the symptoms, a CT scan should be considered. It should encompass not only the pancreas but also the liver, retroperitoneal lymph nodes, and pelvis, as pancreatic cancer frequently spreads within the abdomen. While more costly than ultrasonography, CT is technically simpler, more reproducible, provides better definition of the body and tail of the pancreas, and requires less interpretive skill. CT generally detects a malignant pancreatic lesion in>80% of cases; in 5 to 15% of patients with proven pancreatic carcinoma, the CT scan shows only generalized pancreatic enlargement suggesting pancreatitis rather than malignancy. False-positive results occur in about 5 to 10% of cases where no tumor was found on laparotomy. Magnetic resonance imaging (MRI) has not been shown to be better than CT in the evaluation of pancreatic lesions. The value of positron emission tomography (PET) has not been defined. When clinical circumstances dictate additional diagnostic evaluation, endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic ultrasonography (EUS) may clarify the cause of ambiguous CT or ultrasound findings. The characteristic findings are stenosis or obstruction of either the pancreatic or the common bile duct; both duct systems are abnormal in over half the cases. Carcinoma and chronic pancreatitis can be difficult to distinguish by ERCP, particularly if both diseases are present. False-negative results with ERCP are infrequent (<5%) and usually occur in the setting of islet cell, rather than ductal, carcinomas.

Selective and superselective angiography may be of value in some patients. Angiography is an effective means of detecting carcinomas in the body and tail of the pancreas by the demonstration of vascular narrowing, displacement, or occlusion by tumor. Angiography is being replaced as a diagnostic and staging procedure by spiralCTscanning with contrast imaging. This high-resolution technology predicts the

resectability of the tumor if no disease is found outside the pancreas, obstruction of the superior mesenteric-portal vein confluence is absent, or tumor extension to the celiac axis and superior mesenteric arteries is not found. Radiographic staging criteria are shown inTable 92-2.

Regardless of the results of the above diagnostic studies, a histologic confirmation of pancreatic cancer is mandatory; similar findings can result from other neoplasms such as islet cell tumor or lymphoma, for which the therapeutic approach and prognosis differ from those for ductal carcinoma. In patients with unresectable disease or medical contraindications to surgical resection, tissue may be obtained through a percutaneous needle aspiration biopsy of the pancreas withCT or ultrasonographic guidance.

Unfortunately, however, even laparotomy may not provide a definitive diagnosis, because chronic pancreatitis may also produce a hard mass in the head of the pancreas indistinguishable from carcinoma by palpation. Furthermore, a superficial biopsy of such a mass may not show neoplastic tissue, revealing only evidence of pancreatitis, as the cancer is often surrounded by edematous, inflamed, and fibrotic tissue (i.e., chronic pancreatitis).

TREATMENT

Complete surgical resection of pancreatic tumors offers the only effective treatment for this disease. Unfortunately, such "curative" operations are only possible in 10 to 15% of patients with pancreatic cancer, usually those individuals with a tumor in the pancreatic head in whom jaundice was the initial symptom. Patients considered for such a procedure should have no evidence of metastatic spread on a chest radiograph and abdominal-pelvicCT scan and should be operated on by an experienced surgeon, as mortality rates of>15% have been associated with this procedure. Curative resection is usually preceded by laparoscopic inspection of the abdomen to confirm absence of occult disease spread to the omentum, peritoneum, or liver, which would preclude curative resection. Although the potential for cure in patients with pancreatic cancer is restricted to the few who are able to undergo a complete surgical resection, the 5-year survival rate following such operations is only 10%. Nonetheless, the procedure is worth attempting, particularly for lesions in the pancreatic head, since ductal carcinomas often cannot be distinguished preoperatively from ampullary, duodenal, and distal bile duct tumors or pancreatic cyst adenocarcinomas, all of which have far higher rates of resectability and cure. Furthermore, patients who undergo resection and eventually experience disease recurrence survive three to four times longer than those whose tumor is not excised, indicating that such operations have a palliative effect. The risk for tumor recurrence is not affected by the type of operative procedure -- i.e., total pancreatectomy versus pancreaticoduodenectomy ("Whipple resection") -- but it is increased by the presence of lymph node metastases or tumor invasion into adjacent viscera. As a rule, pancreaticoduodenectomy or distal pancreatectomy seems preferable to total pancreatectomy because of the retention of exocrine function and avoidance of brittle diabetes.

The median survival for patients whose pancreatic cancers are surgically unresectable is 6 months. Management is directed at palliation of symptoms. Ambulatory patients having tumors in the pancreatic head should be considered for surgical diversion of the

biliary system. If jaundice has already developed, therapeutic options include either nonoperative biliary decompression by endoscopic or percutaneous, transhepatic biliary drainage or surgical biliary bypass. External beam radiation in patients with unresectable tumors that have not spread beyond the pancreas does not appear to prolong survival, although a sufficient reduction in tumor size may lead to palliation of pain. However, the addition of chemotherapy with fluorouracil (5-FU) to external beam irradiation has increased the survival time for these patients, perhaps because 5-FU acts as a radiosensitizing agent. In a small patient population, a similar combination of radiation therapy and 5-FU appears to have prolonged the survival and increased the cure rate as compared to a prospectively randomized nontreatment control group of patients who had a complete surgical resection of their pancreatic cancer. This observation needs to be confirmed before it can be accepted. The possibility of administering such chemoradiation therapy at diagnosis and before surgery ("neoadjuvant" treatment), to increase the potential for resectability, is under investigation. Intraoperative radiation therapy has the potential to deliver higher doses of radiation to the tumor while sparing neighboring tissues but does not give better results than external beam treatment.

Chemotherapy in the management of patients with widely metastatic pancreatic cancer has been disappointing. Gemcitabine, a deoxycytidine analogue, produces improvement in the quality of life for patients with advanced pancreatic cancer. However, duration of survival is only moderately improved. Newer forms of treatment, including combining gemcitabine with other cytotoxic agents or therapies directed at specific molecular targets, such as K-*ras*, or p53 are being evaluated. Experimental therapy should constitute the initial treatment for consenting, ambulatory patients.**Pancreatic endocrine tumors are discussed in Chap. 93.*

93. ENDOCRINE TUMORS OF THE GASTROINTESTINAL TRACT AND PANCREAS - *Robert T. Jensen*

Gastrointestinal neuroendocrine tumors (NETs) are derived from the diffuse neuroendocrine system of the gastrointestinal (GI) tract, which is composed of amine- and acid-producing cells with different hormonal profiles, depending on the site of origin. The tumors they produce can be divided into carcinoid tumors and pancreatic endocrine tumors (PETs). These tumors were originally classified as APUDomas (for *a*mine *p*recursor *u*ptake and *d*ecarboxylation), as were pheochromocytomas, melanomas, and medullary thyroid carcinomas because they share certain cytochemical, pathologic, and biologic features (Table 93-1). APUDomas were thought to have a similar embryonic origin from neural crest cells, but the peptide-secreting cells are not of neuroectodermal origin.

CLASSIFICATION, PATHOLOGY, AND TUMOR BIOLOGY OF NETS

NETs are generally composed of monotonous sheets of small round cells with uniform nuclei; mitoses are uncommon. They can be tentatively identified on routine histology; however, these tumors are principally recognized by their histologic staining patterns due to shared cellular proteins. Historically, silver staining was used, and tumors were classified as showing an argentaffin reaction if they took up and reduced silver or as being argyrophilic if they did not reduce it. Immunocytochemical localization of chromogranins (A,B,C), neuron-specific enolase, or synaptophysin, which are all neuroendocrine cell markers, are now used (Table 93-1). Chromogranin A is the most widely used.

Ultrastructurally, these tumors possess electron-dense neurosecretory granules and frequently contain small clear vesicles that correspond to synaptic vesicles of neurons.NETssynthesize numerous peptides, growth factors, and bioactive amines that may be ectopically secreted, giving rise to a specific clinical syndrome (Table 93-2). The diagnosis of the specific syndrome, such as a VIPoma [vasoactive intestinal peptide (VIP)-secreting tumor], requires the clinical features of the disease and cannot be made from the immunocytochemistry results only (Table 93-1). Furthermore, pathologists cannot distinguish between benign and malignant NETs unless metastases or invasion are present.

Carcinoid tumors are frequently classified according to their anatomic area of origin (i.e., foregut, midgut, hindgut) because tumors with similar areas of origin share functional manifestations, histochemistry, and secretory products (Table 93-3). Foregut tumors generally have a low serotonin [5-hydroxytryptamine (5-HT)] content, are argentaffin-negative but argyrophilic, occasionally secrete adrenocorticotropic hormone (ACTH) or 5-hydroxytryptophan (5-HTP) causing an atypical carcinoid syndrome (Fig. 93-1), make several hormones, and may metastasize to bone. They uncommonly produce a clinical syndrome due to the secreted products. Midgut carcinoids are argentaffin-positive, have a high serotonin content, most frequently cause the typical carcinoid syndrome when they metastasize (Table 93-3,Fig. 93-1), release serotonin and tachykinins (substance P, neuropeptide K, substance K), rarely secrete 5-HTP or ACTH, and uncommonly metastasize to bone. Hindgut carcinoids (rectum and transverse and descending colon) are argentaffin-negative, often argyrophilic, rarely

contain serotonin or cause the carcinoid syndrome, rarely secrete 5-HTP or ACTH, contain numerous peptides, and may metastasize to bone.

PETscan be classified into specific functional or nonfunctional syndromes (Table 93-2). Each of the functional syndromes is associated with symptoms due to the specific hormone released. In contrast, nonfunctional PETs release no products that cause a specific clinical syndrome. "Nonfunctional" is a misnomer in the strict sense because these tumors frequently ectopically secrete a number of peptides [pancreatic polypeptide (PP) chromogranin A, neurotensin]; however, they cause no specific clinical syndrome. The symptoms caused by nonfunctional PETs are entirely due to the tumor per se.

Carcinoid tumors can occur in almost any GI tissue (Table 93-3); however, most (70%) originate from one of four sites; bronchus, jejunum/ileum, rectum, or appendix. In the past, carcinoid tumors most frequently occurred in the appendix (i.e., 40%); however, the bronchus/lung is now the most common site (32%). Overall, the GI tract is the most common site for these tumors, comprising 74%, with the respiratory tract a distant second at 25%.

The term *pancreatic endocrine tumor*, although widely used, is also a misnomer, because these tumors can occur either almost exclusively in the pancreas (insulinomas, glucagonomas, nonfunctionalPETs, PETs causing hypercalcemia) or at both pancreatic and extrapancreatic sites [gastrinomas,VIPomas, somatostatinomas, GRFomas (GRF, growth hormone-releasing factor)]. PETs are also called *islet cell tumors*; however, this term is discouraged because it is not established that many originate from the islets and many can occur at extrapancreatic sites.

The exact incidence of carcinoid tumors orPETsvaries according to whether only symptomatic or all tumors are considered. The incidence of clinically significant carcinoids is 7 to 13 cases per million population per year, whereas malignant carcinoids are reported at autopsy in 21 to 84 cases per million population per year. Clinically significant PETs have a prevalence of 10 cases per million population, with insulinomas, gastrinomas, and nonfunctional PETs having an incidence of 0.5 to 2 cases per million population per year (Table 93-2); VIPomas are 2- to 8-fold less common, glucagonomas are 17- to 30-fold less common, and somatostatinomas the least common. In autopsy studies 0.5 to 1.5% of all cases have a PET; however, in fewer than 1 in 1000 cases was a functional tumor present.

Both carcinoid tumors andPETscommonly show malignant behavior (Tables 93-2,93-3). With PETs, except for insulinomas in which <10% are malignant, 50 to 100% are malignant. With carcinoid tumors the percentage showing malignant behavior varies in different locations. For the four most common sites of occurrence the incidence of metastases varies greatly: jejunum/ileum (70%) > appendix (35%)> lung/bronchus (27%)> rectum (14%). A number of factors are important in determining survival and the aggressiveness of the tumor (Table 93-4). The presence of liver metastases is the single most important prognostic factor for both carcinoid tumors and PETs. The size of the primary tumor is particularly important in the development of liver metastases. For example, with small-intestinal carcinoids, which are the most frequent cause of the carcinoid syndrome due to metastatic disease in the liver (Table 93-2), metastases

occur in 15 to 25% if the tumor diameter is <1 cm, in 58 to 80% if it is 1 to 2 cm and in >75% if it is>2 cm. The size of the primary tumor has also been shown to be an independent predictor of the development of liver metastases for gastrinomas and other PETs. The presence of lymph node metastases, the depth of invasion, various histologic features (differentiation, mitotic rates, growth indices), and flow cytometric results such as the presence of aneuploidy are all important prognostic factors for the development of metastatic disease. The development of the carcinoid syndrome, older age, male gender, the presence of a symptomatic tumor, or greater increases in a number of tumor markers [5-hydroxyindolacetic acid (5-HIAA), neuropeptide K, chromogranin A] also adversely affect prognosis in patients with carcinoid tumors (Table 93-4). With PETs or gastrinomas, a worse prognosis is associated with female gender, overexpression of the *Ha-Ras* oncogene or p53, the absence of multiple endocrine neoplasia (MEN) type 1, and higher levels of various tumor markers (e.g., chromogranin A, gastrin).

A number of genetic disorders are associated with an increased incidence of neuroendocrine tumors (Table 93-5). Each one is caused by a loss of a possible tumor suppressor gene. The most important isMEN-1, an autosomal dominant disorder due to a defect in a 10-exon gene on 11q13, which encodes for a 610-amino-acid nuclear protein, menin (Chap. 339). In patients with MEN-1, 95 to 100% develop hyperparathyroidism due to parathyroid hyperplasia, 80 to 100% develop nonfunctionalPETs, 54 to 80% develop pituitary adenomas, and bronchial carcinoids develop in 8%, thymic carcinoids in 8%, and gastric carcinoids in 13 to 30% of patients with Zollinger-Ellison syndrome. Functional PETs occur in 80% of patients with MEN-1, with 54% developing Zollinger-Ellison syndrome, 21% insulinomas, 3% glucagonomas, and 1%VIPomas. MEN-1 is present in 20 to 25% of all patients with Zollinger-Ellison syndrome, in 4% of those with insulinomas, and in <5% of those with other PETs.

Three phakomatoses associated withNETs are von Hippel-Lindau disease, von Recklinghausen's disease, or neurofibromatosis type 1 (NF-1), and tuberous sclerosis (Bourneville's disease). Von Hippel-Lindau disease is an autosomal dominant disorder due to defects in a gene on chromosome 3p25, which encodes a 213-amino-acid protein that interacts with the elongin family of proteins as a transcriptional regulator and in abnormal protein destruction (Chap. 370). In addition to cerebellar hemangioblastomas, renal cancer, and pheochromocytomas, 10 to 17% of these patients develop aPET. Most are nonfunctional, although insulinomas andVIPomas are reported. Patients with NF-1 have defects in a gene on chromosome 17q11.2 encoding for a 2845-amino-acid protein, neurofibromin, which functions in normal cells as a suppressor of the Ras signaling cascade (Chap. 370). Up to 12% of these patients develop an upper GI carcinoid tumor, characteristically in the periampullary region (54%). Many of such tumors are classified as somatostatinomas because they contain somatostatin immunocytochemically; however, they seldom produce a clinical somatostatinoma syndrome. NF-1 has rarely been associated with insulinomas and Zollinger-Ellison syndrome. Tuberous sclerosis is caused by mutations that alter either the 1164-amino-acid protein, hamartin (TSC1), or the 1807-amino-acid protein, tuberin (TSC2) (Chap. 370). Both hamartin and tuberin interact in a pathway related to cytosolic G protein regulation. A few cases including nonfunctional and functional PETs (insulinomas and gastrinomas) have been reported (Table 93-5).

Changes in theMEN-1 gene, p16/MTS1 tumor suppressor gene, and DPC 4/Smad 4 gene; amplification of the HER-2/neu protooncogene; and deletions of unknown tumor suppressor genes on chromosomes 1 and 3p may be important in the pathogenesis ofPETs. Loss of heterozygosity at the MEN-1 locus on chromosome 11q13 has been found in 93% of sporadic PETs (patients without MEN-1) and in 26 to 75% of sporadic carcinoid tumors. Mutations in the MEN-1 gene were found in 31 to 34% of sporadic gastrinomas.

CARCINOID TUMORS AND CARCINOID SYNDROME

GENERAL TUMOR CHARACTERISTICS OF THE MOST COMMON GI CARCINOID TUMORS

Appendiceal Carcinoids These occur in 1 in every 200 to 300 appendectomies, usually in the appendiceal tip. More than 90% are <1 cm in diameter; 35% have metastases. In one study of 1570 appendiceal carcinoids, 62% were localized and 27% had regional and 8% distant metastases. Half of the carcinoids between 1 and 2 cm in diameter had metastasized to lymph nodes.

Small-Intestinal Carcinoids These are frequently multiple. Between 70 and 80% are present in the ileum and 70% within 60 cm (24 in.) of the ileocecal valve; 40% are<1 cm in diameter, 32% are 1 to 2 cm, and 29% are>2 cm; and 35 to 70% are associated with metastases. They characteristically cause a marked fibrotic reaction, which can lead to intestinal obstruction. Distant metastases occur to liver in 36 to 60% of patients, to bone in 3%, and to lung in 4%. Between 15 and 25% of small (<1 cm) carcinoid tumors of the small intestine have metastases; 58 to 100% of tumors 1 to 2 cm in diameter have metastases. Carcinoids also occur in the duodenum, with 21% having metastases. In one study, no duodenal tumor <1 cm metastasized, whereas 33% of those >2 cm had metastases. Small-intestinal carcinoids are the most common cause (60 to 87%) of the carcinoid syndrome (Table 93-6).

Rectal Carcinoids Rectal carcinoids are found in 1 of every 2500 proctoscopies. Nearly all occur 4 to 13 cm above the dentate line. Most are small, with 66 to 80% being <1 cm in diameter; 5% metastasize. Tumors 1 to 2 cm in diameter metastasize in 5 to 30% of patients, and tumors>2 cm, which are uncommon, in>70%.

Bronchial Carcinoids Bronchial carcinoids are not related to smoking. A number of different classifications of bronchial carcinoid tumors are proposed. In some studies lungNETs are classified into four categories: typical carcinoid (also called bronchial carcinoid tumor, Kulchitsky cell carcinoma-I, KCC-I); atypical carcinoid (also called well-differentiated neuroendocrine carcinoma, KC-II); intermediate small cell neuroendocrine carcinoma; and small cell neuroendocarcinoma (KC-III). Another proposed classification includes three categories of lung NETs: benign or low-grade malignant (typical carcinoid); low-grade malignant (atypical carcinoid), and high-grade malignant (poorly differentiated carcinoma of the large cell or small cell type). These different categories of lung NETs have different prognoses, varying from excellent for typical carcinoid to poor for small cell neuroendocrine carcinomas.

Gastric Carcinoids These account for 3 of every 1000 gastric neoplasms. Three

different subtypes of gastric carcinoids are noted. Each originates from gastric enterochromaffin-like (ECL) cells in the gastric mucosa. Two subtypes are associated with hypergastrinemic states: (1) chronic atrophic gastritis (type I) (80% of all gastric carcinoids); and (2) Zollinger-Ellison syndrome, almost always as part of theMEN-1 syndrome (type II) (6% of all cases). These tumors generally pursue a benign course, with 9 to 30% associated with metastases. They are usually multiple and small and infiltrate only to the submucosa. The third subtype of gastric carcinoid (type III) (sporadic) occurs without hypergastrinemia (14% of all carcinoids) and pursues an aggressive course, with 54 to 66% developing metastases. Sporadic carcinoids are usually single, large tumors; 50% have atypical histology and can be a cause of the carcinoid syndrome.

CARCINOID TUMORS WITHOUT THE CARCINOID SYNDROME

The age of patients at diagnosis ranges from 10 to 93 years, with a mean age of 63 years for carcinoid tumors of the small intestine and 66 years for those of the rectum. The presentation is diverse and related to the site of origin and extent of malignant spread. In the appendix, carcinoid tumors are usually found incidentally during surgery for suspected appendicitis. Small-intestinal carcinoids in the jejunum/ileum present with periodic abdominal pain (51%), intestinal obstruction with ileus/invagination (31%), an abdominal tumor (17%), or GI bleeding (11%). Because of the vagueness of the symptoms the diagnosis is usually delayed approximately 2 years from onset of the symptoms, with a range up to 20 years. Duodenal, gastric, and rectal carcinoids are most frequently found by chance at endoscopy. The most common symptoms of rectal carcinoids are melena/bleeding (39%), constipation (17%), and diarrhea (12%). Bronchial carcinoids are frequently discovered as a lesion on a chest radiograph, and 31% of the patients are asymptomatic. Thymic carcinoids present as anterior mediastinal masses, usually on chest radiograph of computed tomography (CT) scan. Ovarian and testicular carcinoids usually present as masses discovered on physical examination or by ultrasound. Metastatic carcinoid tumor in the liver presents frequently as hepatomegaly in a patient who may have minimal symptoms and near-normal liver function test results.

CARCINOID TUMORS WITH SYSTEMIC SYMPTOMS DUE TO SECRETED PRODUCTS

Carcinoid tumors can contain numerous GI peptides: gastrin, insulin, somatostatin, motilin, neurotensin, tachykinins (substance K, substance P, neuropeptide K), glucagon, gastrin-releasing peptide,VIP,PP, other biologically active peptides (ACTH, calcitonin, growth hormone-releasing hormone), prostaglandins, and bioactive amines (serotonin). These substances may or may not be released in sufficient amounts to cause symptoms. In patients with carcinoid tumors, elevated serum levels of PP were found in 43%, motilin in 14%, gastrin in 15%, and VIP in 6%. Foregut carcinoids are more likely to produce various GI peptides than midgut carcinoids. Ectopic ACTH production causing Cushing's syndrome is increasingly seen with foregut carcinoids (respiratory tract primarily), and in some series foregut carcinoid was the most common cause of the ectopic ACTH syndrome, accounting for 64% of all cases. Acromegaly due to GRF release occurs with foregut carcinoids, as does the somatostatinoma syndrome with duodenal carcinoids. The most common systemic syndrome is the carcinoid syndrome.

CARCINOID SYNDROME

Clinical Features The cardinal features at presentation as well as during the disease course are shown in Table 93-6. Flushing and diarrhea are the two most common symptoms, occurring in up to 73% initially and in up to 89% during the course of the disease. The characteristic flush is of sudden onset: it is a deep red or violaceous erythema of the upper body (especially the neck and face), often associated with a feeling of warmth, and occasionally associated with pruritus, lacrimation, diarrhea, or facial edema. Flushes may be precipitated by stress, alcohol, exercise, or certain foods such as cheese or by certain agents such as catecholamines, pentagastrin, and serotonin reuptake inhibitors. Flushing episodes may be brief, lasting 2 to 5 min, especially initially, or they may last for hours, especially later in the disease course. Flushing is usually seen with midgut carcinoids but can also occur with foregut carcinoids. With bronchial carcinoids the flushes are frequently prolonged for hours to days, reddish in color, and associated with salivation, lacrimation, diaphoresis, diarrhea, and hypotension. The flush associated with gastric carcinoids is also reddish in color but patchy in distribution over the face and neck. It may be provoked by food and have accompanying pruritus.

Diarrhea is present in 32 to 73% of patients initially and in 68 to 84% at some time in the disease course. Diarrhea usually occurs with flushing (85% of cases). The diarrhea is usually watery, with 60% having <1 L per day or diarrhea. Steatorrhea is present in 67%, and in 46% it is >15 g/day (normal <7 g). Abdominal pain may be present with the diarrhea or independently in 10 to 34% of cases.

Cardiac manifestations occur in 11% of patients initially and in 14 to 41% at some time in the disease course. The cardiac disease is due to fibrosis involving the endocardium, primarily on the right side, although left side lesions can occur also. The dense fibrous deposits are most common on the ventricular aspect of the tricuspid valve and less common on the pulmonary valve cusps. They can result in constriction of the valves and pulmonic stenosis is usually predominant, whereas the tricuspid valve is often fixed open, resulting in regurgitation. Up to 80% of patients with cardiac lesions develop heart failure. Lesions on the left side are much less extensive, are found in 30% at autopsy, and most frequently affect the mitral valve.

Other clinical manifestations include wheezing or asthma-like symptoms (8 to 18%) and pellagra-like skin lesions (2 to 25%). A variety of noncardiac problems due to increased fibrous tissue have been reported, including retroperitoneal fibrosis causing urethral obstruction, Peyronie's disease of the penis, intrabdominal fibrosis, and occlusion of the mesenteric arteries or veins.

Pathobiology In different studies covering 8876 patients with carcinoid tumors, carcinoid syndrome occurred in 8%, with a range of 1.4 to 18.4%. It occurs only when sufficient concentrations of tumor-secreted products reach the systemic circulation. In 91% of cases this occurs after metastasis to the liver. Rarely, the carcinoid syndrome can occur without hepatic metastases, caused by primary gut carcinoids with nodal metastases with extensive retroperitoneal invasion, pancreatic carcinoids with retroperitoneal lymph nodes, or carcinoids of the lung or ovary with direct access to the

systemic circulation. All carcinoid tumors do not have the same propensity to metastasize and cause the carcinoid syndrome (Table 93-3). Midgut carcinoids account for 60 to 67% of cases of carcinoid syndrome, foregut tumors for 2 to 33%, hindgut for 1 to 8%, and unknown primary sites for 2 to 15%.

One of the main secretory products of carcinoid tumors involved in the carcinoid syndrome is serotonin [5-hydroxytryptamine (5-HT)] (Fig. 93-1), which is synthesized from tryptophan. Up to 50% of dietary tryptophan can be used in this synthetic pathway by tumor cells, which can result in inadequate supplies for conversion to niacin; hence 2 to 5% of patients can develop pellagra-like lesions. Serotonin has numerous biologic effects including stimulating intestinal secretion, inhibiting absorption, stimulating increases in intestinal motility, and stimulating fibrogenesis. While 56 to 88% of carcinoid tumors are associated with serotonin overproduction, 12 to 26% of patients do not have the carcinoid syndrome. Serotonin overproduction is noted in 90 to 100% of patients with the carcinoid syndrome. Serotonin is thought to be predominantly responsible for the diarrhea by its effects on gut motility and intestinal secretion. Serotonin receptor antagonists (especially 5-HT_3antagonists) relieve the diarrhea in most patients. Prostaglandin E_2 and tachykinins may be important mediators of the diarrhea in some patients. Flushing is not relieved by serotonin receptor antagonists. In patients with gastric carcinoids the red, patchy pruritic flush is likely due to histamine release because it can be prevented by H_1 and H_2receptor antagonists. Numerous studies show tachykinins are stored in carcinoid tumors and released during flushing. Octreotide can relieve the flushing induced by pentagastrin in these patients without altering stimulated increase in plasma substance P, suggesting other mediators must be involved in the flushing. Both histamine and serotonin may be responsible for the wheezing as well as the fibrotic reactions involving the heart, causing Peyronie's disease and intraabdominal fibrosis. The exact mechanism of the heart disease is unclear. The valvular heart disease caused by the appetite-suppressant drug, dexfenfluramine, is histologically indistinguishable from that observed in carcinoid disease or after long exposure to 5-HT_2-selective ergot drugs. Metabolites of fenfluramine have high affinity for 5-HT_2receptors, whose activation is known to cause fibroblast mitogenesis. Lastly, high levels of 5-$HT_{2B}$and 5-HT_{2C}receptor transcripts are known to occur in heart valves. These observations support the conclusion that serotonin overproduction is important for the valvular changes, possibly by activating 5-HT_2receptors in the endocardium.

Patients may develop either a typical or atypical carcinoid syndrome (Fig. 93-1). In patients with the typical form, characteristically caused by a midgut carcinoid tumor, the conversion of tryptophan to5-HTP is the rate-limiting step. 5-HTP is rapidly converted to5-HT and stored in secretory granules of the tumor or in platelets. A small amount remains in plasma and is converted to5-HIAA, which appears in large amounts in the urine. These patients have an expanded serotonin pool size, increased blood and platelet serotonin levels, and increased urinary 5-HIAA. Some carcinoid tumors cause an atypical carcinoid syndrome thought to be due to a deficiency in the enzyme dopa decarboxylase; thus, 5-HTP cannot be converted to 5-HT (serotonin) and is secreted into the bloodstream. In these patients, plasma serotonin levels are normal but urinary levels may be increased because some 5-HTP is converted to 5-HT in the kidney. Characteristically, urinary 5-HTP and 5-HT are increased, but urinary 5-HIAA levels are only slightly elevated. Foregut carcinoids are the most likely to cause an atypical

carcinoid syndrome.

One of the most life-threatening complications of the carcinoid syndrome is the development of a carcinoid crisis. This is more frequent in patients who have intense symptoms from foregut tumors or have greatly increased urinary5-HIAAlevels (i.e., >200 mg/d). The crisis may occur spontaneously or be provoked by stress, anesthesia, chemotherapy, or a biopsy. Patients develop intense flushing, diarrhea, abdominal pain, and cardiac abnormalities including tachycardia, hypertension, or hypotension. If not adequately treated, it can be fatal.

Diagnosis The diagnosis of carcinoid syndrome relies on measurement of urinary or plasma serotonin or its metabolites in the urine. The measurement of5-HIAAis most frequently used. False-positive elevations may occur if the patient is eating serotonin-rich foods (e.g., bananas, pineapple, walnuts, pecans, avocados, or hickory nuts) or taking certain medications (e.g., cough syrup containing guaifanesin, acetaminophen, salicylates, or L-dopa). The normal range in daily urinary 5-HIAA excretion is between 2 and 8 mg. The 5-HIAA level has a 73% sensitivity and 100% specificity for carcinoid syndrome.

Most physicians use only the urinary5-HIAAexcretion rate; however, plasma and platelet serotonin levels, if available, may give additional information. Platelet serotonin levels are more sensitive than urinary 5-HIAA but are not generally available. If an atypical carcinoid syndrome is suspected and the urinary 5-HIAA is minimally elevated or normal, other urinary metabolites of tryptophan such as5-HTP or5-HTshould be measured.

Flushing occurs in a number of other conditions or diseases including systemic mastocytosis; chronic myelogenous leukemia with increased histamine release; menopause; reactions to alcohol or glutamate; and side effects of chlorpropamide, calcium channel blockers, and nicotinic acid. None of these conditions cause an increase in urinary5-HIAA.

The diagnosis of carcinoid tumor can be suggested by the carcinoid syndrome, by recurrent abdominal symptoms in a healthy-appearing individual, or by discovering hepatomegaly or hepatic metastases associated with minimal symptoms. Ileal carcinoids, which make up 25% of all clinically detected carcinoids, should be suspected in patients with bowel obstruction, abdominal pain, flushing, or diarrhea.

Serum chromogranin A levels are elevated in 50 to 100% of patients with carcinoid tumors, and the level correlates with tumor bulk. Serum chromogranin A levels are not specific for carcinoid tumors because they are also elevated in patients withPETs and otherNETs. Plasma neuron-specific enolase levels are also used as a marker of carcinoid tumors but are less sensitive than chromogranin A, being increased in only 17 to 47% of patients.

TREATMENT

Carcinoid Syndrome Treatment includes avoiding conditions that precipitate flushing, dietary supplementation with nicotinamide, treatment of heart failure with diuretics,

treatment of wheezing with oral bronchodilators, and controlling the diarrhea with antidiarrheal agents such as loperamide or diphenoxylate. If patients still have symptoms, serotonin receptor antagonists or somatostatin analogues are the drugs of choice.

There are 14 subclasses of serotonin (5-HT) receptors, and antagonists for most are not available. The $5\text{-HT}_1$and 5-HT_2receptor antagonists methysergide, cyproheptadine, and ketanserin have all been used to control the diarrhea but usually do not decrease flushing. The use of methysergide is limited because it can cause or enhance retroperitoneal fibrosis. Ketanserin diminishes diarrhea in 30 to 100% of patients. 5-HT_3receptor antagonists (ondansetron, tropisetron, alosetron) can control diarrhea and nausea in up to 100% of patients and occasionally ameliorate the flushing. A combination of histamine H_1 and H_2receptor antagonists (i.e., diphenhydramine and cimetidine or ranitidine) may control flushing in patients with foregut carcinoids.

Synthetic analogues of somatostatin (octreotide, lanreotide) are now the most widely used agents to control the symptoms of patients with carcinoid syndrome (Fig. 93-2). These drugs are effective at relieving symptoms and decreasing urinary5-HIAAlevels when self-administered every 6 to 12 h. Octreotide controls symptoms in>80% of patients, including the diarrhea and flushing, and 70% of patients show a >50% decrease in urinary 5-HIAA excretion. Patients with mild to moderate symptoms should initially be treated with 100 ug subcutaneously every 8 h. Individual responses vary, and patients have received doses as high as 3000 ug/d. About 40% of patients escape control after a median of 4 months, and the dose may need to be increased. Similar results are reported with lanreotide.

In patients with carcinoid crises, somatostatin analogues are effective at both treating the condition as well as preventing its development during known precipitating events such as surgery, anesthesia, chemotherapy, or stress. It is recommended that octreotide (150 to 250 ug subcutaneously every 6 to 8 h) be used 24 to 48 h before anesthesia and then continued throughout the procedure.

Sustained-release preparations of both octreotide [octreotide-LAR (long-acting release)] and lanreotide [lanreotide-PR (prolonged release)] are useful. Octreotide-LAR (30 mg/month) gives a plasma level ^{3}1 ng/mL for 25 days, whereas this level would require three to six injections per day of the non-sustained-release form. Lanreotide-PR is given intramuscularly every 10 to 14 days. Both sustained-release forms are highly effective.

Short-term side effects occur in 40 to 60% of patients receiving subcutaneous somatostatin analogues. Pain at the injection site and GI side effects (59% discomfort, 15% nausea, diarrhea) are the most common. They are usually short-lived and do not interrupt treatment. Important long-term side effects include gallstone formation, steatorrhea, and poor glucose tolerance. The overall incidence of gallstones/biliary sludge is 52%, with 7% of patients having symptomatic disease requiring surgical treatment.

Interferona is effective in controlling symptoms of the carcinoid syndrome, either alone or combined with hepatic artery embolization. The response rate is 42% for interferon a alone; when given with hepatic artery embolization, diarrhea was controlled for 1 year in

43% and flushing in 86% of patients.

Hepatic artery embolization alone or with chemotherapy (chemoembolization) has been used to control the symptoms of carcinoid syndrome. Embolization alone controls symptoms in up to 76% of patients, and chemoembolization (5-fluorouracil, doxorubicin, cisplatin, mitomycin) in 60 to 75% of patients. Hepatic artery embolization can have major side effects including nausea, vomiting, pain, and fever. In two studies, between 5 and 7% of patients died from complications of hepatic artery occlusion.

Other drugs have been used successfully in small numbers of patients to control the symptoms of carcinoid syndrome. Parachlorophenylalanine can inhibit tryptophan hydroxylase and the conversion of tryptophan to 5-HTP (Fig. 93-1). However, its severe side effects, including psychiatric disturbances, make it intolerable for long-term use.a-Methyldopa inhibits the conversion of 5-HTP to 5-HT; however, its effects are only partial.

Carcinoid Tumors (Nonmetastatic) Surgery is the only potentially curative therapy. Because the probability of metastases increases with increasing primary tumor size, the extent of surgical resection is determined accordingly. With appendiceal carcinoids, simple appendectomy is curative. With rectal carcinoids<1 cm, local resection is curative. With small-intestinal carcinoids <1 cm there is no consensus. Because 15 to 69% of small-intestinal carcinoids this size have metastases, some recommend a wide resection with *en bloc* resection of the adjacent lymph-bearing mesentery. If the carcinoid tumor is>2 cm for rectal, appendiceal, or small intestine, a full cancer operation should be done, including a right hemicolectomy for appendiceal carcinoid, an abdominoperineal or low anterior resection for rectal carcinoids, and an *en bloc* resection of adjacent lymph nodes for small-intestinal carcinoids. For carcinoids 1 to 2 cm in diameter in the appendix, a simple appendectomy is proposed by some, whereas others favor a right hemicolectomy. For 1- to 2-cm rectal carcinoids, a wide local full-thickness excision is recommended.

With type I or II gastric carcinoids, which are usually<1 cm, endoscopic removal is recommended. In type I or II gastric carcinoids if the tumor is >2 cm or if there is local invasion, some recommend total gastrectomy, others recommend antrectomy in type 1. For types I and II gastric carcinoids 1 to 2 cm, some recommend endoscopic treatment, others surgical treatment. With type III gastric carcinoids, if >2 cm, excision and regional lymph node clearance is recommended. Most tumors <1 cm are treated endoscopically.

PANCREATIC ENDOCRINE TUMORS

*Functional*PETsusually present with symptoms due to hormone excess. Only late in the course of the disease does the tumor itself cause prominent symptoms such as abdominal pain. In contrast, all of the symptoms due to *nonfunctional* PETs are due to the tumor. Thus, some functional PETs may present with severe symptoms with a small or undetectable primary tumor, whereas nonfunctional tumors almost always present late in their course when they are large and often metastatic. The mean delay between onset of continuous symptoms and diagnosis of a functional PET syndrome is 4 to 7 years. Therefore, the diagnoses are frequently missed for extended periods of time.

Treatment ofPETsrequires two different strategies. Treatment must be directed at the hormone excess state, such as the gastric acid hypersecretion in gastrinomas or hypoglycemia in insulinomas. Ectopic hormone secretion usually causes the presenting symptoms and can cause life-threatening complications. Except for insulinomas, >50% are malignant (Table 93-2); therefore treatment must also be directed against the tumor per se. These tumors are frequently not curable by surgery due to the extent of disease. Individual PETs are discussed below.

GASTRINOMA (ZOLLINGER-ELLISON SYNDROME) (See also Chap. 285)

A gastrinoma is aNETsecreting gastrin, a hormone that causes gastric acid hypersecretion (Zollinger-Ellison syndrome). The chronic hypergastrinemia results in marked gastric acid hypersecretion and growth of the gastric mucosa, with increased numbers of parietal cells and proliferation of gastricECLcells. The gastric acid hypersecretion characteristically causes peptic ulcer disease, often refractory and severe, as well as diarrhea. The most common presenting symptoms are abdominal pain (70 to 100%), diarrhea (37 to 73%), and gastroesophageal reflux disease (GERD) (30 to 35%) and 10 to 20% have diarrhea only. Although peptic ulcers may occur in unusual locations, most patients have a typical duodenal ulcer. The diagnosis of gastrinoma should be considered in patients with peptic ulcer disease with diarrhea; with peptic ulcers in an unusual or in multiple locations; and with peptic ulcer disease that is refractory to treatment or persistent, associated with prominent gastric folds, associated with findings suggestive ofMEN-1 (hyperparathyroidism, family history of ulcer or endocrinopathy, pituitary tumors), or without *Helicobacter pylori* present. *H. pylori* is present in >90% of patients with idiopathic peptic ulcers but is present in <50% of patients with gastrinomas. Chronic unexplained diarrhea should also suggest gastrinoma.

About 20 to 25% of patients haveMEN-1, and in most cases the hyperparathyroidism is present before the gastrinoma. These patients are treated differently from those without MEN-1; therefore, MEN-1 should be sought in all patients by family history and by measuring plasma calcium and plasma hormones (parathormone, growth hormone, prolactin).

Most gastrinomas (50 to 70%) are present in the duodenum, followed by the pancreas (20 to 40%) and other intraabdominal sites (mesentery, lymph nodes, biliary tract, liver, stomach, ovary). Gastrinomas may also occur in the left ventricular septum. InMEN-1 the gastrinomas are also usually in the duodenum (70 to 90%), followed by the pancreas (10 to 30%), and they are almost always multiple. Between 60 and 90% of gastrinomas are malignant (Table 93-2) with metastatic spread to lymph nodes and liver. Distant metastases to bone occur in 12 to 30% of patients with liver metastases.

Diagnosis The diagnosis of gastrinoma requires the demonstration of fasting hypergastrinemia and an increased basal gastric acid output (BAO; hyperchlorhydria). More than 98% of patients with gastrinomas have fasting hypergastrinemia, although in 40 to 60% the level may be less than 10 times normal. Therefore, when the diagnosis is suspected, a fasting gastrin level should be determined first. Gastric acid-suppressant drugs such as proton pump inhibitors (omeprazole, pantoprazole, lansoprazole) can suppress acid secretion sufficiently to cause hypergastrinemia and need to be

discontinued for a week before the gastrin determination. If the gastrin level is elevated, document that the gastric pH<2.5; hypergastrinemia secondary to achlorydria (atrophic gastritis, pernicious anemia) is one of the most common causes of hypergastrinemia. If the fasting gastrin is >1000 ng/L; 10 times normal) and the pH <2.5, which occurs in 40 to 60% of patients with gastrinoma, the diagnosis is established after ruling out the possibility of retained antrum syndrome by history. In patients with hypergastrinemia with fasting gastrins<1000 ng/L and gastric pH<2.5, other conditions such as *H. pylori* infections, antral G cell hyperplasia/hyperfunction, gastric outlet obstruction, or, rarely, renal failure can masquerade as a gastrinoma. To establish the diagnosis in this group, a determination of BAO and a secretin provocative test should be done. In >80%of patients with gastrinomas, BAO is elevated, i.e., 15 meq/h, and the secretin provocative test is positive, i.e., >200 ng/L increase in serum gastrin level.

TREATMENT

The gastric acid hypersecretion in patients with gastrinomas can be controlled in almost every case by oral gastric antisecretory drugs. Because of their long duration of action and potency, the proton pump inhibitors (H^+,K^+-ATPase inhibitors) are the drugs of choice. Histamine H_2-receptor antagonists are also effective, although more frequent dosing (every 4 to 8 h) and high doses are frequently required. In patients withMEN-1 with hyperparathyroidism, correction of the hyperparathyroidism increases the sensitivity to gastric antisecretory drugs and decreases the basal acid output.

With the increased ability to control acid hypersecretion, >50% of the patients who are not cured (>60% of patients) will die from tumor-related causes. At presentation, careful imaging studies are essential to localize the extent of the tumor (see below). About one-third of patients present with hepatic metastases; in <15% of those with hepatic metastases, the disease is limited so that surgical resection may be possible. Surgical cure is possible in 30% of all patients withoutMEN-1 or liver metastases (40% of all patients). In patients with MEN-1, long-term surgical cure is rare because the tumors are multiple, frequently with lymph node metastases. Therefore, all patients with gastrinomas without MEN-1 or a medical condition limiting life expectancy should undergo surgery.

INSULINOMAS

Insulinomas are endocrine tumors of the pancreas thought to be derived fromb cells that autonomously secrete insulin, which results in hypoglycemia. The average age of occurrence is in persons 40 to 50 years old. The most common clinical symptoms are due to the effect of the hypoglycemia on the central nervous system (neuroglycemic symptoms) and include confusion, headache, disorientation, visual difficulties, irrational behavior, or even coma (Chap. 334). Also, most patients have symptoms due to excess catecholamine release secondary to the hypoglycemia, including sweating, tremor, and palpitations. Characteristically these attacks are associated with fasting.

Insulinomas are generally small (>90% are <2 cm in diameter), usually solitary (90%), and only 5 to 15% are malignant. They almost invariably occur only in the pancreas, distributed equally in the pancreatic head, body and tail. Insulinomas should be suspected in all patients with hypoglycemia, especially with a history suggesting attacks

provoked by fasting or with a family history ofMEN-1. Insulin is synthesized as proinsulin, which consists of a 21-amino-acida chain and a 30-amino-acidb chain connected by a 33-amino-acid connecting peptide (C peptide). In insulinomas, in addition to elevated plasma insulin levels, elevated plasma proinsulin levels are found and C-peptide levels can be elevated.

Diagnosis The diagnosis of insulinoma requires the demonstration of an elevated plasma insulin level at the time of hypoglycemia. Other causes of fasting hypoglycemia include inadvertent or surreptitious use of insulin or oral hypoglycemic agents, severe liver disease, alcoholism, poor nutrition, or other extrapancreatic tumors. The most reliable test for diagnosing insulinoma is a fast up to 72 h with serum glucose, C-peptide, and insulin measurements every 4 to 8 h. If at any point the patient becomes symptomatic or glucose levels are persistently<2.2 mmol/L (40 mg/dL), the test should be terminated and repeat samples for the above studies obtained before glucose is given. Some 70 to 80% of patients will develop hypoglycemia during the first 24 h and 98% by 48 h. In nonobese normal subjects, serum insulin levels should decrease to >43 pmol/L (6 uU/mL) when blood glucose decreases to £2.2 mmol/L (40 mg/dL) and the ratio of insulin to glucose is <0.3 (in mg/dL). In addition to having an insulin level >6 uU/ml when blood glucose is £40 mg/dL, some investigators also require elevated C-peptide and serum proinsulin levels and/or insulin:glucose ratio >0.3 for the diagnosis of insulinoma. The effects of surreptitious use of insulin or hypoglycemic agents may be difficult to distinguish from the symptoms of insulinomas. The combination of proinsulin levels (normal in exogenous insulin/hypoglycemic agent users), C-peptide levels (low in exogenous insulin users), antibodies to insulin (positive in exogenous insulin users), and sulfonylurea levels in serum or plasma will allow the correct diagnosis to be made.

TREATMENT

Only 5 to 15% of insulinomas are malignant; therefore, after appropriate imaging, surgery should be performed. Between 75 and 95% of patients are cured by surgery. Before surgery the hypoglycemia can be controlled by frequent small meals and the use of diazoxide (150 to 800 mg/d). Diazoxide is a benozthiadiazide whose hyperglycemic effect is attributed to inhibition of insulin release; 50 to 60% of patients respond to diazoxide. Its side effects are sodium retention and GI symptoms such as nausea. Other agents effective in some patients to control the hypoglycemia include verapamil and diphenylhydantoin. Long-acting somatostatin analogues such as octreotide are acutely effective in 40% of patients. However, octreotide needs to be used with care because it inhibits growth hormone secretion and can lower plasma glucagon levels and so worsen the hypoglycemia.

For the 5 to 15% of patients with malignant insulinomas, the above drugs or somatostatin analogues are used initially. If they are not effective, hepatic arterial embolization, chemoembolization, or chemotherapy have been used. These will be discussed below.

GLUCAGONOMAS

Glucagonomas are endocrine tumors of the pancreas that secrete excessive amounts of glucagon that causes a distinct syndrome characterized by dermatitis, glucose

intolerance or diabetes, and weight loss. Glucagonomas mainly occur in persons between 45 and 70 years old. They are heralded clinically by a characteristic dermatitis (migratory necrolytic erythema; in 67 to 90%), accompanied by glucose intolerance (40 to 90%), weight loss (66 to 96%), anemia (33 to 85%), diarrhea (15 to 29%), and thromboembolism (11 to 24%). The characteristic rash usually starts as an annular erythema at intertriginous and periorificial sites, especially in the groin or buttock. It subsequently becomes raised and bullae form; when the bullae rupture, eroded areas form. The lesions can wax and wane. A characteristic laboratory finding is hypoaminoacidemia, which occurs in 26 to 100% of patients.

Glucagonomas are generally large tumors at diagnosis, with an average size of 5 to 10 cm. Between 50 and 80% occur in the pancreatic tail and 50 to 82% have evidence of metastatic spread at presentation, usually to the liver. Glucagonomas are rarely extrapancreatic and usually occur singly.

Diagnosis The diagnosis is confirmed by demonstrating an increased plasma glucagon level [normal is<150 ng/L]. In one study plasma glucagon levels were >1000 ng/L in 90%, between 500 and 1000 ng/L in 7%, and <500 ng/L in 3%. A plasma glucagon level>1000 ng/L is considered diagnostic. Other diseases causing increased plasma glucagon levels include renal failure, acute pancreatitis, hypercortisolism, hepatic failure, prolonged fasting, or familial hyperglucagonemia. Except for cirrhosis, these disorders do not usually increase plasma glucagon to >500 ng/L.

TREATMENT

Metastases are present at presentation in 50 to 80% of patients, so curative surgical resection is not possible. Surgical debulking in patients with advanced disease or other antitumor treatments may be beneficial (see below). Long-acting somatostatin analogues (octreotide, lanreotide) improve the skin rash in 75% of patients and may improve the weight loss, pain, and diarrhea but not the glucose intolerance.

SOMATOSTATINOMA SYNDROME

Somatostatinomas are endocrine tumors that secrete excessive amounts of somatostatin, which causes a syndrome characterized by diabetes melitus, gallbladder disease, diarrhea, and steatorrhea. The mean age of onset is 51 years. Somatostatinomas occur primarily in the pancreas and small intestine, and the frequency of the symptoms differs in each. The usual symptoms are more frequent in pancreatic than intestinal somatostatinomas: diabetes mellitus (95% vs. 21%), gallbladder disease (94% vs. 43%), diarrhea (92% vs. 38%), steatorrhea (83% vs. 12%), hypochlorhydria (86% vs. 12%), and weight loss (90% vs. 69%). Somatostatinomas occur in the pancreas in 56 to 74% of cases, with the primary location being in the pancreatic head. The tumors are usually solitary (90%) and large (mean diameter, 4.5 cm). Liver metastases are present in 69 to 84% of patients.

Somatostatin is a tetradecapeptide (Fig. 93-2), widely distributed in the central nervous system and gastrointestinal tract where it functions as a neurotransmitter or has paracrine and autocrine actions. It is a potent inhibitor of many processes, including release of almost all hormones, acid secretion, intestinal and pancreatic secretion, and

intestinal absorption. Most of the clinical manifestations are directly related to these inhibitory actions.

Diagnosis In most cases somatostatinomas have been found incidentally either at the time of cholecystectomy or during endoscopy. The presence of psammoma bodies in a duodenal tumor should particularly raise suspicion. Duodenal somatostatin-containing tumors are increasingly associated with von Recklinghausen's disease. Most of these do not cause the somatostatinoma syndrome as patients are usually asymptomatic and have normal plasma somatostatin levels. The diagnosis of somatostatinoma requires elevated plasma somatostatin levels.

TREATMENT

Pancreatic tumors are frequently metastatic at presentation (70 to 92%), whereas 30 to 69% of small-intestinal somatostatinomas have metastases. Symptoms are improved by octreotide treatment (Fig. 93-2).

VIPOMAS

VIPomas are endocrine tumors that secrete excessive amounts ofVIP, which causes a distinct syndrome characterized by large-volume diarrhea, hypokalemia, and dehydration. This syndrome is also called Verner-Morrison syndrome, pancreatic cholera, or WDHA syndrome (*w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria), which some patients develop. The mean age of patients is 49 years; however, the syndrome can occur in children; when it does, it is usually caused by a ganglioneuroma or ganglioneuroblastoma.

The principal symptoms are large-volume diarrhea (in 100%) severe enough to cause hypokalemia (80 to 100%), dehydration (83%), hypochlorhydria (54 to 76%), and flushing (20%). The diarrhea is secretory in nature, persists during fasting, and is almost always>1 L per day and >3 L per day in 70%. Most patients do not have accompanying steatorrhea (16%), and the increased stool volume is due to increased excretion of sodium and potassium, which, with the anions, accounts for the osmolality of the stool. Patients frequently have hyperglycemia (25 to 50%) and hypercalcemia (25 to 50%).

VIPis a 28-amino-acid peptide neurotransmitter, ubiquitously present in the central nervous system and GI tract. Its known actions include stimulation of small-intestinal chloride secretion as well as effects on smooth-muscle contractility, inhibition of acid secretion, and vasodilatory effects which explain most features of the clinical syndrome.

In adults 80 to 90% of VIPomas are pancreatic;VIP-secreting pheochromocytomas, intestinal carcinoids, and occasional ganglioneuromas account for the rest. These tumors are usually single; 50 to 75% are in the pancreatic tail and 37 to 68% have hepatic metastases at diagnosis.

Diagnosis The diagnosis requires the demonstration of an elevated plasmaVIPlevel and the presence of large-volume diarrhea. A stool volume of<700 mL/day excludes the diagnosis of VIPoma. A number of causes of diarrhea can be excluded by fasting the patient. Other diseases that can cause secretory large-volume diarrhea include

gastrinomas, chronic laxative abuse, carcinoid syndrome, systemic mastocytosis, diabetic diarrhea, AIDS, and rarely medullary thyroid cancer. Of these conditions, only VIPomas causes a marked increase in plasma VIP.

TREATMENT

The most important initial treatment in these patients is to correct their dehydration, hypokalemia, and electrolyte losses with fluid and electrolyte replacement. Patients may require 5 L/day of fluid and>350 mmol/day (350 meq/day) of potassium. Because 37 to 68% of adults withVIPomas have metastatic disease in the liver at presentation, a significant number of patients cannot be cured surgically. In these patients, long-acting somatostatin analogues such as octreotide or lanreotide (Fig. 93-2) are the drugs of choice.

Octreotide will control the diarrhea in 87% of patients. In nonresponsive patients, the combination of glucocorticoids and octreotide has proved helpful in a few. Other drugs that may be helpful include prednisone (60 to 100 mg/d), clonidine, indomethacin, phenothiazines, loperamide, lidamidine, lithium, proparanolol, and metoclopramide. Treatment of advanced disease with embolization, chemoembolization, and chemotherapy may also be helpful (see below).

NONFUNCTIONAL PANCREATIC ENDOCRINE TUMORS

NonfunctionalPETs are endocrine tumors that originate in the pancreas and either secrete no products or their secreted products do not cause a specific clinical syndrome. The symptoms are due entirely to the tumor per se. Nonfunctional PETs almost always secrete chromogranin A (90 to 100%), chromogranin B (90 to 100%),PP(58%), a-human chorionic gonadotropin (hCG) (40%), andb-HCG (20%), but none cause a specific syndrome. Patients with nonfunctional PETs usually present late in their disease course with invasive tumors and hepatic metastases (in 64 to 92%), and the tumors are usually large (72% >5 cm). These tumors are usually solitary except in patients withMEN-1, where they are multiple; they occur primarily in the pancreatic head; and though they do not cause a functional syndrome, they synthesize numerous peptides and cannot be distinguished from functional tumors by immunocytomchemistry.

The most common symptoms are abdominal pain (30 to 80%), jaundice (20 to 35%), and weight loss, fatigue, or bleeding; 10 to 15% are found incidentally. The average time from the beginning of symptoms to diagnosis is 5 years.

Diagnosis The diagnosis is established by histology in a patient with aPETwithout either clinical symptoms or elevated plasma hormone levels of one of the established syndromes (Table 93-2). Even though chromogranin A levels are elevated in almost every patient, this can be found in functional PETs, carcinoids, and other neuroendocrine disorders. PlasmaPP is increased in 22 to 71% of patients and should suggest the diagnosis in a patient with a pancreatic mass because it is usually normal in patients with pancreatic adenocarcinomas. However, elevated plasma PP is not diagnostic of this tumor because it is elevated in a number of other conditions such as chronic renal failure, old age, inflammatory conditions, and diabetes.

TREATMENT

Unfortunately, surgical curative resection can be considered in only a minority of patients because 64 to 92% present with metastatic disease. Treatment needs to be directed against the tumor itself using chemotherapy, embolization, chemoembolization, or hormonal therapy (see below).

GRFOMAS

GRFomas are endocrine tumors that secrete excessive amounts ofGRF that causes acromegaly. The frequency is not known. GRF (also called growth hormone-releasing hormone, GHRH) is a 44-amino-acid peptide, and 25 to 44% ofPETshave GRF immunoreactivity, although excess secretion is uncommon. GRFomas are lung tumors in 47 to 54% of cases, PETs in 29 to 30%, and small-intestinal carcinoids in 8 to 10% and up to 12% occur at other sites. Patients have a mean age of 38 years, and the symptoms are usually due to either acromegaly or the tumor per se. The acromegaly caused by GRFomas is indistinguishable from classic acromegaly. The pituitary abnormality is growth hormone-secreting somatotrope cell hyperplasia rather than a pituitary adenoma. The pancreatic tumors are usually large (>6 cm), and liver metastases are present in 39%. They should be suspected in any patient with acromegaly and an abdominal tumor, in a patient withMEN-1 with acromegaly, or in a patient without a pituitary adenoma with acromegaly or associated with hyperprolactinemia, which occurs in 70% of GRFomas. GRFomas are an uncommon cause of acromegaly. The diagnosis is established by performing plasma assays for GRF and growth hormone. The normal level for GRF is<5 ng/L (5 pg/mL) in men and<10 ng/L (10 pg/mL) in women. Most GRFomas have a plasma GRF level ³300 ng/L (300 pg/mL). Patients with GRFomas also have increased plasma insulin-like growth factor 1 levels similar to those in classic acromegaly. Surgery is the treatment of choice if diffuse metastases are not present. Long-acting somatostatin analogues such as octreotide or lanreotide (Fig. 93-2) induce responses in 75 to 100% of patients.

OTHER RARE PET SYNDROMES

Cushing's syndrome (ACTHoma) due to aPEToccurs in 4 to 16% of all patients with ectopic Cushing's syndrome. It occurs in 5% of cases of sporadic gastrinomas, almost invariably in patients with hepatic metastases, and is an independent, poor prognostic factor. Paraneoplastic hypercalcemia due to PETs releasing parathyroid hormone-related peptide is rare. The tumors are usually large, and liver metastases are usually present. PETs secreting calcitonin may cause a specific clinical syndrome. In one study, half the patients had diarrhea, which disappeared with resection of the tumor. InTable 93-2, this is a possible specific disorder because so few cases have been described.

TUMOR LOCALIZATION

Localization of the primary tumor and defining the extent of the disease are essential to the proper management of all carcinoids andPETs. Numerous tumor localization methods are used in both types ofNETs, including conventional imaging studies

[CTscanning, magnetic resonance imaging (MRI), transabdominal ultrasound, selective angiography] and somatostatin receptor scintigraphy (SRS). In PETs, endoscopic ultrasound (EUS) and functional localization by measuring venous hormonal gradients are also reported useful. Bronchial carcinoids are usually detected by a standard chest radiography and assessed by CT. Rectal, duodenal, colonic, and gastric carcinoids are usually detected by GI endoscopy.

PETsas well as carcinoid tumors possess high-affinity somatostatin receptors in both their primary tumors and their metastases. Of the five types of somatostatin receptors (sst_{1-5}), radiolabeled octreotide binds with high affinity to sst_2, lower for sst_3 and sst_5, and has very low affinity for sst_1 and sst_4. Between 90 and 100% of carcinoid tumors and PETs express sst_2, and many also have the other four sst subtypes. Interaction with these receptors can be used to localizeNETsusing [^{111}In-DTPA-D-Phe$_1$] octreotide (Fig. 93-2) and radionuclide scanning (SRS) as well as for treatment of the hormone excess state with octreotide or lanreotide. Because of its greater sensitivity than conventional imaging and its ability to localize tumor throughout the body at one time, SRS is now the imaging modality of choice for localizing both primary and metastastic NET tumors. SRS localizes tumors in 73 to 89% of patients with carcinoids and in 56 to 100% of patients with PETs, except for insulinomas. Insulinomas are usually small and have low densities of sst receptors, which results in SRS being positive in only 12 to 50% of patients with insulinomas.Figure 93-3 shows an example of the increased sensitivity of SRS in a patient with a gastrinoma. TheCT scan (Fig. 93-3, *top*) did not show any disease after primary tumor resection; however, hypergastrinemia remained, and the SRS demonstrated a metastasis in the liver (Fig. 93-3, *bottom*). Occasional false-positive responses with SRS can occur (12% in one study) because numerous other normal and abnormal cells can have high densities of sst receptors including granulomas (sarcoid, tuberculosis, etc.), thyroid diseases (goiter, thyroiditis), and activated lymphocytes (lymphomas, wound infections). For PETs located in the pancreas,EUS is highly sensitive, localizing 77 to 93% of insulinomas, which occur almost exclusively within the pancreas. EUS is less sensitive for extrapancreatic tumors. If liver metastases are identified by SRS, a CT scan orMRI is then recommended to assess the size and exact location of the metastases, because SRS does not provide reliable information on tumor size. Functional localization measuring hormone gradients after intraarterial calcium injections in insulinomas (insulin) or gastrin gradients after secretin injections in gastrinoma will be positive in 80 to 100% of patients. However, this method gives only regional localization and therefore is reserved for cases where other imaging tests are negative.

TREATMENT

Advanced Disease (Diffuse Metastatic Disease) The single most important prognostic factor for survival is the presence of liver metastases (Fig. 93-4). For patients with carcinoids without hepatic metastases, the 5-year survival is 80%; with limited liver metastases, it is also 80%; but with diffuse metastases, it is 50% (Fig. 93-4, *bottom*). With gastrinomas, the 5-year survival without liver metastases is 98%; with limited metastases in one hepatic lobe it is 78%; and with diffuse metastases, 16% (Fig. 93-4, *top*). A number of different modalities are effective, including cytoreductive surgery (removal of all visible tumor), treatment with chemotherapy, somatostatin analogues, interferona, hepatic embolization alone or with chemotherapy (chemoembolization),

radiotherapy, and liver transplantation.

Specific Antitumor Treatments Cytoreductive surgery is only possible in the 9 to 22% of patients who have limited hepatic metastases. No randomized studies have proven it extends life, but it appears to increase survival and therefore is recommended if possible.

Chemotherapy for metastatic carcinoid tumors has been disappointing, with response rates of 0 to 40% with various two- or three-drug combinations. Chemotherapy forPETs has been more successful, with tumor shrinkage reported in 30 to 70% of patients. The current regimen of choice is streptozotocin and doxorubicin.

Long-acting somatostatin analogues (octreotide, lanreotide) and interferon a rarely decrease tumor size (i.e., 0 to 17%); however, these drugs have tumoristatic effects, stopping additional growth in 50 to 95% of patients withNETs. How long tumor stabilization lasts or whether it prolongs survival has not been established.

Hepatic embolization and chemoembolization (with dacarbazine, cisplatin, doxorubicin, 5-fluorouracil, or streptozotocin) decrease tumor bulk and help control the symptoms of hormone excess. These modalities are generally reserved for patients in whom treatment with somatostatin analogues, interferon (carcinoids), or chemotherapy (PETs) fails.

Radiotherapy is being used with two different somatostatin radionuclides coupled by a DOTA-chelating group to octreotide (Fig. 93-2): [^{111}In-DTPA-D-Phe$_1$] octreotide (emits g rays, internal conversion, and Auger electrons) and yttrium-90 (emits high energy bparticles). The^{111}In compound showed disease stabilization in 40% and a decrease in tumor size in 30% of patients with advanced metastatic disease.

The use of liver transplantation has been abandoned for treatment of most metastatic tumors to the liver. However, for metastaticNETs it is still a consideration. Liver transplantation in 103 cases of malignant NETs (48 werePETs, 43 were carcinoids) achieved 2- and 5-year survival rates of 60% and 47%, respectively. However, recurrence-free survival was low (<24%). Liver transplantation may be justified for younger patients with metastatic NETs limited to the liver.

94. BLADDER AND RENAL CELL CARCINOMAS - *Howard I. Scher*, *Robert J. Motzer*

BLADDER CANCER

A transitional cell epithelium lines the urinary tract from the renal pelvis to the ureter, urinary bladder, and the proximal two-thirds of the urethra. Carcinomas may occur at any point, but generally 90% develop in the bladder, 8% in the renal pelvis, and 2% in the ureter or urethra. Overall, urinary bladder cancer is the fourth most common cancer in men and the ninth in women, with an estimated 53,200 new cases (38,300 males and 14,900 females) and 12,200 deaths (8100 males and 4100 females) predicted for the year 2000. The median age at diagnosis is 65 years. Once diagnosed, these tumors exhibit the tendency to recur over time and in new locations in the urothelial tract. As long as urothelium is present, continuous monitoring of the urothelial tract is required.

EPIDEMIOLOGY

Cigarette smoking is believed to contribute to up to 50% of the diagnosed urothelial cancers in men. The risk of developing a urothelial cancer in smokers is increased two- to fourfold relative to nonsmoking males and may persist for 10 years or longer after smoking is stopped. Other agents that have been implicated include exposure to aniline dyes, the drugs phenacetin and chlornaphazin, and external beam radiation. Chronic cyclophosphamide exposure increases risk nine-fold. Diets rich in meat and fat predispose to bladder cancer; ingestion of vitamin A supplements appears to be protective. Exposure to *Schistosoma haematobium*, a parasite found in many developing countries, is associated with an increase in both squamous (70%) and transitional cell (30%) carcinomas of the bladder.

PATHOLOGY

In the United States, 90 to 95% of bladder tumors diagnosed are transitional cell tumors. Pure squamous tumors with keratinization comprise 3%, adenocarcinomas 2%, and small cell tumors (with paraneoplastic syndromes)<1%. Adenocarcinomas develop primarily in the urachal remnant in the dome of the bladder or in the periurethral tissues. Some assume a signet cell histology. Lymphomas or melanomas are rare. Overall, 75% of tumors present as superficial lesions, 20% with muscle invasion, and 5% with metastatic disease. Of the transitional cell tumors, low-grade papillary lesions that grow on a central stalk are most common. They are very friable, have a tendency to bleed, and are at a high risk for recurrence, yet they rarely progress to the more lethal invasive variety. In contrast, carcinoma in situ (CIS) is a high-grade tumor that is considered a precursor of the more lethal muscle-infiltrating cancers. Tumors are rated by histologic type and grade. Grade I lesions (highly differentiated tumors) rarely progress to a higher stage, while grade III tumors usually do.

PATHOGENESIS

The multicentric nature of the disease and high rate of recurrence has led to the hypothesis that a field defect develops in the urothelium. Molecular genetic analyses of bladder tumors representing defined stages and different grades have shown a series of

primary chromosomal aberrations associated with cancer *development*, and *secondary changes* associated with *progression* to a more advanced stage. Using paired bladder tumor and normal tissues from the same patient, 9q deletions are an early event in cancer development, while 3p and 5q deletions were more prevalent in invasive vs. superficial tumors. Deletions of 17p (*TP53* locus), 18q (the *DCC* gene locus), and the *RB* gene locus on chromosome 13q24 were seen only in invasive disease, while deletions of 3p and 11p occur in both superficial and invasive tumors. p53 overexpression correlates with a higher probability of progression to a more advanced stage and bladder cancer mortality for patients with Ta, Tis, T1 and muscle-infiltrating lesions. These factors have not been routinely used for clinical decision-making.

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING

Hematuria occurs in 80 to 90% of patients with exophytic tumors, while irritative symptoms are more common for patients with in situ disease. The bladder is the most common source of gross hematuria (40%), but benign cystitis (22%) is a more common cause than bladder cancer (15%) (Chap. 48). Microscopic hematuria is more commonly of prostatic origin (25%), while 2% of bladder cancers produce microscopic hematuria. The documentation of hematuria requires evaluation with a urinary cytology, visualization of the urothelial tract by sonography or an intravenous pyelogram (IVP), and cystoscopy. Screening of asymptomatic subjects for hematuria has been evaluated and shown to increase the frequency of tumor diagnosis at an early stage. Screening has not been shown to confer a survival benefit. Ureteral obstruction may result in flank pain or discomfort. Symptoms of metastatic disease are documented less commonly as the first presenting sign of a urothelial cancer.

The endoscopic evaluation includes an examination under anesthesia to determine whether or not a palpable mass is present. A flexible endoscope is then inserted into the bladder, and a bladder barbotage is performed to assess the presence or absence of malignant cells. A visual inspection is then carried out and a cystoscopic map completed that includes the size, location, and number of lesions and their growth pattern (solid vs. papillary) (Fig. 94-1). An attempt should be made to resect all visible tumors along with a sample of the underlying muscle so that the depth of invasion can be documented. A notation is also made as to whether or not a tumor was completely removed. Random biopsies of "normal" mucosal areas are conducted to assess for a field defect. Each site that is biopsied should be recorded separately. For patients with a positive cytology and no apparent tumor within the bladder, selective catheterization of the ureter is required with retrograde examination to evaluate for upper tract disease.

The critical issue in management is whether or not the tumor has invaded muscle, which is difficult to assess with noninvasive procedures alone. Ultrasonography, computed tomography (CT) and/or magnetic resonance imaging (MRI) may assist in distinguishing a tumor that extends to the perivesical fat (T3b) from one that does not (T3a), and to document whether or not regional lymph nodes are involved (N+). They are also important in the assessment of the upper tracts. Distal metastases are assessed by CT of the abdomen, pulmonary x-rays, or radionculide imaging of the skeleton. The need for these studies is based in part on the local extent of the lesion.

The revised 1997 TNM (tumor, nodes, metastasis) staging system is illustrated inFig.

94-2. Ta lesions grow as exophytic lesions, whileCISstarts on the surface and tends to invade muscle. As the degree of muscle infiltration increases, the probability of nodal and subsequent distal spread also increases.

TREATMENT

Treatments are based on the extent and depth of invasion of the tumor within the primary site and the presence or probability of metastatic spread. At a minimum, the management of a tumor that has not invaded the bladder wall is a complete endoscopic resection with or without intravesical therapy. Recurrences are seen in 50% or more of cases, of which 5 to 20% will progress to a more advanced stage. The decision to recommend additional therapy is based on the histologic subtype, the number of lesions, the depth of invasion, and whether or notCIS is present. Solitary papillary lesions are generally treated by surgery alone. Intravesical therapy is usually recommended for recurrent disease.

CISfrequently follows a more aggressive course. As such, intravesical therapy is generally recommended earlier in the clinical course. The standard treatment for a tumor that has invaded muscle, either at the time of diagnosis or following treatment for superficial disease, is radical cystectomy. Depending on the findings at surgery, systemic chemotherapy may or may not be advised.

Superficial Disease Intravesical therapies are applied in two contexts: as an adjuvant to a complete endoscopic resection to prevent recurrence, or, less commonly, to eliminate disease that cannot be controlled by endoscopic resection alone. Intravesical treatments are advised for patients with four or more recurrences in a given year, >40% involvement of the bladder surface by tumor, the presence of diffuseCIS, or documented T1 disease. A number of agents are available, but based on randomized comparisons, Bacillus Calmette-Guerin (BCG) is considered standard. Thiotepa, doxorubicin, mitomycin-C, and interferon have also been used. Side effects include dysuria, frequency, and, depending on the drug, myelosuppression or a contact dermatitis (from mitomycin C). Rarely, intravesical BCG may produce a systemic illness associated with granulomatous infections in multiple sites that requires anti-tuberculin therapy for control. Significant BCG toxicities occur in <6% of patients.

Following endoscopic resection, patients are reevaluated at 3-month intervals to ensure that no recurrences have developed. Those with persistent disease or new tumors are generally considered for a second course ofBCG or intravesical chemotherapy. Those with persistent disease may be considered for cystectomy, although the specific indications vary. Obvious candidates are those with new invasive tumors or persistentCIS, and those with bladder function that has been compromised to the point where persistent pain, blood loss, frequency, or a severely limited bladder capacity is present. Recurrences may develop anywhere along the urothelial tract, including the renal pelvis, ureter, or urethra. In fact, one consequence of the "successful" treatment of tumors in the bladder is an increase in the frequency of extravesical recurrences.

Muscle-Infiltrating Disease The treatment of a tumor that has invaded muscle can be separated into control of the primary tumor and control of systemic disease. Radical cystectomy is considered the standard treatment, although in selected cases

bladder-sparing approaches using an aggressive endoscopic resection, partial cystectomy, or a combined modality approach with resection, systemic chemotherapy, and external beam radiation therapy are used. The latter should not be considered outside of a research setting.

Radical cystectomy involves an evaluation of the pelvic lymph nodes, removal of the primary tumor, and creation of a conduit or reservoir for urinary flow. At the time of surgery, grossly abnormal lymph nodes are evaluated by frozen section. If metastases are confirmed, the procedure is often aborted unless a diversion is required for palliation of local symptoms. The results of treatment of node-positive disease are shown in Table 94-1. In males radical cystectomy involves the removal of the bladder, prostate, seminal vesicles, proximal vas deferens, and proximal urethra, with a margin of adipose tissue and peritoneum. Impotence is universal unless the *nervi erigentes*, responsible for erectile capacity, can be preserved. In females the procedure includes removal of the bladder, urethra, uterus, fallopian tubes, ovaries, anterior vaginal wall, and surrounding fascia.

Urine flow is directed through either an internal reservoir that drains to the urethra or the abdominal wall, or via a Bricker procedure in which urine flows through an ileal conduit from the ureters to the abdominal wall, where it is collected in an external appliance without an internal reservoir. A segment of colon, jejunum, or ileum can be used to bridge the gap between the ureters and the skin. Use of absorbable sutures may prevent formation of calculi at the sutures. A uretero-ileal conduit probably is the most widely used. A syndrome characterized by hypochloremic acidosis, hyperkalemia, hyponatremia, and uremia has been described when a segment of jejunum is utilized. Concurrent diseases in the bowel, such as ulcerative colitis or Crohn's disease, may hinder the use of resected bowel.

Alternatives to an external appliance include internal reservoirs that are created from detubularized bowel segments and are periodically self-catheterized by the patient. A number of procedures have been described that use either ileocecal or ileal reservoirs, which are anastamosed to either the abdominal wall or the urethra. When an anastomosis to the urethra is created, primarily in men with no urethral disease, the patient can then void in a manner that is similar to natural voiding. Several indications for urethrectomy (includingCIS or exophytic tumor in the urethra and diffuse CIS in the urinary bladder) preclude the creation of a urethral anastomosis. Continent reservoirs are being applied with increasing frequency, but are still not constructed for the majority of patients, for technical or disease-related reasons. Intercurrent diseases, impaired renal function, hesitancy to prolong the surgical trauma, dilated ureters, and bowel diseases all decrease the use of continent reservoirs. Patients with ureterosigmoid diversion require periodic colonoscopy because of the risk of cancer.

Cystectomy is major surgery, and appropriate medical clearance is essential. This includes optimizing cardiac medications and nutritional status. In approximately 5 to 10% of cases, depending on the location of the tumor, a partial cystectomy is possible. This procedure can be considered when a lesion develops on the dome of the bladder where a 2-cm margin can be achieved,CIS is absent in other sites of the bladder, and bladder capacity is adequate after the tumor is removed. Carcinomas in the ureter or in the renal pelvis are treated by nephroureterectomy with a bladder cuff.

Indications for cystectomy include: (1) muscle-invading tumors not suitable for segmental resection; (2) low-stage tumors unsuitable for conservative management due to, for example, multicentric and frequent recurrences resistant to intravesical instillations; (3) high grade tumors (T1G3) associated withCIS or bladder symptoms such as frequency or hemorrhage rendering the patient a "bladder cripple." Outcomes are reported on the basis of 5-year survivals. As shown in Table 94-2, survival varies inversely with depth of invasion and lymph node status. For the majority of cases, however, extension to a single lymph node predicts a poor outcome with a median time to recurrence of 22 months. In some countries external beam radiation therapy is considered standard. This is not the case in the United States, where its role is limited to those patients deemed unfit for cystectomy or those with unresectable local disease, and as part of an experimental approach that seeks to spare the bladder.

Metastatic Disease Patients with metastatic disease include those whose tumor has recurred after definitive local treatment and those who present with metastases. A number of chemotherapeutic agents have shown activity as single agents, of which cisplatin, paclitaxel, and gemcitabine are considered most active (Table 94-3). Responses to single agents are generally incomplete and not durable. Using multidrug regimens, response rates in excess of 50% have been reported with combinations such as M-VAC (methotrexate, vinblastine, doxorubicin, and cisplatin), PT (cisplatin and paclitaxel), and gemcitabine variants. Based on randomized comparisons, M-VAC is considered standard but can be associated with significant toxicities, including neutropenia and fever; mucositis in 10 to 20%; a decrease in renal and auditory function; and a peripheral neuropathy. Alopecia is universal; fatigue can be dose-limiting in some cases. More recently 2- and 3-drug combinations based on cisplatin/carboplatin, paclitaxel, and gemcitabine have been explored. In a direct comparison to M-VAC, gemcitabine/cisplatin showed similar response proportions and survival with fewer side effects. Long-term survival may be obtained in 10 to 15% of patients with metastatic disease and 20 to 25% of patients with unresectable nodal disease at presentation. In general, the proportion of patients rendered tumor-free is higher in patients with disease limited to nodal sites as opposed to visceral or bone sites. Patients with adverse features, such as a compromised performance status, visceral disease, or bone metastases, are rarely cured with chemotherapy alone. In these cases, median survivals rarely exceed 6 months.

Chemotherapy for Invasive Disease Chemotherapy can be given before (neoadjuvant) or after (adjuvant) definitive local therapy. Cumulative results of nonrandomized phase II trials have shown that the proportion of bladders rendered free of tumor varies inversely with T stage; but only 20 to 25% of bladders are tumor-free after chemotherapy alone. To date, neoadjuvant chemotherapy has not been shown to prolong life. Several groups are investigating bladder-sparing strategies but these approaches are not considered routine practice. The need for adjuvant therapy is based on a pathologic determination of risk. In general, the finding of nodal disease at surgery, extravesical tumor extension, or vascular invasion in the resected specimen are considered indications for postoperative adjuvant therapy. When administered, a minimum of four cycles at full dose is recommended.

Overview Superficial TaG1 lesions rarelyprogress to an invasive lesion and can be

handled with an endoscopic resection. Muscle-invasive disease may require both aggressive local therapy and systemic therapy of micrometastases for cure, while metastatic urinary bladder cancer is the most lethal for the majority of patients. Only a small proportion of patients with metastatic disease can be cured with chemotherapy. Current refinements in therapy include identifying subgroups of patients with superficial disease where the intensity of follow-up can be reduced or where intravesical therapy is needed. For muscle-invasive disease, efforts are being made to identify patients for whom organ preservation is possible without compromising overall survival, as well as those with subclinical micrometastases for whom systemic therapy is needed for cure. Efforts to improve therapy include better surgical techniques and the incorporation of newly identified chemotherapeutic agents into combination regimens. For the majority of patients, combined modality approaches are essential to optimal management.

RENAL CELL CARCINOMA

Renal cell carcinoma accounts for 90 to 95% of malignant neoplasms arising from the kidney. Notable features include refractoriness to cytotoxic agents, infrequent but reproducible responses to biologic response modifiers such as interferona and interleukin (IL) 2, and a variable clinical course for patients with metastatic disease, including anecdotal reports of spontaneous regression.

EPIDEMIOLOGY AND ETIOLOGY

In the year 2000, 31,200 new cases of renal cancer were diagnosed, and 11,900 people died of the disease. The male:female ratio is 2:1. Incidence peaks between the ages of 50 and 70, although this malignancy may be diagnosed at any age. Many environmental factors have been investigated as possible contributing causes. The strongest association is with cigarette smoking (accounting for 20 to 30% of cases) and obesity. The risk is increased for patients who have acquired cystic disease of the kidney associated with end-stage renal disease.

Most cases are sporadic, although familial forms have been reported. One is associated with von Hippel-Lindau (VHL) syndrome. Nearly 35% of patients with VHL disease develop renal cell cancer. An increased incidence has also been reported for patients with tuberous sclerosis and polycystic kidney disease.

Most of the cancers arise from the epithelial cells of the proximal tubules. A number of genetic alterations have been described, of which abnormalities on chromosome 3 are most frequent. A t(3;8) translocation was first described in a pedigree of patients with the familial form of the disease, while deletions of 3p21-26 (where *VHL* maps) have been identified in familial as well as sporadic tumors. *VHL* mutations are identified in a high proportion of sporadic, nonpapillary renal cell cancers and associated cell lines.

PATHOLOGY

Renal cell neoplasia represents a heterogeneous group of tumors with distinct histopathologic, genetic, and clinical features ranging from benign to high-grade malignant. Categories include clear cell carcinoma (60% of cases), papillary (5 to 15%), chromophobic tumors (5 to 10%), oncocytomas (5 to 10%), and collecting or Bellini duct

tumors (<1%). Clear cell tumors are characterized by tumor cells with clear cytoplasm and consistently show a deletion of 3p. Papillary tumors tend to be bilateral and multifocal. Trisomy 7 and/or 17 are the most frequent genetic markers. Chromophobic tumors are characterized by multiple chromosomal losses but do not exhibit 3p deletions; they also have a more indolent clinical course. Oncocytomas have a characteristic morphology including a deeply eosinophilic cytoplasm, do not exhibit 3p deletions or trisomy 7 or 17, and are considered benign neoplasms. In contrast, Bellini duct carcinomas are very rare and are thought to arise from the collecting ducts within the renal medulla. They tend to afflict younger patients and are very aggressive tumors.

CLINICAL PRESENTATION

The presenting signs and symptoms include hematuria, abdominal pain, and a flank or abdominal mass. This classic triad occurs in 10 to 20% of patients. Other symptoms are fever, weight loss, anemia, and a varicocele (Table 94-4); the tumor can be found incidentally on a radiograph.

The presentation has changed over the past two decades, due to the advent and widespread use of radiologic cross-sectional imaging procedures (CT, ultrasound,MRI). The more frequent use of sensitive abdominal imaging modalities in recent years contributes to earlier detection, including incidental low-stage renal masses detected during evaluation for other medical conditions. The increasing number of incidentally discovered low-stage tumors contributes to an improved 5-year survival for patients with renal cell carcinoma and increased use of nephron-sparing surgery (partial nephrectomy).

A spectrum of paraneoplastic syndromes has been associated with these malignancies, including erythrocytosis, hypercalcemia, nonmetastatic hepatic dysfunction (Stauffers' syndrome) and acquired dysfibrinogenemia. Erythrocytosis is present at presentation in only about 3% of patients. More frequently anemia, a sign of advanced disease, is reported.

The standard evaluation of patients with suspected renal cell tumors includes aCT scan of the abdomen and pelvis, a chest radiograph, urine analysis, and urine cytology. A CT of the chest is warranted if metastatic disease is suspected from the chest radiograph, as it will detect significantly smaller lesions, and their presence may influence the approach to the primary tumor.MRI is useful in evaluating the inferior vena cava in cases of suspected tumor involvement or invasion by thrombus, as well as for patients in whom iodinated contrast cannot be administered owing to either allergy or renal dysfunction. In clinical practice any solid renal masses should be considered malignant until proved otherwise and require a definitive diagnosis. If no metastases are demonstrated, surgery is indicated, even if there is invasion of the renal vein. The differential diagnosis of a renal mass includes cysts, benign neoplasms (adenoma, angiomyolipoma, oncocytoma), inflammatory lesions (pyelonephritis or abscesses), and other primary or metastatic malignant neoplasms. Other malignancies that may involve the kidney include transitional cell carcinomas of the renal pelvis, sarcoma, lymphoma, Wilms' tumor, and metastatic disease, especially from melanoma primaries. All of these are less common than renal cell carcinoma as kidney masses.

STAGING AND PROGNOSIS

Two staging systems used commonly are the Robson classification and the American Joint Committee on Cancer (AJCC) staging system. According to the former, stage I tumors are confined to the kidney; stage II tumors extend through the renal capsule but are confined to Gerota's fascia; stage III tumors involve the renal vein or vena cava (stage III A) or the hilar lymph nodes (stage III B); and stage IV disease includes tumors that are locally invasive to adjacent organs (excluding the adrenal gland) or distant metastases. Five-year survival rate varies by stage: 66% for stage I, 64% for stage II, 42% for stage III, and 11% for stage IV. The prognosis for patients with stage IIIA lesions is similar to that of stage II disease, whereas the 5-year survival rate for patients with stage IIIB lesions is only 20%, closer to that of stage IV.

TREATMENT

Localized Tumors The standard management for stage I or II tumors and selected cases of stage III disease is radical nephrectomy. This procedure involves en bloc removal of Gerota's fascia; its contents including the kidney, the ipsilateral adrenal gland, and adjacent hilar lymph nodes. The role of a regional lymphadenectomy is controversial. For patients with stage IIIA disease, the tumor should be resected from the renal vein or vena cava.

In selected patients who have only one kidney, a partial nephrectomy may be performed, depending on the size and location of the lesion. Partial nephrectomy may also be performed for patients with bilateral tumors, accompanied by a radical nephrectomy on the opposite side. Partial nephrectomy techniques are being applied electively to resect small masses for patients with a normal contralateral kidney. There is no proven role for adjuvant chemotherapy, immunotherapy, or radiation therapy following successful surgical removal of the tumor, even in cases with a poor prognosis.

Advanced Disease Metastatic renal cell carcinoma, for which there is no effective therapy, is associated with dismal survival. A number of options have been explored, including hormonal therapy, chemotherapy (cytotoxic agents), and immunotherapy. Responses to hormonal therapy (progestins) are rare (1 to 2%) and of short duration. No chemotherapy agent has been shown to consistently produce tumor regressions in>20% of patients.

Two biologic therapies, interferona andIL-2, have been studied extensively for the treatment of advanced disease. Both reproducibly produce responses in 10 to 20% of patients; the response is durable in fewer than 5% of patients. It was the observation of occasional durable complete remissions that resulted in the Food and Drug Administration's approval of IL-2 as a treatment for this disease. IL-2 is usually administered by infusion of 720,000 IU/k every 8 h per day for 5 to 7 days. Toxicities from IL-2 include a capillary leakage syndrome, fever, chills, fatigue, and hypotension.

Surgery in the Setting of Metastases Nephrectomy may be indicated in highly selected cases for the alleviation of symptoms, including pain or recurrent urinary hemorrhage, and particularly if the latter is severe or associated with obstruction. Some physicians advocate the performance of a nephrectomy in the presence of metastases

in the hope either that a spontaneous regression will occur or that the sensitivity to a cytokine will be increased. The observed frequency of spontaneous regression, 0.8%, coupled with the morbidity and mortality of the procedure itself, does not justify the approach. Nephrectomy in the presence of metastatic disease followed by IFN-a is associated with a modest survival benfit over IFN-aalone.

There are reports of long-term survival at rates of 15 to 50% for patients who relapse following nephrectomy at a solitary site and undergo surgical resection of the metastasis. Because renal cell tumors are radioresistant, surgical resection is also advised for palliation of solitary central nervous system metastases, repair of actual or impending fractures in weight-bearing bones, or relief of spinal cord compression.

Observation Alone Renal cell carcinoma is one of several malignancies in which spontaneous regressions have been reported anecdotally. A more frequent occurrence is prolonged periods of stable disease: up to 10% of patients with metastatic disease show no progression for >12 months. Because responses to systemic therapy are uncommon, and all systemic therapies are associated with treatment-related toxicity, an option for management in asymptomatic patients with metastases is close observation until evidence of disease progression or symptoms occur, at which time appropriate therapy is initiated. It is important to document the presence of progressive disease before initiating an experimental treatment; this will avoid attributing stable disease to the drug when it may be a feature of the tumor.

CARCINOMA OF THE RENAL PELVIS AND URETER

About 500 cases of renal pelvis and ureter cancer occur each year; nearly all are transitional cell carcinomas similar to bladder cancer in biology and appearance. This tumor also is associated with chronic phenacetin abuse and with Balkan nephropathy, a chronic interstitial nephritis endemic in Bulgaria, Greece, Bosnia-Herzegovina, and Romania.

The most common symptom is painless gross hematuria, and the disease usually is detected onIVPduring the workup for hematuria. Patterns of spread are like those in bladder cancer. For disease localized to the renal pelvis and ureter, nephroureterectomy (including excision of the distal ureter with a portion of the bladder) is associated with a 5-year survival of 80 to 90% for low-grade lesions. More invasive or histologically poorly differentiated tumors are more likely to recur locally and metastasize. Metastatic disease is treated with M-VAC or CMV (cisplatin, methotrexate, vinblastine) chemotherapy, as used in bladder cancer, and the outcome is similar to that for metastatic transitional cell cancer of bladder origin.

95. HYPERPLASTIC AND MALIGNANT DISEASES OF THE PROSTATE - *Howard I. Scher*

The process of aging is associated with an increasing frequency of both benign and malignant alterations of the prostate gland. These conditions reflect the uncontrolled growth of both the stromal and epithelial components of the gland. Autopsies of men in the eighth decade of life show hyperplastic changes in>90% and malignant changes in>70%. Most men with benign or malignant conditions of the prostate are not diagnosed during their lifetimes. The high prevalence of these diseases, coupled with comorbid conditions and competing causes of death that are frequent in this age group, mandates a careful consideration of the risk/benefit ratio of any proposed intervention. Management is centered on the continual reassessment of the disease as it unfolds in the individual. For the benign proliferative disorders, the symptoms of urinary frequency, infection, and potential for obstruction are counterbalanced by the side effects and complications of medical or surgical therapy. For malignant disease, the risk of developing symptoms or death from cancer is balanced against treatment efficacy and treatment-related morbidity for interventions proposed at different points in the natural history.

The incidence and mortality of prostate cancer have declined over the past few years. The decline is not clearly related to any meaningful decrease in the disease or its severity. Instead, the number of cases diagnosed increased dramatically in the early 1990s based on the widespread use of serum prostate-specific antigen (PSA) levels. The test led to the diagnosis of more asymptomatic cancers, some of which may never have produced symptoms -- so-called lead-time bias (Chap. 80). Screening for prostate cancer has not been proven effective in prospective randomized trials. Prostate cancer is the most common cancer diagnosis and the second leading cause of cancer death in men. In 2000, 180,400 cases were diagnosed and 31,900 men died of prostate cancer, down from the peak of 352,000 new cases in 1996. The projected lifetime risk of developing prostate cancer for a 50-year-old man is 42%, of being diagnosed is 9.5%, and of dying from prostate cancer is 2.9%.

ANATOMY

The prostate is located in the pelvis and is surrounded by the rectum, bladder, dorsal and periprostatic venous complexes, musculature of the pelvic sidewall, the urethral sphincter (responsible for passive urinary control), the pelvic plexus, and cavernous nerves (which innervate the pelvic organs and corpora cavernosa). It is divided into a peripheral zone, a central zone, and a transition zone. The anterior surface is covered by the fibromuscular stroma. Most cancers develop in the peripheral zone, while nonmalignant proliferation occurs predominantly in the transition zone. The functional unit is the glandular acinus, which consists of an epithelial compartment including epithelial, basal, and neuroendocrine cells, and a stromal compartment including fibroblasts and smooth-muscle cells. These compartments are separated by a basement membrane.PSA and prostate-specific acid phosphatase are produced in the epithelial cells. Both stromal and epithelial cells express androgen receptors and depend on androgens for growth. Additional growth regulatory signals occur via paracrine signaling between the two compartments. In cancer, the relationship between stromal and epithelial elements contributes to growth both in the primary and in

metastatic sites. The major circulating androgen in the blood is testosterone, which is converted to dihydrotestosterone, the active form, by 5a-reductase. Changes in prostate size occur during two distinct periods: diffuse enlargement during puberty and in focal regions in the periurethral area after the age of 55.

DIAGNOSIS AND SCREENING

Symptoms Most cancers are asymptomatic in their early stages. By contrast, benign proliferative disorders may encroach on the urethra early in the clinical course, giving rise to symptoms of outlet obstruction such as hesitancy, intermittent voiding, diminished stream, incomplete emptying, and postvoid leakage. For the patient with symptoms, the history is focused on the urinary tract to identify other causes of voiding dysfunction. For quantification of symptoms, the preferred questionnaire is the self-administered American Urological Association (AUA) *Symptom Index* in which the symptoms can be classified as mild, moderate, or severe on the basis of seven questions (Table 95-1). This index is useful in planning and in follow-up. Over time, the resistance to the flow of urine reduces the compliance of the detrusor muscle, resulting in nocturia, urgency, and bladder instability and ultimately in urinary retention. The relationship between the signs and symptoms of obstruction and prostate size is not straightforward, and a small gland does not exclude significant blockage. In severe cases the bladder may be palpable on physical examination. Infection, tranquilizing drugs, antihistamines, or alcohol can precipitate urinary retention.

Obstructive symptoms are distinct from irritative symptoms such as frequency, dysuria, or urgency, which may occur from infectious, inflammatory, or neoplastic diseases. Conditions that can mimic cancer include acute prostatitis, granulomatous prostatitis, and prostate calculus. Prostatitis usually produces induration and/or pain and is treated with antibiotics. Prostate cancer may manifest in the same manner, and the distinction can only be established histologically, but a biopsy should not be performed before a trial of antibiotics if prostatitis is a possible diagnosis. In cases where the tumor has extended beyond the confines of the gland, symptoms of hematospermia or erectile dysfunction may occur. Prostate cancer may also present with pain secondary to bone metastases, although many patients are asymptomatic despite extensive spread. Less common presentations include myelophthisic disorders, disseminated intravascular coagulation, or spinal cord compression. The proportion of men diagnosed at these late stages has also decreased significantly as a result ofPSA-based detection strategies.

Physical Examination The standard evaluation for prostatic diseases includes the digital rectal examination (DRE). It should be performed with careful attention to the size and consistency of the gland, the presence of lesions within the gland, or evidence of extension beyond its confines. Its importance can not be overemphasized. The posterior surfaces of the lateral lobes, where carcinoma begins most often, are easily palpable on DRE. Carcinoma characteristically is hard, nodular, and irregular, but induration may also be due to fibrous areas in a benign hyperplastic background or to calculi. Extraprostatic extension to the seminal vesicles can often be detected by rectal examination, while scrotal and/or lower extremity lymphedema secondary to infiltration of pelvic lymph nodes indicates extensive disease. The need for establishing a histologic diagnosis is based on the finding of an abnormal DRE or an elevated serumPSAlevel.

Prostate-Specific Antigen PSA is a serine protease that is produced by both nonmalignant and malignant epithelial cells. In serum, it circulates as an inactive complex with two protease inhibitors -- a_1-antichymotrypsin andb_2-macroglobulin. PSA is prostate specific but not prostate cancer specific and is measured most commonly by radioimmunoassay. The normal range is 0 to 4 ng/mL; ~30% of men with a PSA in the range of 4 to 10 ng/mL and 50% of those with a PSA>10 ng/mL will have cancer. Between 20 and 25% of men with an abnormalDRE have cancer at biopsy, and 20% of men have cancer detected when the PSA is in the normal range. African American men normally have higher PSA levels, even if they do not have prostate cancer. They also have a 50% higher risk of prostate cancer. The reason for the racial differences is not known.

Several refinements have been proposed to increase the sensitivity of the test for younger men more likely to die of the disease, while reducing the frequency of diagnosing cancers of low biologic potential in elderly men more likely to die of other causes. These modifications include age-specific reference ranges, using a lower "upper" limit of normal for younger males and higher "upper" limit for older individuals. Prostate-specific antigen density (PSAD) is calculated by dividing the serumPSAlevel by the estimated prostate weight calculated from transrectal ultrasonography (TRUS). It was proposed to correct for the influence of benign prostatic hyperplasia (BPH) on the measured level of PSA. Values<0.10 are consistent with BPH, while values>0.15 suggest the presence of cancer. PSAD levels also increase with age.

PSA velocity is derived from calculations of the rate of change inPSAbefore the diagnosis of cancer was established. Increases of>0.75 ng/mL per year are suggestive of cancer. For a 50-year-old male, an increase from 2.5 to 3.9 ng/mL in a 1-year period would warrant further testing, even though the level is still in the "normal" range. Free and complexed PSA measurements are used to determine which men require a biopsy when the PSA level is in the range of 4 to 10 ng/mL. In cancer, the level of free PSA is lower. Using a 25% threshold of free PSA for patients with levels in the range of 4 to 10 ng/mL, specificity was improved by 20% while maintaining a sensitivity of 95%. Further refinements to increase the specificity of distinguishing benign and malignant conditions involve the determination of the ratios of free to total, complexed to total, and free to complexed PSA. Using normal ranges for free/total PSA of >0.15, for complexed/total PSA of <0.70, and for free/complexed PSA of >0.25 improved specificity in one study by 20%. These modifications are designed to reduce the frequency of biopsies in men without cancer. Figure 95-1 illustrates a diagnostic algorithm based on the DREand PSA findings.

Transrectal Ultrasonography Most cancers are hypoechoic by ultrasonography. Unfortunately, no single finding on ultrasound permits univeral distinction between cancer and benign conditions and identification of extracapsular disease. Cancers <5 to 7 mm, those that are well differentiated, and those located in the transition zone are difficult to distinguish from the normal prostate. The primary role of ultrasound is to ensure accurate sampling of any index lesions and of the gland during biopsy. Routine sampling includes a minimum of six cores from the peripheral zone of the gland, each of which is identified and labeled separately for histologic examination. A biopsy session, defined as one that procures four or more cores from widely separated areas of the

prostate, has a sensitivity of ~80% for the detection of a cancer.TRUS has also been used in the assessment of local disease extent; accuracy is limited and is generally restricted to determining whether the tumor invades the seminal vesicles. It is also used to determine the size of the gland for the calculation of PSAD and to guide the placement of radioactive seeds during implantation.

Pathology The noninvasive proliferation of epithelial cells within ducts is termed *prostatic intraepithelial neoplasia* (PIN). It is considered the precursor of cancer, but not all PIN lesions develop into invasive cancers. Nevertheless, on a genetic level, these regions are highly unstable and typically multifocal. Of the cancers identified, >95% are adenocarcinomas; the remainder include squamous cell tumors, transitional cell tumors, and, rarely, carcinosarcomas. Metastases to the prostate are rare, but in some cases, transitional cell tumors originating in the bladder or colonic lesions may invade the gland directly. In the evaluation for adenocarcinoma, each core is examined for the presence or absence of cancer. When cancer is identified, the extent and grade are assessed and the presence or absence of perineural invasion or extracapsular extension reported. Histologic grade is based most commonly on the *Gleason system*, in which the dominant and secondary glandular histologic patterns are independently assigned numbers from 1 to 5 (best to least differentiated) and summed to give a total score of 2 to 10 for each tumor. The grading is reproducible and correlates with clinical outcomes. The most poorly differentiated area of tumor (i.e., the area with the highest histologic grade) often determines biologic behavior.

STAGING

The TNM staging system (Table 95-2) includes categories for cancers identified solely on the basis of an abnormalPSA with no palpable abnormalities onDRE(T1c), those that are palpable but clinically confined to the gland (T2), and those that have extended outside of the gland (T3 and T4). The presence or absence of nodal (N) and distant metastases (M) are also recorded. Clinical staging alone is inaccurate in assessing capsular invasion and the probability of spread to nodal or more distant sites. To refine this assessment, the TNM system has been modified to incorporate the results of imaging studies such as ultrasound or magnetic resonance imaging (MRI) in the assignment of T stage.

Computed tomography (CT) scans lack sensitivity and specificity to detect extraprostatic extension and in visualization of lymph nodes. MRI is an improvement, particularly with an endorectal coil and is superior to CT. T1-weighted images demonstrate the periprostatic fat, periprostatic venous plexus, perivesicular tissues, lymph nodes, and bone marrow. T2-weighted images demonstrate the internal architecture of the prostate and seminal vesicles. Most cancers have a low signal, while the normal peripheral zone has a high signal. Nevertheless, MRI lacks sensitivity and specificity. No single test accurately predicts pathologic stage at surgery.

Another limitation of the TNM system is that the majority of men are now being diagnosed with T1c or T2 disease. Thus, to refine the prediction of local disease extent, most groups are now using multiplex staging models based on a combination of the findings of theDRE, biopsy, Gleason score, and baselinePSA(Table 95-3). Others are developing models based on the number of cores and the percentage of each core

involved by tumor. This information can be used to assist patients in selecting treatments, although it remains controversial how recommendations should be affected by a particular level of probability of node-positive disease.

These same parameters are also being used to assess the probability of cure (Fig. 95-2). Some tumors that have extended beyond the confines of the gland may still be curable, while others that are still organ-confined may not. Because successful surgery removes all prostatic tissues, both benign and malignant, and radiation therapy eliminates only the malignant component, different definitions of cure are needed depending on the modality used. Thus, following surgery, thePSAlevel should become undetectable; following radiation therapy, it should generally fall to <1.0 ng/mL. What the models do not address is what probability of cure a patient would accept to proceed with a given approach. For example, would one categorically deny a surgical procedure to a 40-year-old male if the probability of cure was only 15%? These same models can also be used to stratify patients into risk groups to assess outcomes of specific therapies. While this form of analysis does not replace prospective trials, it does eliminate the bias associated with the tendency to refer older and more infirm patients for radiation therapy and younger, healthier individuals for surgery.

To complete the staging evaluation, patients may undergo radionuclide bone scanning. This test is highly sensitive but relatively nonspecific, because areas of increased uptake are not always secondary to osteoblastic activity from metastases. Healing fractures, arthritis, Paget's disease, and numerous other conditions will also show abnormal uptake. True-positive bone scan results are rare if thePSA is<8 and uncommon when the PSA is<10 ng/mL. More common is a false-positive scan, which, in turn, leads to additional low-yield testing.CT scans yield little useful clinical information unless the probability of lymph node metastases is >30% using nomogram predictions; anMRI is more likely to detect pathologically significant nodal disease. Molecular diagnostics are being performed that seek to identify the presence of circulating prostate cancer cells using an assay for PSA based on reverse transcriptase polymerase chain reaction (RT-PCR) in the leukocyte fraction of the peripheral blood or bone marrow. A large proportion of men with tumors seemingly confined to the organ test positive; the significance is unclear. These procedures are in their infancy, and application is not advised on a routine basis.

TREATMENT SELECTION: THE MODEL OF CLINICAL STATES

The framework for evaluating the risks from an enlarging but nonmalignant gland, the probability that a clinically significant cancer is present in an individual with or without urinary symptoms, and the probability that a patient with cancer will develop symptoms or die of prostate cancer are provided by the clinical states model illustrated in Fig. 95-3. It includes clinically significant milestones where interventions might be considered and allows for the assessment of the prognosis of the treated patient. In the first state are patients with no cancer diagnosis. It includes patients with benign proliferative disorders or those who warrant screening on the basis of family history or a level ofPSA or symptoms. In the second state are those with a cancer that is clinically confined to the gland. For these patients the issue is to determine which tumors require treatment based on their biologic potential, which can be eradicated by local means alone, and which require a combined-modality approach that includes systemic therapy to effect

cure. The third state includes those who have a rising PSA level after surgery or radiation for localized disease but who have no clinically detectable lesions on scans. Next are patients with detectable metastases who have not undergone castration, and the last level is those who have detectable disease on scan despite castration. The risk of death from cancer relative to the risk of death from comorbid conditions increases over time, being greatest for the patient who has progressed after hormonal therapy.

At any point, a patient resides in only one state and remains there until the disease progresses. Thus, a patient who presents with a localized prostate cancer who has had all cancer removed surgically remains in the state of localized disease as long as hisPSAremains undetectable. In this way, both time factors and that the fact that a patient has been treated are accounted for. Overall treatment effects are assessed by measuring time within a particular state. The scheme also allows a distinction between cure, elimination of all cancer cells, with an undetectable PSA and cancer control, i.e., modulating the rate of growth so that the patient dies of other causes. In this paradigm, a patient with a detectable PSA who dies of other causes having suffered no morbidity from the disease or its treatment, PSA level, is considered a therapeutic success.

MANAGEMENT BY STATES

NO CANCER DIAGNOSIS

Screening The American Cancer Society (ACS) and the AUA recommend an annualDRE and a determination ofPSAlevel for all men aged 50 to 79. Individuals with a first-degree relative with prostate cancer and African Americans, who have a higher risk of dying of the disease, are advised to begin testing at age 45. Routine screening for prostate cancer has been advised despite a lack of prospective, randomized, controlled trials proving the benefit of the approach because the disease rarely causes symptoms until it is advanced. The more widespread use of routine DREs and PSA testing has resulted in a significant increase in the proportion of men with clinically localized tumors, a reduced frequency of nodal spread, and a decreased frequency of nodal and osseous disease at presentation. Risks of screening are unnecessary morbidity or mortality from overdetection and overtreatment. Formal clinical trials are underway, but until the studies are complete and the results available, men must make an informed decision to be screened or not.

Hyperplasia A patient with an enlarged prostate who has no symptoms and normalPSAlevels generally does not require treatment. Those with symptoms such as an inability to urinate, renal insufficiency, urinary tract infection, gross hematuria, or bladder stones are candidates for prostate surgery. As the natural history is not well defined, it is not always clear whether to intervene and, if so, how. The majority of men do not develop significant obstruction, and in many, minor irritative and/or obstructive symptoms change slowly or not at all. In these cases urine flow studies can identify those whose maximum flows are normal and who are unlikely to benefit from treatment. Measuring postvoid residual volume identifies patients likely to fail a "watch and wait" approach, while pressure-flow studies may identify those with primary bladder dysfunction. A cystoscopic examination is advised for all patients with hematuria and to assess the urinary outflow tract before a surgical intervention. Imaging of the upper urinary tract by ultrasonography or intravenous pyelography should be reserved for

patients with indications such as hematuria, a history of stones, or prior urinary tract problems.

Most patients are monitored and/or treated medically, after a discussion with their physicians about the degree of incapacity and/or discomfort present and the likely outcome of each potential treatment strategy. A variety of decision diagrams have been proposed. Patients who opt for deferred therapy should be evaluated on an annual basis by the reassessment of symptoms and clinical manifestations. Medical therapies include finasteride, which blocks the conversion of testosterone to dihydrotestosterone, the principal androgen in the prostate, by competitively inhibiting the 5a-reductase enzyme. A dose of 5 mg/d causes an average decrease in prostate size of ~24%, an increase in urine flow rates, and, in some, improvement in symptoms. Long-term efficacy has not been documented, but symptomatic improvement has been documented for[3]3 years provided therapy is continued.a-Adrenergic blockers such as terazosin act by relaxing the smooth muscle of the bladder neck, increasing peak urinary flow rates and reducing symptoms. No data prove that these agents influence the progression of the disease.

Patients who do not improve or who progress on medical therapy require surgical intervention. Surgical approaches include a transurethral resection of the prostate (TURP); transurethral incision; or removal of the gland by a retropubic, suprapubic, or perineal route. Other approaches include ultrasound, coils, stents, lasers, or hyperthermia. Overall, surgery offers the best chance for improving symptoms, at the cost of the highest rate of complications. TURP is the most common surgical procedure. Transurethral incision of the prostate is of similar efficacy in men with relatively small prostates and can be performed in ambulatory settings. Open prostatectomy is usually reserved for men with massive prostates; it has the longest recovery time and the highest morbidity, particularly impotence. Transurethral incision has the least morbidity overall and is least disruptive to ejaculatory function.

ElevatedPSAand No Cancer Diagnosis on Biopsy Patients who have undergone a biopsy procedure and do not have a cancer diagnosis should continue to be monitored. In some cases, a repeat biopsy session with particular attention to the transition zone is advised. The frequency ofPIN is similar in men of different ethnic backgrounds around the world, while the incidence of the clinical disease varies in different ethnic groups. Prevention of progression from PIN to cancer is an area of active research. Proving the benefit of a prevention strategy is difficult because of the long-term follow-up that is necessary, the large sample sizes required to demonstrate a difference in outcome, and the absence of surrogate measures that predict for efficacy. Agents under study include the retinoids, vitamin D, selenium, soy, and modifications of dietary fat. Most are based on epidemiologic data suggesting a decreased prostate cancer risk. A large-scale, double-blind, randomized, multicenter trial of finasteride in men over age 55 has accrued 18,000 men, and follow-up is awaited.

CLINICALLY LOCALIZED DISEASE

Localized prostate cancer (stages T1-2, NX or 0, M0) may require no therapy, may be curable with localized therapy, or may require combined-modality systemic and local therapy. The key is to distinguish these distinct prognostic groups. Treatment planning

includes an assessment of the probability of local control, local failure, and systemic failure. The more advanced the disease, the lower the probability of local control and the higher the probability of systemic relapse. In general, these tumors are managed by watchful waiting, radical surgery, or radiation therapy. Comparisons between these approaches are limited by the lack of prospective comparative trials, referral biases, and differences in the endpoints evaluated.

Conservative Management (Watchful Waiting) The concept of watchful waiting, or deferred therapy, evolved from the recognition of the high prevalence of the disease in the population, the low probability that some cancers would affect an individual's quality-adjusted life expectancy, and the fact that morbidities associated with the local treatment options were unacceptable to many patients. Watchful waiting acknowledges the facts that the natural history of an untreated prostate cancer is to progress and that it may be difficult to monitor progression within the gland so that the "window of curability" is not lost. That the disease is often multifocal leads to the possibility that the biopsy on which the decision to defer therapy is made may not represent accurately the malignant potential of a second unidentified cancer. Within 10 years of diagnosis, most tumors produce local symptoms such as urinary retention, incontinence, hematuria, ureteral and bowel obstruction, and pelvic pain, but these complications rarely lead to the death of the patient. Some tumors may metastasize, but few patients succumb to the disease. Case selection criteria are evolving, but in general, watchful waiting is not advised for patients with high-grade disease or for those with a>10-year life expectancy. Some physicians consider observation only for patients with low-grade tumors (Gleason score£6) that do not involve more than a small percentage of a single core.

Radical Prostatectomy The objective of a radical prostatectomy is the removal of all prostate tissue with a clear margin of resection, preservation of the external sphincter to maintain continence, and sparing of the autonomic nerves in the neurovascular bundle so that potency is retained. The procedure is performed through a retropubic or perineal approach. In contemporary series, hospital stays are short; mortality <0.4%; and complications such as rectal injury, deep vein thrombosis, and embolic events are rare. The procedure is recommended primarily for patients with clinically localized disease (T1c-T3a, N0 or NX, M0 or MX) who have a life expectancy of>10 years. The operation is not justified in men with a life expectancy <5 years. Properly performed, the procedure requires appropriate case selection and meticulous technique that permits the delineation of the anatomy of the gland and surrounding tissues. In one review, the overall rate of positive margins was 25%. Careful planning can reduce this rate. For example, by considering the laterality and extent of disease, it may be apparent that nerve-sparing cannot be achieved without compromising cancer control. A positive margin increases the risk of progression significantly. ThroughPSA-based detection, the proportion of men with positive nodes and positive margins continues to decline.

Complication rates, specifically the probability of developing a bladder neck contracture, incontinence, or impotence, vary depending on the experience of the surgeon and whether the patient or the physican is describing the outcome. Rates of incontinence based on physician reporting are 5 to 10%, compared to 19 to 31% based on independent questioning by a third party. Time is also a consideration, as full recovery of function may not occur for weeks or months following the procedure. Factors associated with incontinence include older age, functional length of the urethra, surgical

technique, preservation of neurovascular bundles, and development of an anastomotic stricture. If the nerves are preserved, ~70% of men recover the ability to achieve an erection sufficient for penetration. Most men are impotent immediately after the procedure and gradually recover function over 6 to 12 months. Often the quality of the erection is decreased from preoperative levels. Nevertheless, with orally active drugs such as sildenafil, intraurethral inserts of alprostadil, and intracavernosal injections of vasodilators, many patients can achieve nearly natural erections and recover satisfactory sexual activity. Factors associated with recovery include younger age, quality of erections before the operation, and the absence of damage to the neurovascular bundles. Loss of one bundle is associated with a 75% reduction in the recovery of function.

After a successful radical prostatectomy in which all prostate tissue has been removed, serumPSAlevels should become undetectable within 4 weeks, based on the half-life of 3 days. If the PSA level remains detectable or becomes detectable after having been undetectable, the patient is considered to have persistent disease or to have a recurrence. In the absence of adjuvant treatment, most patients destined to recur do so within the first 5 years after surgery. Thus, one early benchmark of "success" is the probability of freedom from PSA (or "biochemical") progression. This varies as a function of initial clinical stage, Gleason grade, and serum PSA level before surgery. In one series of 1359 men with clinical stages T1/T2 cancer followed for a mean of 44 months (range 1 to 170), the PSA relapse-free survival rates were 78% at 5 years and 73% at 10 years. In a separate series of T1c patients, 89% were free of progression at 5 years. Considered by baseline PSA levels, 95% of those with a normal level (<4 ng/mL) and 68% of those with a PSA>10 ng/mL were free of progression at 5 years. Considered by grade or Gleason sum in the biopsy specimen, 5- and 10-year PSA relapse-free survivals were 56% and 46%, respectively, for those with tumors of Gleason score of 7, and 46 to 53% at 5 years for those with tumors of Gleason score ³8. These outcomes appear superior to those reported with watchful waiting, recognizing the limitations in comparing the results of nonrandomized selected series.

The most significant predictor of recurrence is pathologic stage. When the disease is confined to the organ and has not extended into the periprostatic soft tissue, 91 to 97% of patients remain free of progression at 5 years and 85 to 92% at 10 years. Extension to the periprostatic soft tissues (pT3a and N0) decreasesPSArelapse-free probabilities to 74% and 68% at 5 and 10 years, respectively, which is decreased further to 40 to 47% and 25% if there is seminal vesicle invasion (pT3c and N0). The high frequency of extracapsular extension and positive surgical margins in patients with clinically localized prostate cancers that were presumed to be confined to the gland led to the investigation of neoadjuvant hormonal therapy. The results of several large contemporary series evaluating 3 months of hormone therapy before surgery showed that, on average, positive margins are reduced from 41% to 17%, serum PSA levels by 96%, and prostate volume by 34% with neoadjuvant hormone therapy. The surrogate of a reduction in positive margin rates was not predictive of a reduction in failure rates, as the time to PSA relapse was no different between groups receiving and not receiving hormones. As such, neoadjuvant hormonal therapy is not recommended. Several recurrence models are available that incorporate all of these factors.

Radiation Therapy Radiation therapy can be delivered externally, by implantation of

radioactive sources into the gland, or a combination of both. As is the case with surgery, outcomes vary as a function of the method, the dose, the endpoints, and whether outcomes were based on clinical or pathologic staging of the lymph nodes. Some groups report local control, and othersPSArelapse-free survival, time to metastases, or overall survival. Cause-specific survivals are rarely reported. Local control can be reported on the basis of aDREalone or the more stringent criterion of a negative biopsy at 18 to 24 months following treatment. Length of follow-up can also influence the results. To standardize reporting, the American Society of Therapeutic Radiation Oncology has developed a consensus definition of PSA relapse as three consecutive rising PSA values from the nadir value.

External Beam Therapy Overall, outcomes with external beam therapy are similar for patients with T1 and T2a disease to those obtained with radical surgery. Outcomes for patients with locally advanced disease (T2bc and T3/T4) are less favorable, the result of both inadequate control of the primary tumor and the high rate of systemic failure associated with more advanced disease. For the latter group, 30 to 40% of patients relapse locally using standard doses.

Conventional techniques use simulators and CTscans of the pelvis to determine the location and shape of the target volume and the surrounding normal organs. Typical treatment plans use a four-field pelvic box designed to include the prostate, seminal vesicles, and the locally draining lymph nodes. Normal structures are protected by shaping the beams with cerrobend trim blocks. Therapy is delivered on a daily basis, excepting weekends, in 1.8- to 2.0-Gy fractions. Outcomes are dose-dependent; in one series of stage C patients, actuarial 7-year local recurrence rates were 36% for those receiving 60 to 64.9 Gy, 32% for those receiving 65 to 69.9 Gy, and 24% for those treated at ³70 Gy. Complication rates also increase with increasing dose. Using standard doses, grade 2 or greater rectal and/or urinary symptoms requiring medication occur in 60% of cases, while late sequelae such as cystitis, hematuria, stricture, or bladder contracture occur in 7% of cases. The frequency of adverse events is significantly higher in patients who have undergone aTURP, while the frequency of rectal complications is directly related to the volume of the anterior rectal wall receiving full-dose treatment. The frequency of erectile dysfunction is related to the quality of erections before treatment, the dose administered, and the time of assessment. Impotence is related to a disruption of the vascular supply and not the nerve fibers.

More contemporary approaches use three-dimensional conformal radiation therapy (3D-CRT) techniques with sophisticated computer-generated treatment plans to deliver the prescribed radiation dose to the entire target volume, while conforming to the anatomic boundaries of the tumor in its entire three-dimensional configuration. This treatment method has increased the ability to control the cancer through the administration of higher radiation doses, with less morbidity to the surrounding normal organs. In a series of 743 patients treated with 3D-CRT, 90% of patients receiving 75.6 or 81.0 Gy achieved aPSAnadir of £1 ng/mL compared with 76% and 56% of those treated with 70.2 Gy and 64.8 Gy, respectively ($p < .001$).

As is the case with surgically treated patients, pre-therapy nomograms can be used to stratify patient groups. In one series, the 5-year actuarialPSArelapse-free survival for patients with favorable prognostic indicators (stage T1/T2, pretreatment PSA of 10.0

ng/mL, and Gleason score of 6) was 85%; it was 65% for those with an intermediate prognosis (one of the prognostic indicators with a higher value) and 35% for those with unfavorable features (two or more indicators with higher values) (p <.001).

Tolerance of3D-CRThas been excellent despite the use of higher radiation doses; grade 3 to 4 rectal or urinary toxicities were seen in 2.1% of patients. In contrast, among patients treated with conventional external-beam radiotherapy, the incidence of grade 3 to 4 toxicities for patients who received radiation doses of>70 Gy was 6.9%.

To improve outcomes for patients with unfavorable features, several groups have explored hormone therapy before radiation therapy. Prospective randomized trials showed improved local control and a delay in time toPSArelapse in patients receiving 2 to 3 years of treatment. The impact on survival has been less clear.

Interstitial Therapy Interstitial brachytherapy is based on the principle that the deposition of radiation energy in tissues decreases exponentially as a function of distance from the radiation source. By infiltrating tumor tissue with radioactive sources, intensive irradiation is delivered to the prostate with minimal irradiation of the surrounding tissues. In a series of 197 patients followed for a median of three years, 5-year actuarialPSArelapse-free survival for patients with pre-therapy PSA levels of 0 to 4, 4 to 10, and >10 were 98%, 90%, and 89%, respectively. Nevertheless, many physicians feel that implantation is best reserved for patients with good or intermediate prognostic features.

Overall, the procedure is well tolerated, although most patients experience urinary frequency and urgency, which can persist for several months. Incontinence has been seen in 2 to 4% of cases. Higher complication rates are observed in patients who have undergone a priorTURP or who have obstructive symptoms at baseline. Proctitis has been reported in<2% of patients. Longer follow-up will be necessary to see whether the overall frequency of impotence is lower, higher, or the same as that observed using external radiation delivery techniques.

RISING PSA

Included in the group of patients with a risingPSA and no evidence of metasatic disease on scans are those who have progressed after watchful waiting, radical prostatectomy, radiation therapy, or both surgery and radiation, with or without prior hormone exposure. For these individuals, the issue is to determine whether the rising PSA is due to local persistence or recurrence (additional therapy to the primary site might be curative) or the result of micrometastatic disease. Imaging studies such asCT,MRI, or bone scan are typically uninformative. The objective is to assess the probability of disease progressing to the point where metastases will occur or cause symptoms. This is the point in the disease where the probability of death from disease exceeds the probability of death from other causes. Difficulty in making these predictions comes from the fact that most patients with a rising PSA receive some form of therapy before the development of metastatic disease, making it virtually impossible to assess the natural history.

To estimate the probability of having a local or systemic recurrence, many investigators use the time toPSAfailure or the rate of rise of PSA as predictive factors. In general,

recurrences documented >1 year after primary treatment tend to be localized, while those recurring in<1 year tend to be systemic. These predictions are not hard and fast. In one series of patients with PSA recurrence after surgery who did not receive systemic therapy until metastatic disease was documented, the median time to metastatic progression was 8 years, and 63% of the patients with rising PSA values remained free of metastases at 5 years. Patients with tumors of Gleason score 8 to 10 had a probability of metastatic progression of 37%, 51%, and 71% at 3, 5, and 7 years, respectively. Combining a high-grade histology and rapid PSA doubling time, the proportion with metastases was 23%, 32%, and 53% during the same time intervals if the time to recurrence was<2 years and the PSA doubling time was>10 months and 47%, 69%, and 79% for the same recurrence interval with <10 months doubling time. For those with tumors of Gleason score 5 to 7, a PSA recurrence in the first 2 years and a doubling time of <10 months identified a group of patients with a frequency of metastases of 19%, 65%, and 85% at 3, 5, and 7 years, respectively.

Prostascint scanning uses a radioactive antibody to prostate-specific membrane antigen (PSMA), which is highly expressed on prostate epithelial cells. For a patient who has undergone a radical prostatectomy, antibody localization to the prostatic fossa is suggestive of local recurrence, in which case external beam radiation therapy might be recommended. Others recommend that a biopsy of the urethrovesical anastamosis be obtained before considering radiation. Most, however, rely on clinical criteria with the additional caveat that the probability of durablePSAcontrol varies inversely with the level of PSA at the start of radiation therapy. Radiation therapy is usually not recommended if the PSA level exceeds 1 to 2 ng/mL or if the PSA was persistently elevated after surgery (indicating that disease-free status was not achieved). For patients with a rising PSA after radiation therapy, a salvage prostatectomy can be considered if (1) residual disease is detected in the gland based on a repeat biopsy, (2) the tumor was amenable to surgical extirpation before radiation therapy, and (3) metastatic disease is absent on imaging studies. Unfortunately, case selection is poorly defined in most series, and morbidities have been significant. As currently performed, virtually all patients are impotent, and ~45% have either incontinence or stress incontinence. Bleeding, bladder neck contractures, and rectal injury are not uncommon.

METASTATIC DISEASE

Noncastrate The removal or blockade of androgens by medical or surgical means is the mainstay of treatment for patients with advanced disease. Surgical orchiectomy is the "gold standard" but is the least preferred by patients. Medical therapies can be subdivided into those that result in a lowering of serum testosterone levels, e.g., gonadotropin-releasing hormone (GnRH) agonists and antagonists and estrogens, and the antiandrogens (Fig. 95-4). Inhibitors of adrenal enzyme synthesis such as ketoconazole and aminoglutethimide are typically used as second-line treatment. The antitumor effects of agents that lower serum testosterone levels are similar, but toxicities differ. Castration is associated with gynecomastia, impotence, weakness, fatigue, hot flushes, loss of muscle mass, changes in personality, anemia, depression, and loss of skeletal mass. Loss of bone mass can be reduced by coadministration of bisphosphonates.

GnRHanalogues (leuprolide acetate and goserelin acetate) initially produce a rise in

luteinizing hormone (LH) and follicle-stimulating hormone (FSH), followed by a downregulation of receptors in the pituitary gland, which effects a chemical castration. The initial rise in testosterone may result in a clinical flare of the disease. As such, these agents are contraindicated in men with significant obstructive symptoms, cancer-related pain, or spinal cord compromise. The flare can be prevented by pretreatment with antiandrogens. Pure GnRH antagonists that do not produce the initial rise in testosterone will shortly be available.

Diethylstilbestrol (3 mg/d) produces castrate levels of testosterone in 1 to 2 weeks and is inexpensive. Its significant cardiovascular toxicities include edema, congestive heart failure, myocardial infarction, cerebrovascular accidents, phlebitis, and pulmonary embolism. Gynecomastia, a common adverse event, can be reduced by prophylactic irradiation of the breasts. Progestational agents such as medroxyprogesterone acetate (Provera) and megestrol acetate (Megace), are inferior to conventional castration and are not used as first-line treatment. The antifungal agent ketoconazole administered at a dose of 1200 mg/d (six times the antifungal dose) produces a chemical castration in 24 h. It is absorbed in an acid environment and typically prescribed with citrus juices to improve absorption; antacids or H_2blocking agents reduce absorption and should be avoided when the pills are administered. The effects on testosterone synthesis, however, are not sustained, and long-term use is limited by hepatoxicity. It can be useful for the unusual patient who presents with a coagulopathy or spinal neurologic compromise and who requires a rapid response. Aminoglutethimide, a second adrenal synthesis inhibitor, was originally developed as an antiseizure medication. It is administered with hydrocortisone. Side effects include somnolence, fatigue, rash, and, after prolonged periods, hypothyroidism; its use is limited.

Nonsteroidal antiandrogens such as flutamide (Eulexin), bicalutamide (Casodex), or nilutamide (Anandron) block the binding of androgens to the receptor. They do not block the production ofLHcentrally, and as a result, serum testosterone levels increase. These drugs have been used clinically in several situations: (1) to block the flare from the initial rise in testosterone fromGnRHuse, (2) as monotherapy to preserve potency, and (3) as part of a combined androgen-blockade approach designed to simultaneously inhibit testicular and adrenal androgens. Toxicities differ among the agents but generally include gynecomastia (which can be significant), fatigue, elevations in serum transaminases, and diarrhea. The latter is the most common reason the drug is discontinued. Nilutamide is also associated with impaired adaptation to darkness, alcohol intolerance, and, rarely, pneumonitis.

Hormonal therapy is the treatment of choice, but the timing of treatment is not as clear. Early administration of hormones delays progression, but the survival benefit is less clear. It is controversial whether hormonal therapy should be initiated with a risingPSAlevel or whether treatment should be held until metastatic disease is detectable on scans. Most physicians recommend use of hormonal therapy with PSA elevation, based on evidence from clinical trials suggesting a survival advantage to such an approach.

A second controversy is whether a combined androgen-blockade that includes an antiandrogen is superior to castration without an antiandrogen. In randomized comparisons, both positive and negative trials have been reported but the majority have

shown no difference. Some feel that the method of primary castration (GnRHanalogue vs. orchiectomy) and the class of antiandrogen (steroidal vs. nonsteroidal) may influence outcome, but this is controversial. A meta-analysis of 22 randomized trials that included 5710 patients showed an absolute 2.1% difference in mortality at 5 years. This translated into a 6.4% reduction in the annual odds of death. A similar analysis by the Blue Cross/Blue Shield Association Evidence-Based Practice Center concluded that no benefit was seen with combined androgen blockade.

Castrate The management of patients who progress on hormone therapy requires documentation of a castrate status and an evaluation for residual hormone sensitivity. For patients on hormonal therapy, this involves discontinuing all hormonal therapy to evaluate for a withdrawal response. Responses are noted within a few weeks of stopping the medication, with the exception of nilutamide and bicalutamide, both of which have a long terminal half-life. For these agents, the response may be delayed. Signs of benefit include declines inPSAlevel, regression of measurable disease, palliation of pain, and improvements in cancer-related anemia.

Patients who are documented to be castrated, and/or who progress after a trial of withdrawal, are often given one additional hormonal manipulation. Depending on prior hormone exposure, options include inhibitors of adrenal steroid hormone synthesis such as ketoconazole and aminoglutethimide, glucocorticoids, antiandrogens, estrogens, or progestational agents. The responses are often short-lived and do not occur in the majority of patients. Nevertheless, the response can be durable in some patients and provide significant palliation in the absence of curative therapies. Glucocorticoids have been associated with clinical benefit and declines inPSAlevels in 30 to 40% of cases.

Estramustine (Emcyt) is a synthetic combination of estrogen with a nitrogen mustard moiety at C17 that affects microtubule assembly and disassembly. It has no alkylating effects in vivo. About 20% of the drug is metabolized to pure estrogenic moieties, which exert an antigonadotropin effect and which account for the side effect profile. It is often used in patients who have failed hormone therapy and has additive/synergistic effects with other drugs including the vinca alkaloids (vinblastine and navelbine), taxanes (paclitaxel, docetaxel), and the podophyllotoxins (etoposide).

Patients who progress on primary hormone therapy and after hormone withdrawal and receive one additional (second-line) intervention are considered to have "hormone-independent" or "hormone-refractory" disease. At this point, chemotherapy is often considered, although some feel it has no role in the management of prostate cancer because no single agent or combination of drugs has been shown to improve survival in a prospective randomized trial. In the absence of a proven benefit in survival, it is important to consider the specific goals of therapy before it is recommended. These goals might include palliation of symptoms, delaying progression, or inducing decreases in thePSAlevel. Interpreting reported outcomes with individual agents is limited in part by differences in case selection and the wide range of endpoints used.

Mitoxantrone has modest activity as a single agent and is more effective at relieving pain and improving quality of life when given together with prednisone. No effect on survival has been shown. However, mitoxantrone plus prednisone and estramustine plus vinblastine are often used to palliate symptoms of disease. The most frequently

utilized contemporary regimens are weekly combinations of estramustine and a taxane (paclitaxel or docetaxel). Weekly doxorubin also provides palliation.

PALLIATION OF PAIN

Pain is one of the most feared debilitating manifestations of advanced disease. Palliation of pain can be achieved with external beam radiation therapy, bone-seeking radioisotopes, cold bisphosphonates, and chemotherapy. The goals are to relieve symptoms, prevent complications, and improve quality-adjusted life expectancy. To optimize treatment selection, it is important to consider the sites and distribution of the pain and the presence or absence of neurologic compromise. Spinal cord compression is one of the most devastating complications. Once a loss of function is documented, the probability of recovery is small. Particular areas where a high index of suspicion is required are the base of the skull, which can produce a variety of symptoms including diplopia, deafness, difficulty swallowing, dysarthria, and facial weakness; and mental nerve compression in the jaw, resulting in a numb lip and chin, which can interfere with eating. In these situations, external beam radiation together with glucocorticoids are required.

For a solitary lesion that is symptomatic and can be treated through a single port, external beam radiation therapy is the treatment of choice. Depending on the clinical situation, a single high-dose fraction (6 to 9 Gy) may be all that is necessary. The overall utility is limited by the facts that metastases are rarely solitary and that additional untreated areas often become symptomatic in a relatively short time. In other cases, wide-field portals are needed. For those with more diffuse disease, bone-seeking radioisotopes are available.^{153}Sm-EDTMP (quadramet) emits b particles and a photon; its half-life is about 22 h. When given at 37 MBq/kg (1 mCi/kg), half the administered dose goes to bone, and 70 to 95% of patients experience decreased bone pain within 2 weeks that lasts 8 to 15 weeks.^{89}Sr (metastron) is a pure b-emitter with a half-life of 50 days that emits a 1.46-MeV electron with a 2- to 3-mm range in bone. Used alone it has modest effects on the level ofPSA but does provide a degree of palliation that is similar to external beam approaches. The results of randomized comparisons suggest a systemic effect, as fewer patients treated with the isotope developed new areas of pain or required additional radiation therapy compared to patients receiving radiation therapy alone. Cold bisphosphonates have been shown to be superior to placebo in the prevention of skeletal events for patients with breast cancer, lung cancer, and multiple myeloma. They may be active in prostate cancer as well.

96. TESTICULAR CANCER - *Robert J. Motzer*, *George J. Bosl*

Primary germ cell tumors (GCTs) of the testis, arising by the malignant transformation of primordial germ cells, constitute 95% of all testicular neoplasms. Infrequently, GCTs arise from an extragonadal site, including the mediastinum, retroperitoneum and, very rarely, the pineal gland. This disease is notable for the young age of the afflicted patients, the totipotent capacity for differentiation of the tumor cells, and its curability;>90% of all newly diagnosed patients will be cured. Experience in the management of GCTs leads to improved outcome.

INCIDENCE AND EPIDEMIOLOGY

Nearly 6900 new cases of testicularGCT were diagnosed in the United States in 2000; the incidence of this malignancy has increased slowly over the past 40 years. The tumor occurs most frequently in men between the ages of 20 and 40. A testicular mass in a man 50 years or older should be regarded as a lymphoma until proved otherwise. GCT is at least 4 to 5 times more common in white than in African-American males, and a higher incidence has been observed in Scandinavia and New Zealand than in the United States.

ETIOLOGY AND GENETICS

Cryptorchidism is associated with a severalfold higher risk ofGCT. Abdominal cryptorchid testes are at a higher risk than inguinal cryptorchid testes. Orchiopexy should be performed before puberty, if possible. Early orchiopexy reduces the risk of GCT and improves the ability to save the testis. An abdominal cryptorchid testis that cannot be brought into the scrotum should be removed. About 2% of men with GCTs of one testis will develop a primary tumor in the other testis. Testicular feminization syndromes increase the risk of testicular GCT, and Klinefelter's syndrome is associated with mediastinal GCT.

An isochromosome of the short arm of chromosome 12 [i(12p)] is pathognomonic forGCT of all histologic types. Excess 12p copy number either in the form of i(12p) or as increased 12p on aberrantly banded marker chromosomes occurs in nearly all GCT, but the gene(s) on 12p involved in the pathogenesis are not yet defined.

CLINICAL PRESENTATION

A painless testicular mass is pathognomonic for a testicular malignancy. More commonly, patients present with testicular discomfort or swelling suggestive of epididymitis and/or orchitis. In this circumstance, a trial of antibiotics is reasonable. However, if symptoms persist or a residual abnormality remains, then testicular ultrasound examination is indicated.

Ultrasound of the testis is indicated whenever a testicular malignancy is considered and for persistent or painful testicular swelling. If a testicular mass is detected, a radical inguinal orchiectomy should be performed. Because the testis develops from the gonadal ridge, its blood supply and lymphatic drainage originate in the abdomen and descend with the testis into the scrotum. An inguinal approach is taken to avoid

breaching anatomic barriers and permitting additional pathways of spread.

Back pain from retroperitoneal metastases is common and must be distinguished from musculoskeletal pain. Dyspnea from pulmonary metastases occurs infrequently. Patients with increased serum levels of human chorionic gonadotropin (hCG) may present with gynecomastia. A delay in diagnosis is associated with a more advanced stage and possibly worse survival.

The staging evaluation for GCTincludes a determination of serum levels of afetoprotein (AFP) andhCG. After orchiectomy, a chest radiograph and a computed tomography (CT) scan of the abdomen and pelvis should be performed. A chest CT scan is required if pulmonary nodules, mediastinal or hilar disease is suspected. *Stage I disease* is limited to the testis, epididymis, or spermatic cord. *Stage II disease* is limited to retroperitoneal (regional) lymph nodes. *Stage III disease* is disease outside the retroperitoneum, involving supradiaphragmatic nodal sites or viscera. The staging may be "clinical" -- defined solely by physical examination, blood marker evaluation, and radiographs -- or "pathologic" -- defined by an operative procedure.

The regional draining lymph nodes for the testis are in the retroperitoneum, and the vascular supply originates from the great vessels (for the right testis) or the renal vessels (for the left testis). As a result, the lymph nodes that are involved first by a right testicular tumor are the interaortocaval lymph nodes just below the renal vessels. For a left testicular tumor, the first involved lymph nodes are lateral to the aorta (para-aortic) and below the left renal vessels. In both cases, further nodal spread is inferior and contralateral and, less commonly, above the renal hilum. Lymphatic involvement can extend cephalad to the retrocrural, posterior mediastinal, and supraclavicular lymph nodes. Treatment is determined by tumor histology (seminoma versus nonseminoma) and clinical stage (Table 96-1).

PATHOLOGY

GCTsare divided into nonseminoma and seminoma subtypes. Nonseminomatous GCTs are most frequent in the third decade of life and can display the full spectrum of embryonic and adult cellular differentiation. This entity comprises four histologies: embryonal carcinoma, teratoma, choriocarcinoma, and endodermal sinus (yolk sac) tumor. Choriocarcinoma, consisting of both cytotrophoblasts and syncytiophoblasts, represents malignant trophoblastic differentiation and is invariably associated with secretion ofhCG. Endodermal sinus tumor is the malignant counterpart of the fetal yolk sac and is associated with secretion ofAFP. Pure embryonal carcinoma may secrete AFP or hCG, or both; this pattern is biochemical evidence of differentiation. Teratoma is composed of somatic cell types derived from two or more germ layers (ectoderm, mesoderm, or endoderm). Each of these histologies may be present alone or in combination with others. Nonseminomatous GCTs tend to metastasize early to sites such as the retroperitoneal lymph nodes and lung parenchyma. One-third of patients present with disease limited to the testis (stage I), one-third with retroperitoneal metastases (stage II), and one-third with more extensive supradiaphragmatic nodal or visceral metastases (stage III).

Seminoma represents about 50% of allGCTs, has a median age in the fourth decade,

and generally follows a more indolent clinical course. Most patients (70%) present with stage I disease, about 20% with stage II disease, and 10% with stage III disease; lung or other visceral metastases are rare. Radiation therapy is the treatment of choice in patients with stage I disease and stage II disease where the nodes are<5 cm in maximum diameter. When a tumor contains both seminoma and nonseminoma components, patient management is directed by the more aggressive nonseminoma component.

TUMOR MARKERS

Careful monitoring of the serum tumor markersAFP andhCG is essential in the management of patients withGCT, as these markers are important for diagnosis, as prognostic indicators, in monitoring treatment response, and in the detection of early relapse. Approximately 70% of patients presenting with disseminated nonseminomatous GCT have increased serum concentrations of AFP and/or hCG. While hCG concentrations may be increased in patients with either nonseminoma or seminoma histology, the AFP concentration is increased only in patients with nonseminoma. The presence of an increased AFP level in a patient whose tumor showed only seminoma indicates that an occult nonseminomatous component exists and that the patient should be treated accordingly for nonseminomatous GCT. The serum lactate dehydrogenase (LDH) level serves as an additional marker of all GCTs, but it is not as specific as either AFP or hCG. LDH levels are increased in 50 to 60% patients with metastatic nonseminoma and in up to 80% of patients with advanced seminoma.

AFP,hCG, andLDHlevels should be determined before and after orchiectomy. Increased serum AFP and hCG concentrations decay according to first-order kinetics; the half-life is 24 to 36 h for hCG and 5 to 7 days for AFP. AFP and hCG should be assayed serially during and after treatment. The reappearance of hCG and/or AFP or the failure of these markers to decline according to the predicted half-life is an indicator of persistent or recurrent tumor.

TREATMENT

Stage I Nonseminoma If, after an orchiectomy (for clinical stage I disease), radiographs and physical examination show no evidence of disease, and serumAFP andhCGconcentrations either are normal or are declining to normal according to the known half-life, patients may be managed by either a nerve-sparing retroperitoneal lymph node dissection (RPLND) or surveillance. The retroperitoneal lymph nodes are pathologically involved byGCT(pathologic stage II) in 20 to 50% of these patients. The choice of surveillance or RPLND is based on the pathology of the primary tumor. If the primary tumor shows no pathologic evidence for lymphatic or vascular invasion *and* is limited to the testis (T1), then either option is reasonable. If lymphatic or vascular invasion is present *or* the tumor extends into the tunica, spermatic cord, or scrotum (T2 through T4), then surveillance should not be offered. Either approach should cure>95% of patients.

ARPLND is the standard operation for removal of the regional lymph nodes of the testis (retroperitoneal nodes). The operation removes the lymph nodes ipsilateral to the primary site and the nodal groups adjacent to the primary landing zone. The standard

(modified bilateral) RPLND removes all node-bearing tissue down to the bifurcation of the great vessels, including the ipsilateral iliac nodes. The major long-term effect of this operation is retrograde ejaculation and infertility. A nerve-sparing RPLND, usually accomplished by identification and dissection of individual nerve fibers, may avoid injury to the sympathetic nerves responsible for ejaculation. Normal ejaculation is preserved in approximately 90% of patients. Patients with pathologic stage I disease are observed, and only the 10% who relapse require additional therapy. If retroperitoneal nodes are found to be involved at RPLND, then a decision regarding adjuvant chemotherapy is made on the basis of the extent of retroperitoneal disease (see below).

Surveillance is an option in the management of clinical stage I disease when no vascular/lymphatic invasion is found and the primary tumor is classified as T1. Only 20 to 30% of patients have pathologic stage II disease, implying that mostRPLNDsin this situation are not therapeutic. Although surveillance has not been compared to RPLND in a randomized trial, all large studies show that surveillance and RPLND lead to equivalent long-term survival rates. Patient compliance is essential if surveillance is to be successful. Patients must be carefully followed with periodic chest radiography, physical examination,CT scan of the abdomen, and serum tumor marker determinations. The median time to relapse is about 7 months, and late relapses (later than 2 years) are rare. The 70 to 80% of patients who do not relapse require no intervention after orchiectomy; treatment is reserved for those who do relapse. When the primary tumor is classified as T2 through T4 *or* lymphatic/vascular invasion is identified, nerve-sparing RPLND is preferred. About 50% of these patients have pathologic stage II disease and are destined to relapse.

Stage II Nonseminoma Patients with limited, ipsilateral retroperitoneal adenopathy (nodes usually £3 cm in largest diameter) generally undergo a modified bilateralRPLND as primary management. Nearly all patients with pathologic stage II disease whose disease is completely resected by RPLND are cured. The local recurrence rate after a properly performed RPLND is very low. Depending on the extent of disease, the postoperative management options include either surveillance or two cycles of adjuvant chemotherapy. Surveillance is the preferred approach for patients with resected "low-volume" metastases (tumor nodes£2 cm in diameter, *and*<6 nodes are involved) because the probability of relapse is one-third or less. Because relapse occurs in³50% of patients with "high-volume" metastasis (>6 nodes involved, *or* any involved node >2 cm in largest diameter, *or* extranodal tumor extension), two cycles of adjuvant chemotherapy should be considered, as it results in cure in³98% of patients. Regimens consisting of etoposide (100 mg/m$_2$daily on days 1 through 5) plus cisplatin (20 mg/m$_2$daily on days 1 through 5) with or without bleomycin (30 units per day on days 2, 9, and 16) given at 3-week intervals are effective and well tolerated.

Stages I and II Seminoma Inguinal orchiectomy followed by retroperitoneal radiation therapy cures about 98% of patients with stage I seminoma. The dose of radiation (2500 to 3000 cGy) is low and well tolerated, and the in-field recurrence rate is negligible. About 2% of patients relapse with supradiaphragmatic or systemic disease. Surveillance has been proposed as an option, and studies have shown that about 15% of patients relapse. The median time to relapse is 12 to 15 months, and late relapses during surveillance (>5 years) may be more frequent than with nonseminoma. The relapse is usually treated with chemotherapy. Surveillance for clinical stage I seminoma

is generally not recommended.

Nonbulky retroperitoneal disease (stage IIA and IIB) is also treated with radiation therapy. Prophylactic supradiaphragmatic fields are not used. Relapses in the anterior mediastinum are unusual. Approximately 90% of patients achieve relapse-free survival with retroperitoneal masses<5 cm in diameter. Because at least one-third of patients with bulkier disease relapse, initial chemotherapy is preferred for stage IIC disease.

Chemotherapy for Advanced GCT Regardless of histology, patients with stage IIC and stage IIIGCT are treated with chemotherapy. Combination chemotherapy programs based on cisplatin at doses of 100 to 120 mg/m^2per cycle plus etoposide cure 70 to 80% of such patients, with or without bleomycin, depending on risk stratification (see below). A complete response (the complete disappearance of all clinical evidence of tumor on physical examination and radiography plus normal serum levels ofAFP andhCG for 1 month or more) occurs after chemotherapy alone in about 60% of patients, and another 10 to 20% become disease-free with surgical resection of all sites of residual disease. Lower doses of cisplatin result in inferior survival rates.

The toxicity of the cisplatin/bleomycin/etoposide (BEP) regimen may be substantial. Nausea, vomiting, and hair loss occur in most patients, although nausea and vomiting have been markedly ameliorated by modern antiemetic regimens. Myelosuppression is frequent, and symptomatic bleomycin pulmonary toxicity occurs in about 5% of patients. Treatment-induced mortality due to neutropenia with septicemia or bleomycin-induced pulmonary failure occurs in 1 to 3% of patients. Dose reductions for myelosuppression are rarely indicated. Long-term permanent toxicities include nephrotoxicity (reduced glomerular filtration and persistent magnesium wasting), ototoxicity, and peripheral neuropathy. When bleomycin is administered by weekly bolus injection, Raynaud's phenomenon appears in 5 to 10% of patients. Less often, other evidence of small blood vessel damage has been reported, including transient ischemic attacks and myocardial infarction.

Risk-Directed Chemotherapy Because not all patients are cured and treatment may cause significant toxicities, patients are stratified into "good-risk" and "poor-risk" groups according to pretreatment clinical features. For good-risk patients, the goal is to achieve maximum efficacy with minimal toxicity. For poor-risk patients, the goal is to identify more effective therapy with tolerable toxicity.

The International Germ Cell Cancer Consensus Group (IGCCCG) developed criteria to assign patients to three risk groups (good, intermediate, poor) (Table 96-2). Seminoma is either good or intermediate risk based on the absence or presence of nonpulmonary visceral metastases. Marker levels play no role in defining risk. No poor-risk category exists for seminoma. Nonseminomas have good-, intermediate-, and poor-risk categories based on the site of the primary tumor, the presence or absence of nonpulmonary visceral metastases, and marker levels.

For ~90% of patients with good-riskGCTs, four cycles of etoposide plus cisplatin (EP) or three cycles ofBEPproduce durable, complete responses, with minimal acute and chronic toxicity. Pulmonary toxicity is absent when bleomycin is not used and is rare when therapy is limited to 9 weeks; myelosuppression with neutropenic fever is less

frequent; and the treatment mortality rate is negligible. About 75% of intermediate-risk patients and 45% of poor-risk patients achieve durable complete remission with four cycles of BEP, and no regimen has proved superior. More effective therapy is needed.

Postchemotherapy Surgery Resection of residual metastases after the completion of chemotherapy is an integral part of therapy. If the initial histology is nonseminoma and the marker values have normalized, all sites of residual disease should be resected. In general, residual retroperitoneal disease requires a modified bilateralRPLND, which is associated with retrograde ejaculation. Thoracotomy (unilateral or bilateral) and neck dissection are less frequently required to remove residual mediastinal, pulmonary parenchymal, or cervical nodal disease. Viable tumor (seminoma, embryonal carcinoma, yolk sac tumor, or choriocarcinoma) will be present in 15%, mature teratoma in 40%, and necrotic debris and fibrosis in 45% of resected specimens. The frequency of teratoma or viable disease is highest in residual mediastinal tumors. If necrotic debris or mature teratoma is present, no further chemotherapy is necessary. If viable tumor is present but is completely excised, two additional cycles of chemotherapy are given.

If the initial histology is seminoma, mature teratoma is rarely present, and the most frequent finding is necrotic debris. For residual retroperitoneal disease, a completeRPLND is technically difficult owing to extensive postchemotherapy fibrosis. Observation is recommended when no radiographic abnormality exists or a residual mass<3 cm is present. Controversy exists over what to do when the residual mass exceeds 3 cm in diameter. About 25% of such masses contain viableGCT. Some investigators prefer excision or biopsy, but radiation therapy and surveillance are alternatives.

Salvage Chemotherapy Of patients with advancedGCT, 20 to 30% fail to achieve a durable complete response to first-line chemotherapy. A combination of cisplatin, ifosfamide and vinblastine (VeIP) will cure about 25% of patients as a second-line therapy. Patients are more likely to achieve a durable complete response toVeIP if they had a testicular primary tumor and relapsed from a prior complete remission to first-line cisplatin-containing chemotherapy. In contrast, if the patient failed to achieve a complete response or has a primary mediastinal nonseminoma, then VeIP is rarely beneficial. Those patients are candidates for dose-intensive treatment.

Chemotherapy consisting of dose-intensive, high-dose carboplatin (³1500 mg/m$_2$) plus etoposide (³1200 mg/m$_2$), with or without cyclophosphamide or ifosfamide, with peripheral blood stem cell support induces a complete response in 25 to 40% of patients who have progressed after ifosfamide-containing salvage chemotherapy. About one-half of the complete responses will be durable. High-dose therapy is the treatment of choice and standard of care for this patient population. Paclitaxel is active in previously treated patients and is being studied as a new component in conventional-dose and dose-intensive salvage therapy. Cure is still possible in some relapsed patients.

EXTRAGONADAL GCT AND MIDLINE CARCINOMA OF UNCERTAIN HISTOGENESIS

The prognosis and management of patients with extragonadalGCTsdepends on the

tumor histology and site of origin. All patients with a diagnosis of extragonadal GCT should have a testicular ultrasound examination. Nearly all patients with retroperitoneal or mediastinal seminoma achieve a durable complete response toBEP orEP. The clinical features of patients with primary retroperitoneal nonseminoma GCT are similar to those of patients with a primary of testis origin, and careful evaluation will find evidence of a primary testicular GCT in about two-thirds of cases. In contrast, a primary mediastinal nonseminomatous GCT is associated with a poor prognosis; one-third of patients are cured with standard therapy (four cycles of BEP). Patients with newly diagnosed mediastinal nonseminoma are considered to have poor-risk disease and should be considered for clinical trials testing regimens of possibly greater efficacy. In addition, mediastinal nonseminoma is associated with hematologic disorders, including acute myelogenous leukemia, myelodysplastic syndrome, and essential thrombocytosis unrelated to previous chemotherapy. These hematologic disorders are very refractory to treatment. Nonseminoma of any primary site may change into other malignant histologies such as embryonal rhabdomyosarcoma or adenocarcinoma. This is called malignant transformation. i(12p) has been identified in the transformed cell type, indicating GCT clonal origin.

A group of patients (most commonly men) with poorly differentiated tumors of unknown histogenesis, midline in distribution, and not associated with secretion ofAFP orhCG has been described; a few (10 to 20%) are cured by standard cisplatin-containing chemotherapy. i(12p) is present in about 25% of such tumors (the fraction that are cisplatin-responsive), confirming their origin from primitive germ cells. This finding is also predictive of the response to cisplatin-based chemotherapy and resulting long-term survival. These tumors are heterogeneous; neuroepithelial tumors and lymphoma may also present in this fashion.

FERTILITY

Infertility is an important consequence of the treatment ofGCTs. Preexisting infertility or impaired fertility is often present. Azoospermia and/or oligospermia are present at diagnosis in at least 50% of patients with testicular GCTs. Ejaculatory dysfunction is associated withRPLND, and germ cell damage may result from cisplatin-containing chemotherapy. Nerve-sparing techniques to preserve the retroperitoneal sympathetic nerves have made retrograde ejaculation less likely in the subgroups of patients who are candidates for this operation. Spermatogenesis does recur in some patients after chemotherapy. However, because of the significant risk of impaired reproductive capacity, semen analysis and cryopreservation of sperm in a sperm bank should be recommended to all patients before radiation therapy, chemotherapy, or RPLND.

97. GYNECOLOGIC MALIGNANCIES - *Robert C. Young*

OVARIAN CANCER

Incidence and Epidemiology Epithelial ovarian cancer is the leading cause of death from gynecologic cancer in the United States. In 2000, 23,100 new cases were diagnosed and 14,000 women died from ovarian cancer. The disease accounts for 5% of all cancer deaths in women in the United States; more women die of this disease than from cervical and endometrial cancer combined.

The age-specific incidence of the common epithelial type of ovarian cancer increases progressively and peaks in the eighth decade. Epithelial tumors, unlike germ cell and stromal tumors, are uncommon before the age of 40. Epidemiologic studies suggest higher incidences in industrialized nations and an association with disordered ovarian function, including infertility, nulliparity, frequent miscarriages, and use of ovulation-inducing drugs such as clomiphene. Each pregnancy reduces the ovarian cancer risk by about 10%, and breast feeding and tubal ligation also appear to reduce the risk. Oral contraceptives reduce the risk of ovarian cancer in patients with a familial history of cancer and in the general population. Many of these risk-reduction factors support the "incessant ovulation" hypothesis for ovarian cancer etiology, which implies that an aberrant repair process of the surface epithelium is central to ovarian cancer development. Estrogen replacement after menopause does not appear to increase the risk of ovarian cancer, although one study showed a modest increase in risk with >11 years of use.

Familial cases account for about 5% of all ovarian cancer, and a family history of ovarian cancer is a major risk factor. Compared to a lifetime risk of 1.6% in the general population, women with one affected first-degree relative have a 5% risk. In families with two or more affected first-degree relatives, the risk may exceed 50%. Three types of autosomal dominant familial cancer are recognized: (1) site-specific in which only ovarian cancer is seen, (2) families with cancer of the ovary and breast, and (3) the Lynch type II cancer family syndrome with nonpolyposis colorectal cancer, endometrial cancer, and ovarian cancer.

Etiology and Genetics In women with hereditary breast-ovarian cancer, two susceptibility loci have been identified: BRCA-1, located on chromosome 17q12-21, and BRCA-2, on 13q12-13. Both are tumor suppressor genes, and their protein products act as inhibitors of tumor growth. Both genes are large, and numerous mutations have been described; most are frameshift or nonsense mutations, and 86% produce truncated protein products. The implications of the many other mutations including many missense mutations are not known. The cumulative risk of ovarian cancer with critical mutations of BRCA-1 or -2 is 25%, compared to the lifetime risk of 50% for breast cancer for similar mutations. Men in such families have an increased risk of prostate cancer.

Cytogenetic analysis of sporadic epithelial ovarian cancers generally reveals complex karyotypic rearrangements. Structural abnormalities frequently appear on chromosomes 1 and 11, and loss of heterozygosity (LOH) is common on 3q, 6q, 11q, 13q, and 17. Abnormalities of oncogenes are frequently found in ovarian cancer and include c-*myc*,

H-*ras*, K-*ras*, and *neu.*

Ovarian tumors (usually not epithelial) are sometimes components of complex genetic syndromes. Peutz-Jeghers syndrome (mucocutaneous pigmentation and intestinal polyps) is associated with ovarian sex cord stromal tumors and Sertoli cell tumors in men. Patients with gonadal dysgenesis (46XY genotype or mosaic for Y-containing cell lines) develop gonadoblastomas, and women with nevoid basal cell carcinomas have an increased risk of ovarian fibromas.

Clinical Presentation and Differential Diagnosis Most patients with ovarian cancer are first diagnosed when the disease has already spread beyond the true pelvis. The occurrence of abdominal pain, bloating, and urinary symptoms usually indicates advanced disease. Localized ovarian cancer is generally asymptomatic. However, progressive enlargement of a localized ovarian tumor can produce urinary frequency or constipation, and rarely torsion of an ovarian mass causes acute abdominal pain or a surgical abdomen. In contrast to cervical or endometrial cancer, vaginal bleeding or discharge is rarely seen with early ovarian cancer. The diagnosis of early disease usually occurs with palpation of an asymptomatic adnexal mass during routine pelvic examination. However, most ovarian enlargements discovered this way, especially in premenopausal women, are benign functional cysts that characteristically resolve over one to three menstrual cycles. Adnexal masses in premenarchal or postmenopausal women are more likely to be pathologic. A solid, irregular, fixed pelvic mass is usually ovarian cancer. Other causes of adnexal masses include pedunculated uterine fibroids, endometriosis, benign ovarian neoplasms, and inflammatory lesions of the bowel.

Evaluation of patients with suspected ovarian cancer should include measurement of serum levels of the tumor marker CA-125. CA-125 determinants are glycoproteins with molecular masses from 220 to 1000 kDa, and a radioimmunoassay is used to determine circulating CA-125 antigen levels. Between 80 and 85% of patients with epithelial ovarian cancer have levels of CA-125 ³35 U/mL. Other malignant tumors can also elevate CA-125 levels, including cancers of the endometrium, cervix, fallopian tubes, pancreas, breast, lung, and colon. Certain nonmalignant conditions that can elevate CA-125 levels include pregnancy, endometriosis, pelvic inflammatory disease, and uterine fibroids. About 1% of normal females have serum CA-125 levels >35 U/mL. However, in postmenopausal women with an asymptomatic pelvic mass and CA-125 levels³65 U/mL, the test has a sensitivity of 97% and a specificity of 78%.

Screening In contrast to patients who present with advanced disease, patients with early ovarian cancers (stages I and II) are commonly curable with conventional therapy. Thus, effective screening procedures would improve the cure rate in this disease. Although pelvic examination can occasionally detect early disease, it is a relatively insensitive screening procedure. Transvaginal sonography has replaced the slower and less sensitive abdominal sonography, but significant false-positive results are noted, particularly in premenopausal women. In one study, 67 laparotomies were required to diagnose 1 primary ovarian cancer. Doppler flow imaging coupled with transvaginal ultrasound may improve accuracy and reduce the high rate of false positives.

CA-125 has been studied as a screening tool. Unfortunately, half of women with stages I and II ovarian cancer have CA-125 levels <65 U/mL. Other nonmalignant disorders

can elevate the CA-125 level, and both false-negative and -positive results have been high in most screening studies.

Attempts have been made to improve the sensitivity and specificity by combinations of procedures, commonly transvaginal ultrasound and CA-125 levels. In a screening study of 22,000 women, 42 had a positive screen and 11 had ovarian cancer (7 with advanced disease). In addition, eight women with a negative screen developed ovarian cancer. Thus, the false-positive rate would lead to a large number of unnecessary (i.e., negative) laparotomies if each positive screen resulted in a surgical exploration. The National Institutes of Health Consensus Conference recommended against screening for ovarian cancer among the general population without known risk factors for the disease. Although no evidence shows that screening saves lives, many physicians use annual pelvic examinations, transvaginal ultrasound, and CA-125 levels to screen women with a family history of ovarian cancer or breast/ovarian cancer syndromes.

Pathology Common epithelial tumors comprise most (85%) of the ovarian neoplasms. These may be benign (50%), frankly malignant (33%), or tumors of low malignant potential (16%) (tumors of borderline malignancy). Epithelial tumors of low malignant potential have the cytologic features of malignancy but do not invade the ovarian stroma. More than 75% of borderline malignancies present in early stage and generally occur in younger women. They have a much better natural history than their malignant counterpart.

There are five major subtypes of common epithelial tumors: serous (50%), mucinous (25%), endometroid (15%), clear cell (5%), and Brenner tumors (1%), the latter derived from the urothelium. Benign common epithelial tumors are almost always serous or mucinous and develop in women ages 20 to 60. They are frequently large (20 to 30 cm), bilateral, and cystic.

Malignant epithelial tumors are usually seen in women over 40. They present as solid masses, with areas of necrosis and hemorrhage. Masses>10 to 15 cm have usually already spread into the intraabdominal space. Spread eventually results in intraabdominal carcinomatosis, which leads to bowel and renal obstruction and cachexia.

Although most ovarian tumors are epithelial, two other important ovarian tumor types exist -- stromal and germ cell tumors. These tumors are distinct in their cell of origin but also have different clinical presentations and natural histories and are often managed differently (see below).

Metastasis to the ovary can occur from breast, colon, gastric, and pancreatic cancers, and the Krukenberg tumor was classically described as bilateral ovarian masses from metastatic mucin-secreting gastrointestinal cancers.

Staging and Prognostic Factors Laparotomy is often the primary procedure used to establish the diagnosis. Less invasive studies useful in defining the extent of spread include chest x-rays, abdominal computed tomography scans, and abdominal and pelvic sonography. If the woman has specific gastrointestinal symptoms, a barium enema or gastrointestinal series can be performed. Symptoms of bladder or renal dysfunction can

be evaluated by cystoscopy or intravenous pyelography.

A careful staging laparotomy will establish the stage and extent of disease and allow for the cytoreduction of tumor masses in patients with advanced disease. Proper laparotomy requires a vertical incision of sufficient length to ensure adequate examination of the abdominal contents. The presence, amount, and cytology of any ascites fluid should be noted. The primary tumor should be evaluated for rupture, excrescences, or dense adherence. Careful visual and manual inspection of the diaphragm and peritoneal surfaces is required. In addition to total abdominal hysterectomy and bilateral salpingo-oophorectomy, a partial omentectomy should be performed and the paracolic gutters inspected. Pelvic lymph nodes as well as para-aortic nodes in the region of the renal hilus should be biopsied. Since this surgical procedure defines stage, establishes prognosis, and determines the necessity for subsequent therapy, it should be performed by a surgeon with special expertise in ovarian cancer staging. Studies have shown that patients operated upon by gynecologic oncologists were properly staged 97% of the time, compared to 52 and 35% of cases staged by obstetricians/gynecologists and general surgeons, respectively. At the end of staging, 23% of women have stage I disease (cancer confined to the ovary or ovaries); 13% have stage II (disease confined to the true pelvis); 47% have stage III (disease spread into but confined to the abdomen); and 16% have stage IV disease (spread outside the pelvis and abdomen). The 5-year survival correlates with stage of disease: stage I -- 90%, stage II -- 70%, stage III -- 15 to 20%, and stage IV -- 1 to 5% (Table 97-1).

Prognosis in ovarian cancer is dependent not only upon stage but on the extent of residual disease and histologic grade. Patients presenting with advanced disease but left without significant residual disease after surgery have a median survival of 39 months, compared to 17 months for those with suboptimal tumor resection.

Prognosis of epithelial tumors is also highly influenced by histologic grade but less so by histologic type. In early-stage disease, survival is better in mucinous adenocarcinoma than endometrial and serous types, and clear cell carcinomas have the worst prognosis. Although grading systems differ among pathologists, all grading systems show a better prognosis for well- or moderately differentiated tumors and a poorer prognosis for poorly differentiated histologies. Typical 5-year survivals for patients with all stages of disease are: well differentiated -- 88%, moderately differentiated -- 58%, poorly differentiated -- 27%.

The prognostic significance of pre- and postoperative CA-125 levels is uncertain. Serum levels generally reflect volume of disease, and high levels usually indicate unresectability and a poorer survival. Postoperative levels, if elevated, usually indicate residual disease. Nevertheless, on multivariate analysis, CA-125 is not an independent prognostic factor because of the association with volume of disease. The rate of decline of CA-125 levels during initial therapy or the absolute level after one to three cycles of chemotherapy correlates with prognosis but is not sufficiently accurate to guide individual treatment decisions. Even when the CA-125 level falls to normal after surgery or chemotherapy, "second-look" laparotomy identifies residual disease in 60% of women. Other more quantitative approaches to define prognosis include ploidy analysis and image cytometry (automated analysis of cell morphology); they remain

investigational.

Genetic and biologic factors may influence prognosis. Increased tumor levels of p53 are associated with a worse prognosis in advanced disease. Epidermal growth factor receptors in ovarian cancer are associated with a high risk of progression, but the increased expression of HER-2/neu has given conflicting prognostic results, and expression of Mdr-1 has not been of prognostic value. HER-2/neu is being evaluated as a target for antibody therapy.

TREATMENT

The selection of therapy for patients with epithelial ovarian cancer depends upon the stage, extent of residual tumor, and histologic grade. In general, patients are considered in three separate treatment groups: (1) those with early (stages I and II) ovarian cancer and microscopic or no residual disease; (2) patients with advanced (stage III) disease but minimal residual tumor (<1 cm) after initial surgery; and (3) patients with bulky residual tumor and advanced (stage III or IV) disease.

Patients with stage I disease, no residual tumor, and well or moderately differentiated tumors need no adjuvant therapy after definitive surgery and 5-year survival exceeds 95%. For all other patients with early disease and those stage I patients with poor prognosis histologic grade, adjuvant therapy is probably warranted, and single-agent cisplatin or platinum-containing drug combinations used in advanced disease are appropriate. Five-year survival for this group exceeds 80%.

For the patients with advanced (stage III) disease but with limited or no residual disease after definitive cytoreductive surgery (about half of all stage III patients), the primary therapy is platinum-based combination chemotherapy. Approximately 70% of women respond to initial combination chemotherapy, and 40 to 50% have a complete regression of disease. Only about half of these patients are free of disease if surgically restaged. Although a variety of combinations are active, a randomized prospective trial of paclitaxel and cisplatin compared to cyclophosphamide and cisplatin in patients with more advanced disease demonstrated better results for the paclitaxel-cisplatin combination (response rate: 77 versus 64%; complete remission rate: 54 versus 33%, median survival: 37.5 versus 24.4 months). A subsequent trial of paclitaxel, 175 mg/m_2 by 3-h infusion, and carboplatin, dosed to an AUC (area under the curve) of 7.5, showed equal antitumor activity to paclitaxel plus cisplatin but substantially less toxicity.

Patients with advanced disease (stages III and IV) and bulky residual tumor are generally treated with a paclitaxel-platinum combination regimen as well and, while the overall prognosis is poorer, 5-year survival may reach 10 to 15%. In some instances, cytoreductive surgery can be performed after initial response to chemotherapy, and a multicenter European trial demonstrated that this strategy led to a significant improvement in progression-free interval and survival.

Historically, patients who had an excellent initial response to chemotherapy and have no clinical evidence of disease have had a second-look laparotomy. For patients with stage I ovarian cancer or for germ cell tumors, the operation rarely detects residual tumor and has been largely abandoned. Even for those with stages II and III epithelial tumors, the

second-look surgical procedure itself does not prolong overall survival. Its routine use cannot be recommended. Maintenance therapy does not prevent recurrences in patients in complete remission.

Patients with advanced disease whose disease recurs after initial treatment are usually not curable but may benefit significantly from limited surgery to relieve intestinal obstruction, localized radiation therapy to relieve pressure or pain from mass lesions or metastasis, or palliative chemotherapy. The selection of chemotherapy for palliation depends upon the initial regimen and evidence of drug resistance. Patients who have a complete regression of disease that lasts ³6 months respond to reinduction with the same agents. Patients relapsing within the first 6 months of initial therapy rarely do. Chemotherapeutic agents with>15% response rates in patients relapsing after initial combination chemotherapy include gemcitabine, topotecan, ifosfamide, etoposide, and hexamethylmelamine. Intraperitoneal chemotherapy (usually cisplatin) may be used if a small residual volume (<1 cm_3) of tumor exists. Progestational agents and antiestrogens produce responses in 5 to 15% of patients and have minimal side effects.

Borderline malignancy has a 95% 5-year survival even in stage III disease when managed with surgery. Radiation and chemotherapy are not useful.

OVARIAN GERM CELL TUMORS

Fewer than 5% of all ovarian tumors are germ cell in origin. They include teratoma, dysgerminoma, endodermal sinus tumor, and embryonal carcinoma. Germ cell tumors of the ovary generally occur in younger women (75% of ovarian malignancies in women<30), display an unusually aggressive natural history, and are commonly cured with less extensive nonsterilizing surgery and chemotherapy. Women cured of these malignancies are able to conceive and have normal children.

These neoplasms can be divided into three major groups: (1) benign tumors (usually dermoid cysts); (2) malignant tumors that arise from dermoid cysts; and (3) primitive malignant germ cell tumors including dysgerminoma, yolk sac tumors, immature teratomas, embryonal carcinomas, and choriocarcinoma.

Dermoid cysts are teratomatous cysts usually lined by epidermis and skin appendages. They often contain hair, and calcified bone or teeth can sometimes be seen on conventional pelvic x-ray. They are almost always curable by surgical resection. Approximately 1% of these tumors have malignant elements, usually squamous cell carcinoma.

Malignant germ cell tumors are usually large (median -- 16 cm). Bilateral disease is rare except in dysgerminoma (10 to 15% bilaterality). Abdominal or pelvic pain in young women is the usual presenting symptom. Serum human chorionic gonadoptropin (b-hCG) and afetoprotein levels are useful in the diagnosis and management of these patients. Before the advent of chemotherapy, extensive surgery was routine but has now been replaced by careful evaluation of extent of spread followed by resection of bulky disease and preservation of one ovary, uterus, and cervix, if feasible. This allows many affected women to preserve fertility. After surgical staging, 60 to 75% of women have stage I disease and 25 to 30% have stage III disease. Stages II and IV are

infrequent.

Most of the malignant germ cell tumors are managed with chemotherapy after surgery. Regimens used in testicular cancer such as PVB (cisplatin, vinblastine, bleomycin) and BEP (bleomycin 30 units IV weekly, etoposide 100 mg/m^2days 1 to 5, and cisplatin 20 mg/m^2days 1 to 5), with three or four courses given at 21-day intervals, have produced 95% long-term survival in patients with stages I to III disease. This regimen is the treatment of choice for all malignant germ cell tumors except grade I, stage I immature teratoma, where surgery alone is adequate, and perhaps early-stage dysgerminoma, where surgery and radiation therapy are used.

Dysgerminoma is the ovarian counterpart of testicular seminoma. The tumor is very sensitive to radiation therapy. The 5-year disease-free survival is 100% in early-stage patients and 61% in stage III disease. Unfortunately, the use of radiation therapy makes many patients infertile. BEP chemotherapy is equally or more effective and does not cause infertility. In incompletely resected patients with dysgerminoma, the 2-year disease-free survival was 95% and infertility was not observed. Combination chemotherapy (BEP) has replaced postoperative radiation therapy as the treatment of choice in women with ovarian dysgerminoma.

OVARIAN STROMAL TUMORS

Stromal tumors make up<10% of ovarian tumors. They are named for the stromal tissue involved: granulosa, theca, Sertoli, Leydig, and collagen-producing stromal cells. The granulosa and theca cell stromal cell tumors occur most frequently in the first three decades of life. Granulosa cell tumors frequently produce estrogen and cause menstrual abnormalities, bleeding, and precocious puberty. Endometrial carcinoma can be seen in 5% of these women, perhaps related to the persistent hyperestrogenism. Sertoli and Leydig cell tumors, when functional, produce androgens with resultant virilization or hirsutism. Some 75% of these stromal cell tumors present in stage I and can be cured with total abdominal hysterectomy and bilateral salpingo-oophorectomy. Stromal tumors generally grow slowly, and recurrences can occur 5 to 10 years after initial surgery. Neither radiation therapy nor chemotherapy have been documented to be consistently effective, and surgical management remains the primary treatment.

CARCINOMA OF THE FALLOPIAN TUBE

The fallopian tube is the least common site of cancer in the female genital tract although its epithelial surface far exceeds that of the ovary, where epithelial cancer is 20 times more common. Approximately 300 new cases occur yearly; 90% are papillary serous adenocarcinomas, with the remainder being mixed mesodermal, endometroid, and transitional cell tumors. BRCA-1 and -2 mutations are found in 7% of cases. The gross and microscopic characteristics and the spread of the tumor are similar to those of ovarian cancer but can be distinguished if the tumor arises from the endosalpinx, the tubal epithelium shows a transition between benign and malignant, and the ovaries and endometrium are normal or minimally involved. The differential diagnosis includes primary or metastatic ovarian cancer, chronic salpingitis, tuberculous salpingitis, salpingitis isthmica nodosa, and cautery artifact.

Unlike patients with ovarian cancer, patients frequently present with early symptoms, usually postmenopausal vaginal bleeding, pain, and leukorrhea. Surgical staging is similar to that used for ovarian cancer, and prognosis is related to stage and extent of residual disease. Patients with stages I and II disease are generally treated with surgery alone or with surgery and pelvic radiation therapy, although radiation therapy does not clearly improve 5-year survival (5-year survival stage I: 74 versus 75%, stage II: 43 versus 48%). Patients with stages III and IV disease are treated with the same chemotherapy regimens used in advanced ovarian carcinoma, and 5-year survival is similar (stage III -- 20%, stage IV -- 5%).

UTERINE CANCER

Carcinoma of the endometrium is the most common female pelvic malignancy. Approximately 36,100 new cases are diagnosed yearly, although in most (75%) tumor is confined to the uterine corpus at diagnosis and therefore most can be cured. The 6500 deaths yearly make uterine cancer only the seventh leading cause of cancer death in females. It is primarily a disease of postmenopausal women, although 25% of cases occur in women <age 50 and 5%<age 40. The disease is common in Eastern Europe and the United States and uncommon in Asia.

Phenotypic characteristics and risk factors common in patients with endometrial cancer include obesity, altered menstruation, low fertility index, late menopause, anovulation, and postmenopausal bleeding. Exposure to unopposed estrogen from either endogenous or exogenous sources may play a central etiologic role. Women taking tamoxifen for breast cancer treatment or prevention have a twofold increased risk.

Endometrial carcinoma occurs most often in the sixth and seventh decades of life. Symptoms often include abnormal vaginal discharge (90%); abnormal bleeding (80%), which is usually postmenopausal; and leukorrhea (10%). Evaluation of such patients should include a history and physical and pelvic examinations followed by an endometrial biopsy or a fractional dilation and curettage. Outpatient procedures such as endometrial biopsy or aspiration curettage can be used but are definitive only when positive.

Between 75 and 80% of all endometrial carcinomas are adenocarcinomas, and the prognosis depends upon stage, histologic grade, and extent of myometrial invasion. Grade I tumors are highly differentiated adenocarcinomas, grade II contain some solid areas, and grade III tumors are largely solid or undifferentiated. Adenocarcinoma with squamous differentiation is seen in 10% of patients; the most differentiated form is known as *adenoacanthoma*, and the poorly differentiated form is called *adenosquamous carcinoma*. Other less common pathologies include mucinous carcinoma (5%) and papillary serous carcinoma (<10%). This latter type has a natural history similar to ovarian carcinoma and should be managed as an ovarian cancer. Rarer histologies include secretory (2%), ciliated, clear cell, and undifferentiated carcinomas.

The staging of endometrial cancer requires surgery to establish the extent of disease and the depth of myometrial invasion. Peritoneal fluid should be sampled; the abdomen and pelvis explored; and pelvic and para-aortic lymphadenectomy performed depending

upon the histology, grade, and depth of invasion in the uterine specimen on frozen section. After evaluation and staging, 74% of patients are stage I, 13% are stage II, 9% are stage III, and 3% are stage IV. Five-year survival by stage is as follows: stage I -- 89%, stage II -- 80%, stage III -- 30%, and stage IV -- 9% (Table 97-1).

Patients with uncomplicated endometrial carcinoma are effectively managed with total abdominal hysterectomy and bilateral salpingo-oophorectomy. Pre- or postoperative irradiation has been used, and although vaginal cuff recurrence is reduced, survival is not altered. In women with poor histologic grade, deep myometrial invasion, or extensive involvement of the lower uterine segment or cervix, intracavitary or external beam irradiation is warranted.

About 15% of women have endometrial carcinoma with extension to the cervix only (stage II), and management depends upon the extent of cervical invasion. Superficial cervical invasion can be managed like stage I disease, but extensive cervical invasion requires radical hysterectomy or preoperative radiotherapy followed by extrafascial hysterectomy. Once disease is outside the uterus but still confined to the true pelvis (stage III), management generally includes surgery and irradiation. Patients who have involvement only of the ovary or fallopian tubes generally do well with such therapy (5-year survivals of 80%). Other stage III patients with disease extending beyond the adnexa or those with serous carcinomas of the endometrium have a significantly poorer prognosis (5-year survival of 15%).

Patients with stage IV disease (outside the abdomen or invading the bladder or rectum) are treated palliatively with irradiation, surgery, and/or progestational agents. Progestational agents produce responses in about 25% of patients. Well-differentiated tumors respond most frequently, and response can be correlated with the level of progesterone receptor expression in the tumor. The commonly used progestational agents hydroxyprogesterone (Dilalutin), megastrol (Megace), and deoxyprogesterone (Provera) all produce similar response rates, and the antiestrogen tamoxifen (Nolvadex) produces responses in 10 to 25% of patients in a salvage setting.

Chemotherapy is not very successful in advanced endometrial carcinoma. The most active single agents with consistent response rates of ^{3}20% include cisplatin, carboplatin, doxorubicin, epirubicin, and paclitaxel. Combinations of drugs with or without progestational agents have generally produced response rates similar to single agents.

CERVIX CANCER

Carcinoma of the cervix was once the most common cause of cancer death in women, but over the past 30 years, the mortality rate has decreased by 50% due to widespread screening with the Pap smear. Cervix cancer trails breast, lung, colorectal, endometrium, and ovarian cancers in incidence. In 2000, ~12,800 new cases of invasive cervix cancer occurred, and >50,000 cases of carcinoma in situ were detected. There were 4600 deaths from the disease, and of those patients, ~85% had never had a Pap smear. It remains the major gynecologic cancer in underdeveloped countries. It is more common in lower socioeconomic groups, in women with early initial sexual activity and/or multiple sexual partners, and in smokers. Venereal transmission of human

papilloma virus (HPV) has an important etiologic role. Over 66 types of HPVs have been isolated, and many are associated with genital warts. Those types associated with cervical carcinoma are 16, 18, 31, 45, and 51 to 53. These, along with many other types, are also associated with cervical intraepithelial neoplasia (CIN). The protein product of HPV-16, the E7 protein, binds and inactivates the tumor suppressor gene Rb, and the E6 protein of HPV-18 has sequence homology to the SV40 large T antigen and has the capacity to bind and inactivate the tumor suppressor gene p53. E6 and E7 are both necessary and sufficient to cause cell transformation in vitro. These binding and inactivation events may explain the carcinogenic effects of the viruses (Chap. 188).

UncomplicatedHPVlower genital tract infection and condylomatous atypia of the cervix can progress toCIN. This lesion precedes invasive cervical carcinoma and is classified as low-grade squamous intraepithelial lesion (SIL), high-grade SIL, and carcinoma in situ. Carcinoma in situ demonstrates cytologic evidence of neoplasia without invasion through the basement membrane, can persist unchanged for 10 to 20 years, but eventually progresses to invasive carcinoma.

The Pap smear is 90 to 95% accurate in detecting early lesions such asCIN but is less sensitive in detecting cancer when frankly invasive cancer or fungating masses are present. Inflammation, necrosis, and hemorrhage may produce false-positive smears, and colposcopic-directed biopsy is required when any lesion is visible on the cervix, regardless of Pap smear findings. The American Cancer Society recommends that women after onset of sexual activity, or>age 20, have two consecutive yearly smears. If negative, smears should be repeated every 3 years. The American College of Obstetrics and Gynecology recommends yearly Pap smears with routine annual pelvic and breast examinations. The Pap smear can be reported as normal (includes benign, reactive or reparative changes); atypical squamous cells of undetermined significance (ASCUS); low- or high-grade CIN; or frankly malignant. Women with ASCUS or low-grade CIN should have repeat smears in 3 to 6 months and be tested forHPV. Women with high-grade CIN or frankly malignant Pap smears should have colposcopic-directed cervical biopsy. Colposcopy is a technique using a binocular microscope and 3% acetic acid applied to the cervix in which abnormal areas appear white and can be biopsied directly. Cone biopsy is still required when endocervical tumor is suspected, colposcopy is inadequate, the biopsy shows microinvasive carcinoma, or when a discrepancy is noted between the Pap smear and the colposcopic findings. Cone biopsy alone is therapeutic for CIN in many patients, although a less radical electrocautery excision may be sufficient.

Approximately 80% of invasive cervix carcinomas are squamous cell tumors, 10 to 15% are adenocarcinomas, 2 to 5% are adenosquamous with epithelial and glandular structures, and 1 to 2% are clear cell mesonephric tumors.

Patients with cervix cancer generally present with abnormal bleeding or postcoital spotting that may increase to intermenstrual or prominent menstrual bleeding. Yellowish vaginal discharge, lumbosacral back pain, and urinary symptoms can also be seen.

The staging of cervical carcinoma is clinical and generally completed with a pelvic examination under anesthesia with cystoscopy and proctoscopy. Chest x-rays, intravenous pyelograms, and computed tomography are generally required, and

magnetic resonance imaging (MRI) may be used to assess extracervical extension. Stage 0 is carcinoma in situ, stage I is disease confined to the cervix, stage II disease invades beyond the cervix but not to the pelvic wall or lower third of the vagina, stage III disease extends to the pelvic wall or lower third of the vagina or causes hydronephrosis, stage IV is present when the tumor invades the mucosa of bladder or rectum or extends beyond the true pelvis. Five-year survivals are as follows: stage I -- 85%, stage II -- 60%, stage III -- 33%, and stage IV -- 7% (Table 97-1).

Carcinoma in situ (stage 0) can be managed successfully by cone biopsy or by abdominal hysterectomy. For stage I disease, results appear equivalent for either radical hysterectomy or radiation therapy. Patients with stages II to IV disease are primarily managed with radical radiation therapy or combined modality therapy. Retroperitoneal lymphadenectomy has no proven therapeutic role. Pelvic exenterations, although uncommon, are performed for centrally recurrent or persistent disease. Advances have been made in the reconstruction of the vagina, bladder, and rectum following this operation.

In women with locally advanced disease (stages IIB to IVA), platinum-based chemotherapy given concomitantly with radiation therapy improves survival compared to radiation therapy alone. Cisplatin, 75 mg/m$_2$over 4 h, followed by 5-fluorouracil (5-FU) 4 g given by 96-h infusion on days 1 to 5 of radiation therapy, is a common regimen. Two additional cycles of chemotherapy are given at 3-week intervals. Concurrent chemoradiotherapy reduced the risk of recurrence by 30 to 50% across wide spectrum of stages and presentations and is the treatment of choice in stages IIB to IV cervix cancer.

Chemotherapy has been used in patients with unresectable advanced disease or recurrent disease. Active agents with^{3}20% response rates include cisplatin,5-FU, ifosfamide, and irinotecan. No combination of agents has proved better than single agents. Intraarterial chemotherapy has been studied, either pre-or postoperatively, but is associated with substantial local toxicity and response rates of 20%.

GESTATIONAL TROPHOBLASTIC NEOPLASIA

Gestational choriocarcinoma accounts for <1% of female gynecologic malignancies and can be cured with appropriate chemotherapy. Deaths from this disease have become rare in the United States. The spectrum of disease ranges from benign hydatidiform mole to trophoblastic malignancy (placental-site trophoblastic tumor and choriocarcinoma).

Epidemiology In the United States, the incidence is about 1 per 1000 pregnancies; in Asia, 2 per 1000 pregnancies. Maternal age >45 years is a risk factor for hydatidiform mole. A prior history of molar pregnancy is also a risk factor. Choriocarcinoma occurs approximately once in 25,000 pregnancies or once in 20,000 live births. Prior history of hydatidiform mole is a risk factor for choriocarcinoma. A woman with a molar pregnancy is 1000 times more likely to develop choriocarcinoma than a woman with a prior normal-term pregnancy.

Pathology and Etiology The trophoblastic neoplasms have been divided by

morphology into complete or partial hydatidiform mole, invasive mole, placental-site trophoblastomas, and choriocarcinomas. Hydatidiform moles contain clusters of villi with hydropic changes, hyperplasia of the trophoblast, and the absence of fetal vessels. Invasive moles differ only by invasion into the uterine myometrium. Placental-site trophoblastic tumors are predominately made up of cytotrophoblast cells arising from the placental implantation site. Choriocarcinomas consist of anaplastic trophoblastic tissue with both cytotrophoblastic and syncytiotrophoblastic elements and no identifiable villi.

Complete moles result from uniparental disomy in which loss of the maternal genes (23 autosomes plus X) occurs by unknown mechanisms and is followed by duplication of the paternal haploid genome (23 autosomes plus X). Uncommonly (5%), moles result from dispermic fertilization of an empty egg, resulting in either 46XY or 46XX genotype. Partial moles result from dispermic fertilization of an egg with retention of the maternal haploid set of chromosomes, resulting in diandric triploidy (Chap. 65).

Clinical Presentation Molar pregnancies are generally associated with first-trimester bleeding, ectopic pregnancies, or threatened abortions. The uterus is inappropriately large for the length of gestation, andb-hCGlevels are higher than expected. Fetal parts and heart sounds are not present. The diagnosis is generally made by the passage of grapelike clusters from the uterus, but ultrasound demonstration of the hydropic mole can be diagnostic. Patients suspected of a molar pregnancy require a chest film, careful pelvic examinations, and weekly serial monitoring of b-hCG levels.

TREATMENT

Patients with hydatidiform moles require surgical evacuation coupled with postevacuation monitoring ofb-hCGlevels. In most women (80%), the b-hCG titer progressively declines within 8 to 10 days of evacuation (serum half-life is 24 to 36 h). Patients should be monitored on a monthly basis and should not become pregnant for at least a year. Patients found to have invasive mole at curettage are generally treated with hysterectomy and chemotherapy. Approximately half of patients with choriocarcinoma develop the malignancy after a molar pregnancy, and the other half develop the malignancy after abortion, ectopic pregnancy, or occasionally after a normal full-term pregnancy.

Chemotherapy is generally used for gestational trophoblastic neoplasia and is often used in hydatidiform mole ifb-hCGlevels rise or plateau or if metastases develop. Patients with invasive mole or choriocarcinoma require chemotherapy. Several regimens are effective, including methotrexate at 30 mg/m^{2}intramuscularly on a weekly basis until b-hCG titers are normal. However, methotrexate (1 mg/kg) every other day for 4 days followed by leukovorin (0.1 mg/kg) intravenously 24 h after methotrexate is associated with a cure rate of ^{3}90% and low toxicity. Intermittent courses are continued until the b-hCG titer becomes undetectable for 3 consecutive weeks, and then patients are monitored monthly for a year.

Patients with high-risk tumors (highb-hCGlevels, disease presenting ^{3}4 months after antecedent pregnancy, brain or liver metastasis, or failure of single-agent methotrexate) are initially treated with combination chemotherapy. MAC chemotherapy with

methotrexate, actinomycin-D, and cyclophosphamide has been the most commonly used regimen, with cycles of therapy given every 3 weeks until complete remission. Other effective regimens include EMA-CO (a cyclic non-cross-resistant combination of etoposide, methotrexate, and dactinomycin alternating with cyclophosphamide and vincristine); cisplatin, bleomycin, and vinblastine; and cisplatin, etoposide, and bleomycin. EMA-CO is now the regimen of choice for patients with high-risk disease because of excellent survival rates (>80%) and less toxicity than MAC. The use of etoposide carries a 1.5% lifetime risk of acute myeloid leukemia (16-fold relative risk). Because of this problem, etoposide-containing regimens should be reserved for patients with high risk features. Patients with brain or liver metastasis are usually treated with local irradiation to metastatic sites in conjunction with chemotherapy. Long-term studies of patients cured of trophoblastic disease have not demonstrated an increased risk of maternal complications or fetal abnormalities with subsequent pregnancies.

98. SOFT TISSUE AND BONE SARCOMAS AND BONE METASTASES -

Shreyaskumar R. Patel*, *Robert S. Benjamin

Sarcomas are rare (less than 1% of all malignancies) mesenchymal neoplasms that arise in bone and soft tissues. These tumors are usually of mesodermal origin, although a few are derived from neuroectoderm, and they are biologically distinct from the more common epithelial malignancies. Sarcomas affect all age groups; 15% are found in children younger than age 15, and 40% occur after age 55. Sarcomas are one of the most common solid tumors of childhood and are the fifth most common cause of cancer deaths in children. Sarcomas may be divided into two groups, those derived from bone and those derived from soft tissues.

SOFT TISSUE SARCOMAS

Soft tissues include muscles, tendons, fat, fibrous tissue, synovial tissue, vessels, and nerves. Approximately 60% of soft tissue sarcomas arise in the extremities, with the lower extremities involved three times as often as the upper extremities. Thirty percent arise in the trunk, the retroperitoneum accounting for 40% of all trunk lesions. The remaining 10% arise in the head and neck.

INCIDENCE

Approximately 7800 new cases of soft tissue sarcomas occurred in the United States in 1999. The annual age-adjusted incidence is approximately 2 per 100,000 population, but the incidence varies with age. Soft tissue sarcomas constitute 0.7% of all cancers in the general population and 6.5% of all cancers in children.

EPIDEMIOLOGY

Malignant transformation of a benign soft tissue tumor is extremely rare, with the exception that malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannoma) can arise from neurofibromas in patients with neurofibromatosis. Several etiologic factors have been implicated in soft tissue sarcomas.

Environmental Factors Trauma or previous injury is rarely involved, but sarcomas can arise in scar tissue resulting from a prior operation, burn, fracture, or foreign body implantation. Chemical carcinogens such as polycyclic hydrocarbons, asbestos, and dioxin may be involved in the pathogenesis.

Iatrogenic Factors Sarcomas in bone or soft tissues occur in patients who are treated with radiation therapy. The tumor nearly always arises in the irradiated field. The risk increases with time.

Viruses Kaposi's sarcoma (KS) in patients with HIV type 1, classic KS, and KS in HIV-negative homosexual men is caused by human herpes virus (HHV8) (Chap. 185). No other sarcomas are associated with viruses.

Immunologic Factors Congenital or acquired immunodeficiency, including therapeutic immunosuppression, increases risk of sarcoma.

Genetic Factors Li-Fraumeni syndrome is a familial cancer syndrome in which affected individuals have germ-line abnormalities of the tumor suppressor gene *p53* and an increased incidence of soft tissue sarcomas and other malignancies, including breast cancer, osteosarcoma, brain tumor, leukemia, and adrenal carcinoma (Chap. 81). Neurofibromatosis 1 (NF-1, peripheral form, von Recklinghausen's disease) is characterized by multiple neurofibromas and cafe au lait spots. Neurofibromas occasionally undergo malignant degeneration to become malignant peripheral nerve sheath tumors. The gene for NF-1 is located in the pericentromeric region of chromosome 17 and encodes neurofibromin, a tumor suppressor protein with GTPase-activating activity that inhibits Ras function (Chap. 370). Germ-line mutation of the *Rb-1* locus (chromosome 13q14) in patients with inherited retinoblastoma is associated with the development of osteosarcoma in those who survive the retinoblastoma and of soft tissue sarcomas unrelated to radiation therapy. Other soft tissue tumors, including desmoid tumors, lipomas, leiomyomas, neuroblastomas, and paragangliomas, occasionally show a familial predisposition.

Ninety percent of synovial sarcomas contain a characteristic chromosomal translocation t(X;18) (p11;q11) involving a nuclear transcription factor on chromosome 18 called *SYT* and two breakpoints on X. Patients with translocations to the second X breakpoint (*SSX2*) may have longer survival than those with translocations involving *SSX1*.

Insulin-like growth factor (IGF) type 2 is produced by some sarcomas and may act as an autocrine growth factor and as a motility factor that promotes metastatic spread. IGF-2 stimulates growth through IGF-1 receptors but its effects on motility are through different receptors. If secreted in large amounts, IGF-2 may produce hypoglycemia (Chaps. 100 and334).

CLASSIFICATION

Approximately 20 different groups of sarcomas are recognized on the basis of the pattern of differentiation toward normal tissue. For example, rhabdomyosarcoma shows evidence of skeletal muscle fibers with cross-striations; leiomyosarcomas contain interlacing fascicles of spindle cells resembling smooth muscle; and liposarcomas contain adipocytes. When precise characterization of the group is not possible, the tumors are called *unclassified sarcomas*. All of the primary bone sarcomas also can arise from soft tissues (e.g., extraskeletal osteosarcoma). The entity *malignant fibrous histiocytoma* includes many tumors previously classified as fibrosarcomas or as pleomorphic variants of other sarcomas and is characterized by a mixture of spindle (fibrous) cells and round (histiocytic) cells arranged in a storiform pattern with frequent giant cells and areas of pleomorphism.

For purposes of treatment, most soft tissue sarcomas can be considered together. However, some specific tumors have distinct features. For example, *liposarcoma* can have a spectrum of behaviors. Pleomorphic liposarcomas and dedifferentiated liposarcomas behave like other high-grade sarcomas; in contrast, well-differentiated liposarcomas (better termed *atypical lipomatous tumors*) lack metastatic potential, and myxoid liposarcomas metastasize infrequently but, when they do, have a predilection for unusual metastatic sites containing fat, such as the retroperitoneum, mediastinum, and

subcutaneous tissue. Rhabdomyosarcomas, Ewing's sarcoma, and other small cell sarcomas tend to be more aggressive, and are more responsive to chemotherapy than other soft tissue sarcomas.

DIAGNOSIS

The most common presentation is an asymptomatic mass. Mechanical symptoms referable to pressure, traction, or entrapment of nerves or muscles may be present. All new and persistent or growing masses should be biopsied, either by a cutting needle (core-needle biopsy) or by a small incision, placed so that it can be encompassed in the subsequent excision without compromising a definitive resection. Sarcomas tend to metastasize through the blood rather than the lymphatic system; lymph node metastases occur in 5%, except in synovial and epithelioid sarcomas, clear-cell sarcoma (melanoma of the soft parts), angiosarcoma, and rhabdomyosarcoma where nodal spread may be seen in 17%. The pulmonary parenchyma is the most common site of metastases. Exceptions are leiomyosarcomas arising in the gastrointestinal tract, which metastasize to the liver; myxoid liposarcomas, which seek fatty tissue: and clear-cell sarcomas, which may metastasize to bones. Central nervous system metastases are rare, except in alveolar soft part sarcoma.

Radiographic Evaluation Imaging of the primary tumor is best with plain radiographs and magnetic resonance imaging (MRI) for tumors of the extremities or head and neck and by computed tomography (CT) for tumors of the chest, abdomen, or retroperitoneal cavity. A radiograph and CT scan of the chest are important for the detection of lung metastases. Other imaging studies may be indicated, depending on the symptoms, signs, or histology.

STAGING AND PROGNOSIS

The histologic grade, relationship to fascial planes, and size of the primary tumor are the most important prognostic factors. The newly revised American Joint Commission on Cancer (AJCC) staging system is shown in Table 98-1. Prognosis is related to the stage. Cure is common in the absence of metastatic disease, but a small number of patients with metastases can also be cured. Most patients with stage IV disease die within 6 to 12 months, but some patients may live with slowly progressive disease for many years.

TREATMENT

AJCC stage I patients are adequately treated with surgery alone. Stage II patients require adjuvant radiation therapy. Stage III patients require adjuvant chemotherapy. Stage IV patients are managed primarily with chemotherapy with or without other modalities.

Surgery Soft tissue sarcomas tend to grow along fascial planes, with the surrounding soft tissues compressed to form a pseudocapsule that gives the sarcoma the appearance of a well-encapsulated lesion. This is invariably deceptive, because "shelling out" or marginal excision of such lesions results in a 50 to 90% probability of local recurrence. Wide excision with a negative margin, incorporating the biopsy site, is the standard surgical procedure for local disease. The adjuvant use of radiation therapy

and/or chemotherapy improves the local control rate and permits the use of limb-sparing surgery with a local control rate (85 to 90%) comparable to that achieved by radical excisions and amputations. Limb-sparing approaches are indicated except when negative margins are not obtainable, when the risks of radiation are prohibitive, or when neurovascular structures are involved so that resection will result in serious functional consequences to the limb.

Radiation Therapy External beam radiation therapy is an adjuvant to limb-sparing surgery for improved local control. Preoperative radiation therapy allows the use of smaller fields and smaller doses but results in a higher rate of wound complications. Postoperative radiation therapy must be given to larger fields, as the entire surgical bed must be encompassed, and in higher doses to compensate for hypoxia in the operated field. Brachytherapy or interstitial therapy, in which the radiation source is inserted into the tumor bed, is comparable in efficacy (except in low grade lesions), less time consuming, and less expensive.

Adjuvant Chemotherapy Chemotherapy is the mainstay of treatment for Ewing's/peripheral neuroepithelial tumors (PNET) and rhabdomyosarcomas. Meta-analysis of 14 randomized trials revealed a highly significant improvement in local control and disease-free survival in favor of doxorubicin-based chemotherapy. Overall survival is improved only for extremity sarcomas, however. An alternative approach is to treat such patients preoperatively with chemotherapy (neoadjuvant therapy); the subset of patients who respond continue adjuvant therapy postoperatively, and the nonresponders can be spared the toxicity of systemic therapy to which they are unlikely to respond. Neither strategy has been proved superior.

Advanced Disease Metastatic soft tissue sarcomas are largely incurable, but up to 20% of patients who achieve a complete response become long-term survivors. The therapeutic intent, therefore, is to produce a complete remission with chemotherapy and/or surgery. Surgical resection of metastases, whenever possible, is an integral part of the management. Some patients benefit from repeated surgical excision of metastases. Despite their histologic heterogeneity, the sensitivity to chemotherapy of most soft tissue sarcomas is poor. The two most active chemotherapeutic agents are doxorubicin and ifosfamide. There is a steep dose-response relationship for these drugs in sarcomas. Dacarbazine (DTIC) in combination with doxorubicin may be more active than the single agents. Vincristine, etoposide, and dactinomycin are effective in Ewing's sarcoma and rhabdomyosarcoma, especially in children. Chondrosarcomas and leiomyosarcomas arising from the gastrointestinal tract are unresponsive to standard chemotherapeutic drugs.

BONE SARCOMAS

INCIDENCE AND EPIDEMIOLOGY

Bone sarcomas are rarer than soft tissue sarcomas; they accounted for only 0.2% of all new malignancies and approximately 2500 new cases in the United States in 1999. Several benign bone lesions have the potential for malignant transformation. Enchondromas and osteochondromas can transform into chondrosarcoma; fibrous dysplasia, bone infarcts, and Paget's disease of bone can transform into either

malignant fibrous histiocytoma or osteosarcoma.

CLASSIFICATION

Benign Tumors The common benign bone tumors include enchondroma, osteochondroma, chondroblastoma, and chondromyxoid fibroma, of cartilage origin; osteoid osteoma and osteoblastoma, of bone origin; fibroma and desmoplastic fibroma, of fibrous tissue origin; hemangioma, of vascular origin; and giant cell tumor, of unknown origin.

Malignant Tumors The most common malignant tumors of bone are plasma cell tumors (Chap. 113). The four most common malignant nonhematopoietic bone tumors are osteosarcoma, chondrosarcoma, Ewing's sarcoma, and malignant fibrous histiocytoma. Rare malignant tumors include chordoma (of notochordal origin), malignant giant cell tumor and adamantinoma (of unknown origin), and hemangioendothelioma (of vascular origin).

Musculoskeletal Tumor Society Staging System Sarcomas of bone are staged according to the Musculoskeletal Tumor Society staging system based on grade and compartmental localization. A Roman numeral reflects the tumor grade: stage I is low-grade, stage II is high-grade, and stage III includes tumors of any grade that have lymph node or distant metastases. In addition, the tumor is given a letter reflecting its compartmental localization. Tumors designated A are intracompartmental (i.e., confined to the same soft tissue compartment as the initial tumor), and tumors designated B are extracompartmental (i.e., extending into the adjacent soft tissue compartment or into bone).

OSTEOSARCOMA

Osteosarcoma, accounting for almost 45% of all bone sarcomas, is a spindle cell neoplasm that produces osteoid (unmineralized bone) or bone. About 60% of all osteosarcomas occur in children and adolescents in the second decade of life, and about 10% occur in the third decade of life. Osteosarcomas in the fifth and sixth decades of life are frequently secondary to either radiation therapy or transformation in a preexisting benign condition, such as Paget's disease. Males are affected 1.5 to 2 times as often as females. Osteosarcoma has a predilection for metaphyses of long bones; the most common sites of involvement are the distal femur, proximal tibia, and proximal humerus. The classification of osteosarcoma is complex, but 75% of osteosarcomas fall in the "classic" category, which include osteoblastic, chondroblastic, and fibroblastic osteosarcomas. The remaining 25% are classified as "variants" on the basis of (1) clinical characteristics, as in the case of osteosarcoma of the jaw, postradiation osteosarcoma, or Paget's osteosarcoma; (2) morphologic characteristics, as in the case of telangiectatic osteosarcoma, small cell osteosarcoma, or epithelioid osteosarcoma; or (3) location, as in parosteal or periosteal osteosarcoma. Diagnosis usually requires a synthesis of clinical, radiologic, and pathologic features. Patients typically present with pain and swelling of the affected area. A plain radiograph reveals a destructive lesion with a moth-eaten appearance, a spiculated periosteal reaction (sunburst appearance), and a cuff of periosteal new bone formation at the margin of the soft tissue mass (Codman's triangle). ACT scan of the primary tumor is best for defining

bone destruction and the pattern of calcification, whereasMRI is better for defining intramedullary and soft tissue extension. A chest radiograph and CT scan are used to detect lung metastases. Metastases to the bony skeleton should be imaged by a bone scan. Almost all osteosarcomas are hypervascular. Angiography is not helpful for diagnosis, but it is the most sensitive test for assessing the response to preoperative chemotherapy. Pathologic diagnosis is established either with a core-needle biopsy, where feasible, or with an open biopsy with an appropriately placed incision that does not compromise future limb-sparing resection. Most osteosarcomas are high-grade. The most important prognostic factor for long-term survival is response to chemotherapy. Preoperative chemotherapy followed by limb-sparing surgery (which can be accomplished in >80% of patients) followed by postoperative chemotherapy is standard management. The effective drugs are doxorubicin, ifosfamide, cisplatin, and high-dose methotrexate with leucovorin rescue. The various combinations of these agents that have been used have all been about equally successful. Long-term survival rates in extremity osteosarcoma range from 60 to 80%. Osteosarcoma is radioresistant; radiation therapy has no role in the routine management. Malignant fibrous histiocytoma is considered a part of the spectrum of osteosarcoma and is managed similarly.

CHONDROSARCOMA

Chondrosarcoma, which constitutes approximately 20 to 25% of all bone sarcomas, is a tumor of adulthood and old age with a peak incidence in the fourth to sixth decades of life. It has a predilection for the flat bones, especially the shoulder and pelvic girdles, but can also affect the diaphyseal portions of long bones. Chondrosarcomas can arise de novo or as a malignant transformation of an enchondroma or, rarely, of the cartilaginous cap of an osteochondroma. Chondrosarcomas have an indolent natural history and typically present as pain and swelling. Radiographically, the lesion may have a lobular appearance with mottled or punctate or annular calcification of the cartilaginous matrix. It is difficult to distinguish low-grade chondrosarcoma from benign lesions by x-ray or histologic examination. The diagnosis is therefore influenced by clinical history and physical examination. A new onset of pain, signs of inflammation, and progressive increase in the size of the mass suggest malignancy. The histologic classification is complex, but most tumors fall within the classic category. Like other bone sarcomas, high-grade chondrosarcomas spread to the lungs. Most chondrosarcomas are resistant to chemotherapy, and surgical resection of primary or recurrent tumors, including pulmonary metastases, is the mainstay of therapy. There are two histologic variants for which this rule does not hold, however. Dedifferentiated chondrosarcoma is a low-grade tumor that dedifferentiates into a high-grade osteosarcoma or a malignant fibrous histiocytoma, a tumor that responds to chemotherapy. Mesenchymal chondrosarcoma, a rare variant composed of a small cell element, also is responsive to systemic chemotherapy and is treated like Ewing's sarcoma.

EWING'S SARCOMA

Ewing's sarcoma, which constitutes approximately 10 to 15% of all bone sarcomas, is common in adolescence and has a peak incidence in the second decade of life. It typically involves the diaphyseal region of long bones and also has an affinity for flat bones. The plain radiograph may show a characteristic "onion peel" periosteal reaction with a generous soft tissue mass, which is better demonstrated byCT orMRI. This mass

is composed of sheets of monotonous, small, round, blue cells and can be confused with lymphoma, embryonal rhabdomyosarcoma, and small cell carcinoma. The presence of p30/32, the product of the *mic-2* gene (which maps to the pseudoautosomal region of the X and Y chromosomes) is a cell-surface marker for Ewing's sarcoma [and other members of a family of tumors called *peripheral primitive neuroectodermal tumors* (*PNETs*)]. Most PNETs arise in soft tissues; they include peripheral neuroepithelioma, Askin's tumor (chest wall), and esthesioneuroblastoma. Glycogen-filled cytoplasm detected by staining with periodic acid-Schiff is also characteristic of Ewing's sarcoma cells. The classic cytogenetic abnormality associated with this disease (and other PNETs) is a reciprocal translocation of the long arms of chromosomes 11 and 22, t(11;22), which creates a chimeric gene product of unknown function with components from the *fli-1* gene on chromosome 11 and *ews* on 22. This disease is very aggressive, and it is therefore considered a systemic disease. Common sites of metastases are lung, bones, and bone marrow. Systemic chemotherapy is the mainstay of therapy, often being used before surgery. Doxorubicin, cyclophosphamide or ifosfamide, etoposide, vincristine, and dactinomycin are active drugs. Local treatment for the primary tumor includes surgical resection, usually with limb salvage or radiation therapy. Patients with lesions below the elbow and below the mid-calf have a 5-year survival rate of 80% with effective treatment. Ewing's sarcoma is a curable tumor, even in the presence of obvious metastatic disease, especially in children less than 11 years old.

TUMORS METASTATIC TO BONE

Bone is a common site of metastasis for carcinomas of the prostate, breast, lung, kidney, bladder, and thyroid and for lymphomas and sarcomas. Prostate, breast, and lung primaries account for 80% of all bone metastases. Metastatic tumors of bone are more common than primary bone tumors. Tumors usually spread to bone hematogenously, but local invasion from soft tissue masses also occurs. In descending order of frequency, the sites most often involved are the vertebrae, proximal femur, pelvis, ribs, sternum, proximal humerus, and skull. Bone metastases may be asymptomatic or may produce pain, swelling, nerve root or spinal cord compression, pathologic fracture, or myelophthisis (replacement of the marrow). Symptoms of hypercalcemia may be noted in cases of bony destruction.

Pain is the most frequent symptom. It usually develops gradually over weeks, is usually localized, and often is more severe at night. When patients with back pain develop neurologic signs or symptoms, emergency evaluation for spinal cord compression is indicated (Chap. 102). Bone metastases exert a major adverse effect on quality of life in cancer patients.

Cancer in the bone may produce osteolysis, osteogenesis, or both. Osteolytic lesions result when the tumor produces substances that can directly elicit bone resorption (vitamin D-like steroids, prostaglandins, or parathyroid hormone-related peptide) or cytokines that can induce the formation of osteoclasts (interleukin 1 and tumor necrosis factor). Osteoblastic lesions result when the tumor produces cytokines that activate osteoblasts. In general, purely osteolytic lesions are best detected by plain radiography, but they may not be apparent until they are larger than 1 cm. These lesions are more commonly associated with hypercalcemia and with the excretion of hydroxyproline-containing peptides indicative of matrix destruction. When osteoblastic

activity is prominent, the lesions may be readily detected using radionuclide bone scanning (which is sensitive to new bone formation), and the radiographic appearance may show increased bone density or sclerosis. Osteoblastic lesions are associated with higher serum levels of alkaline phosphatase, and, if extensive, may produce hypocalcemia. Although some tumors may produce mainly osteolytic lesions (e.g., kidney cancer) and others mainly osteoblastic lesions (e.g., prostate cancer), most metastatic lesions produce both types of lesion and may go through stages where one or the other predominates.

In older patients, particularly women, it may be necessary to distinguish metastatic disease of the spine from osteoporosis. In osteoporosis, the cortical bone may be preserved, whereas cortical bone destruction is usually noted with metastatic cancer.

Treatment of metastatic bone disease depends on the underlying malignancy and the symptoms. Some metastatic bone tumors are curable (lymphoma, Hodgkin's disease), and others are treated with palliative intent. Pain may be relieved by local radiation therapy. Hormonally responsive tumors are responsive to hormone inhibition (antiandrogens for prostate cancer, antiestrogens for breast cancer). Strontium 89 and samarium 153 are bone-seeking radionuclides that can exert antitumor effects and relieve symptoms. Bisphosphonates such as pamidronate may relieve pain and inhibit bone resorption. Monthly administration prevents bone-related clinical events and may reduce the incidence of bone metastases in women with breast cancer. When the integrity of a weight-bearing bone is threatened by an expanding metastatic lesion that is refractory to radiation therapy, prophylactic internal fixation is indicated. Overall survival is related to the prognosis of the underlying tumor. Bone pain at the end of life is particularly common; an adequate pain relief regimen including sufficient amounts of narcotic analgesics is required.**The management of hypercalcemia is discussed in Chap. 341.*

99. METASTATIC CANCER OF UNKNOWN PRIMARY SITE - *Richard M. Stone*

INCIDENCE AND EPIDEMIOLOGY

The presenting findings in a patient with a newly discovered malignancy may not reveal its site of origin. Patients with cancer of unknown primary site (CUPS) present difficult diagnostic and therapeutic dilemmas. First, as additional studies may be many, costly, and/or uncomfortable for the patient, the strategy used in searching for the primary must assess what, if any, result the identification of the site of origin would have on the patient's treatment and survival. Second, while individuals with CUPS fare poorly overall (median survival is 4 to 11 months), certain subgroups of patients are more likely to benefit from treatment and, in some cases, to enjoy long disease-free survival. The literature is a poor guide for the care of such patients, owing to the heterogeneity of the tumors, the selection bias in small retrospective studies, and the variability in the definition of the syndrome and the thoroughness of the evaluation performed to identify a primary site.

No universally accepted definition of theCUPSsyndrome exists. An occult neoplasm should fulfill all of the following criteria: (1) biopsy-proven malignancy; (2) unrevealing history, physical examination, chest film, abdominal and pelvic computed tomography (CT) scans, complete blood counts, chemistry survey, mammography (women),b human chorionic gonadotropin (bhCG) levels (men), afetoprotein (AFP) levels (men), and prostate-specific antigen (PSA) levels (men); (3) histologic evaluation not consistent with a primary tumor at the biopsy site; and (4) failure of additional diagnostic studies (based only on findings from the laboratory and pathologic review) to identify the primary site. Such additional diagnostic tests could include, for example, colonoscopy in a patient whose rectal examination discloses guaiac-positive stool or a meticulous otolaryngologic examination in a patient who presents with squamous cell carcinoma in a cervical node. Many cases that fulfill the definition of CUPS offer clues that a given organ is the probable site of origin. Epidemiologic data suggest that the incidence of cancers for which the primary site is unknown is decreasing. CUPS accounts for about 2% of all cancer diagnoses -- about 24,400 cases in the year 2000. Most patients with CUPS are over age 60.

BIOLOGIC CONSIDERATIONS

The biologic behavior ofCUPS is unique. In ~25% of patients, the primary site becomes apparent during the course of the illness; in about 57% of patients, the primary site can be diagnosed at autopsy; but in almost 20%, the primary site remains obscure even at autopsy. Cancers presenting as CUPS often display unusual patterns of metastatic spread (e.g., pancreatic cancer presenting with bony metastases). The fact that more tumor bulk is present at distant sites than in the tissue of origin suggests that the genetic lesions underlying cases of CUPS produce a distinctly aggressive phenotype. Microsattelite DNA analysis has shown that the same pattern of genetic alterations that appear in a cervical lymph node metastasis can be found in seemingly morphologically normal aerodigestive tissue. Such data imply that clinically evident metastases may be able to arise from microscopic primary lesions. Although physiologic and genetic data that might account for the distinctive natural history of CUPS neoplasms are scant, cell lines derived from such tumors may have abnormalities of chromosome 1, a finding

generally associated with advanced malignancy. In some patients, the primary tumor spontaneously regresses (perhaps under immunologic attack) or necroses. In some, a primary lesion was resected years before presentation (e.g., melanoma).

CLINICAL PRESENTATION, DIAGNOSTIC EVALUATION, AND PATHOLOGY

History and Physical Examination Patients present with a variety of symptoms and signs, including fatigue, weight loss, other systemic symptoms, pain, abnormal bleeding, abdominal swelling, subcutaneous masses, and lymphadenopathy. OnceCUPS is considered, the physician's approach must involve reasonable efforts to identify the primary site or to determine the histology or subcategory of the metastatic tumor to decide on the optimal therapy. Though usually unrevealing, a thorough history and physical examination should be carried out to elicit easily obtainable clues regarding the primary site. The patient should be questioned concerning epigastric pain, which, if present, would mandate careful exclusion of pancreatic carcinoma as well as other gastrointestinal malignancies. Symptoms referable to a given location (e.g., new cough, hematochezia, hemoptysis, change in bowel habits, unusual vaginal bleeding, nipple discharge) should prompt an aggressive specific diagnostic approach. Occupational exposure to asbestos, for example, would raise the suspicion of mesothelioma. The absence of prior smoking reduces the likelihood of lung cancer but does not exclude it. A history of fulguration of a skin lesion, colonic polypectomy, dilatation and curettage, or prostate biopsy should prompt a review of the original histology.

Pathology Review The most important aspect of the workup of a patient withCUPS is the thorough evaluation of the tissue obtained at biopsy by light-microscopy, immunohistochemistry, ultrastructural studies, immunophenotyping, and karyotypic and molecular biologic analysis. First, if the original biopsy sample is inadequate for either confirmation of malignancy or the performance of additional specialized studies, rebiopsy is mandatory. The clinician must have a close working relationship with a pathologist skilled in the evaluation of tumor specimens, especially when the organ of origin is uncertain. Plans may be made to process the tissue for (1) routine light-microscopy, histochemical, and immunohistochemical analysis; (2) freezing for DNA and RNA isolation or for in situ genetic and immunologic evaluation; and (3) special fixation for ultrastructural analysis. Single-cell tumor suspensions in short-term culture permit cytogenetic analysis.

If routine histologic analysis fails to suggest the tissue of origin (e.g., gland formation in adenocarcinoma, psammoma bodies in ovarian or thyroid cancer, or spindle architecture in sarcomas), special histochemical studies may be helpful. For example, mucin positivity is helpful in recognizing a poorly differentiated adenocarcinoma. Light-microscopic analysis will show approximately 60% ofCUPStumors to be well or moderately differentiated adenocarcinomas, 30% poorly differentiated carcinomas/adenocarcinomas, and 5% poorly differentiated malignant neoplasms not further classifiable. In the poorly differentiated neoplasms, immunohistochemical, cytogenetic, and molecular biologic studies can be extremely useful in identifying sarcomas, germ cell carcinomas, lymphomas, neuroendocrine neoplasms (including melanoma), and other tumors whose diagnosis would suggest a more specific therapeutic approach.

Immunohistochemical Analysis Antibodies to specific cell components make it possible to characterize tumors that are not identified by standard techniques.Table 99-1 provides a list of antigens that may be assessed in undifferentiated or poorly differentiated specimens. A diagnosis of lymphoma should be excluded by employing antibodies reactive to the leukocyte common antigen (LCA, CD45). LCA-positive tumors are lymphomas and have the same chances of responding to therapy as if the diagnosis were unambiguous. About half of patients with aggressive-histology lymphoma can be cured with combination chemotherapy (Chap. 112). The immunohistochemical detection of specific types of filament proteins is helpful in the identification of carcinomas and sarcomas. The presence of keratin suggests carcinoma; all epithelial tumors contain this protein. Specific types of cytokeratins (CK) permit a firm diagnosis. For example, ovarian cancers are CK20-/CK7+, colorectal cancers are CK20+/CK7-, and pancreaticobiliary tumors are CK20+/CK7+. However, certain sarcomas, mesotheliomas, and germ cell tumors are also keratin-positive. Sarcomas may react with antibodies to desmin. Sarcoma subgroups may be identified by expression of myoglobin (rhabdomyosarcoma) or factor VIII (angiosarcoma or Kaposi's sarcoma). Prostate, breast, and thyroid carcinomas express, respectively,PSA, gross cystic fluid protein, or thyroglobulin. The finding ofAFP,bhCG, or placental alkaline phosphatase staining is very helpful in assigning a germ cell origin. The S-100 protein is present in virtually all primary and metastatic melanomas, including the amelanotic variety. However, S-100 positivity is also found in other tumors of neuroendocrine origin (e.g., small cell lung cancer, carcinoid, neuroepithelioma); a more specific marker for melanomas is the HMB45 (human melanoma black) antigen.

Other Diagnostic Approaches Electron microscopy can identify cell junctions (i.e., desmosomes, typical of epithelial cancers), neuroendocrine granules, melanosomes, and muscle filaments. Cytogenetic analysis may identify tumors with specific chromosomal translocations or other genetic abnormalities (Table 99-1). Cytogenetic abnormalities can also be determined by fluorescence in situ hybridization with chromosome-specific probes, a technique that does not require cells to divide, as is the case with traditional karyotype analysis. Fresh tissue may be required for detection of estrogen or progesterone receptors (to assess breast cancer) or antigens that are sensitive to fixation. Lineage can be assigned by analysis of DNA for signature gene rearrangements, such as those of immunoglobulin (B cell) or T cell receptor (T cell). Technological advances promise to influence the diagnosis of cancer. Isolation of mRNA from tumor specimens may permit the molecular profiling of tumors by microarray analysis of gene expression. This could lead to novel classifications of tumors based on molecular characteristics that may predict clinical behavior and/or response to specific therapies.

Additional Studies If the pathologist does not identify the likely tissue of origin, it is unlikely that additional expensive diagnostic tests will benefit the patient. In females with metastatic adenocarcinoma or poorly differentiated carcinoma, mammography should be performed, although the diagnostic yield will be quite low except in patients with axillary metastases. Magnetic resonance imaging, positron-emission tomography, or indium-111-pentreotide scanning can identify occult primary breast lesions but are expensive. The use of abdominal/pelvicCT scans leads to the identification of the primary site (often the pancreas) in up to 35% of patients but has little effect on natural history. Whether to measure serum tumor markers such asAFP,bhCG,

carcinoembryonic antigen (CEA), CA-125 (associated with ovarian cancer), andPSA is controversial; value has not been proven. Numerous studies have shown a lack of benefit of contrast studies (upper gastrointestinal series, barium enema, or intravenous pyelogram) in patients withCUPS who have no specific symptoms and no findings referable to the gastrointestinal or urinary tract. Moreover, autopsy series reveal that the most likely primary site of origin includes epithelial tissues such as lung, stomach, colon, and kidney, which give rise to tumors that respond poorly to chemotherapy, minimizing the therapeutic impact of such a diagnosis.

Additional invasive diagnostic studies are indicated if the presentation strongly suggests a particular primary site. For example, radiographic evidence of lung or mediastinal involvement would mandate fiberoptic bronchoscopy to exclude lung cancer. In the relatively unusual case of metastatic squamous cell cancer presenting in an inguinal lymph node, anoscopy and colposcopy should be performed to detect carcinoma of the vulva, cervix, vagina, penis, or anus, all of which may be cured even with lymph node spread. A summary of a reasonable diagnostic approach is found inTable 99-2.

TREATMENT

Prognostic Subgroups The exclusion of treatable and potentially curable neoplasms is important. Patients with squamous cell carcinoma have a somewhat longer median survival (9 months) than do those with adenocarcinoma or unclassifiable neoplasms (4 to 6 months). If laboratory studies indicate a significant likelihood that the neoplasm is a lymphoma, germ cell tumor, sarcoma, neuroendocrine tumor, or breast or prostate cancer, then disease-appropriate therapy should be administered. Patients with lymphoma or a germ cell neoplasm may be cured with combination chemotherapy. In other malignancies, effective palliative chemotherapy (for sarcoma or a breast or neuroendocrine tumor) or hormonal therapy (for breast or prostate cancer) should be strongly considered. Although often requiring electron microscopy for diagnosis, neuroendocrine tumors (especially if anaplastic) often respond to cisplatin-based chemotherapy.

Patients in whom the primary site can be identified fare somewhat better than those in whom it remains undefined. Classification and regression tree (CART) analysis has led to a prognostic index ranging from a median survival of 40 months (those with one or two organ sites involved; not adenocarcinoma in histology; and without adrenal, bone, liver, or pleural involvement) to a median survival of 5 months (liver metastases, nonneuroendocrine histology, age ³62). Patients may often be categorized as having one of several clinical features or syndromes suggesting a specific form of potentially beneficial therapy (Table 99-3).

Syndrome of Unrecognized Extragonadal Germ Cell Cancer A subset of patients with poorly differentiatedCUPS are responsive to chemotherapy. These patients display one or more of the following features: age <50; tumor involving midline structures, lung parenchyma, or lymph nodes; an elevated serumAFP orbhCGlevel; evidence of rapid tumor growth; or tumor responsiveness to previously administered radiotherapy or chemotherapy. Platinum-based chemotherapy has led to long-term survival in a fraction of patients with these features, especially those who have a favorable performance status at diagnosis, suggesting that their tumors behaved like germ cell neoplasms. If all

patients with poorly differentiated carcinoma (including poorly differentiated adenocarcinoma) are treated with a chemotherapy regimen designed for germ cell cancer (e.g., cisplatin plus etoposide or vinblastine, often also with bleomycin) (Chap. 96), about 25% will respond completely and 33% will have a partial response. Patients whose disease does not respond to two cycles of therapy should not continue therapy. One in six patients survives>5 years without evidence of disease. Patients with poorly differentiated carcinoma or adenocarcinoma whose tumors have abnormalities of chromosome 12 similar to those described in patients with proven germ cell cancer are more likely to respond to platinum-based chemotherapy than are patients with a similar presentation whose tumors lack this cytogenetic abnormality.

Peritoneal Carcinomatosis in Women Women who present with increased abdominal girth and a pelvic mass or pain and who are found to have adenocarcinoma throughout the peritoneal cavity without a clear site of origin also may benefit from platinum-based chemotherapy. This syndrome has been termed *primary peritoneal papillary serous carcinoma* or *multifocal extraovarian serous carcinoma*. While breast cancer or a gastrointestinal malignancy can produce these findings, peritoneal carcinomatosis is most commonly ascribed to ovarian cancer, even in patients with apparently normal ovaries at the time of laparotomy. Especially if psammoma bodies or a papillary configuration is noted in the pathology examination or if the CA-125 level is elevated, women with adenocarcinoma of the peritoneal cavity without a defined primary should receive maximum surgical cytoreduction followed by cisplatin (or carboplatin) plus paclitaxel. The stage-specific response to such therapy appears to be comparable to that for patients with proven ovarian cancer. About 10% of patients who present in this fashion may remain free of disease 2 years after diagnosis.

Carcinoma in an Axillary Lymph Node in a Female Women with adenocarcinoma or poorly differentiated carcinoma in an axillary mass should receive treatment for stage II breast cancer whether or not a careful breast examination or mammography suggests the diagnosis of primary breast cancer and whether or not estrogen or progesterone receptors are detectable in the node. Even if no lesion is found in the breast, a breast recurrence will develop in one-half of these patients if no mastectomy is performed. Modified radical mastectomy or breast irradiation reduces the risk of local recurrence. In addition, adjuvant systemic therapy (chemotherapy and/or tamoxifen, depending on menopausal and estrogen receptor status) should be given to reduce the risk of developing evident metastatic breast cancer (Chap. 89). Adjuvant systemic therapy may be administered before definitive local radiation treatment. Women with axillary metastases without an obvious breast primary appear to have the same likelihood of prolonged disease-free survival as patients with typical stage II breast cancer.

Bone Metastases in Males Particularly if the lesions are osteoblastic, the serumPSAlevel should be measured, as the probability of prostate carcinoma is high. Empirical hormonal therapy (e.g., leuprolide and flutamide) should be strongly considered.

Cervical Lymph Node Metastases Patients who present with a neck mass should be considered to have a primary tumor of the upper aerodigestive tract (*head and neck cancer*) until a different source is proven. Especially if the pathologist diagnoses squamous histology and the node is located in a high or midcervical area, a careful ear,

nose, and throat examination including direct laryngoscopy, nasopharyngoscopy, and random blind biopsies should be undertaken. A thyroid examination and scan should be performed to rule out a primary thyroid tumor, especially if the histology is not definitely squamous. Definitive local therapy (external beam radiation or radical neck dissection) combined with platinum-based chemotherapy may lead to prolonged survival in those with head and neck primaries (Chap. 87).

Adenocarcinoma and Liver Metastases Liver metastases from an adenocarcinoma is not as well characterized as a syndrome as the unrecognized germ cell cancer syndrome (nor as responsive to therapy). However, such patients may have a primary stomach, biliary, or colorectal tumor. Tumors with limited hepatic involvement may be amenable to resection. A flexible sigmoidoscopy or colonoscopy may detect a potentially obstructive colonic lesion. If a tumor is found, resection may be beneficial, depending on the tumor's size; even if none is found, treatment with a combination of 5-fluorouracil plus leucovorin is palliative for some patients with presumed metastatic gastrointestinal malignancy. Given the severe diarrhea that may be a consequence of this regimen and the relative resistance of gastrointestinal tumors to chemotherapy, patients should be informed of the risks before treatment.

Patients not falling into one of the preceding categories should be treated palliatively. In some patients, observation is appropriate. For example, individuals without evidence of additional metastatic disease who have undergone resection of a solitary pulmonary nodule containing malignant cells may actually have undergone definitive therapy for a small primary lung tumor. Radiation therapy may relieve symptoms in patients with bony pain or neurologic compromise. The largest and most poorly responsive subgroup are those with moderate to well-differentiated adenocarcinomas. Combination chemotherapy is frequently employed in such patients; however, response rates to "all-purpose" regimens [e.g., FAM (5-fluorouracil, doxorubicin, mitomycin C), FACP (5-fluorouracil, doxorubicin, cyclophosphamide, cisplatin)], or to ICE (ifosfamide, carboplatin, etoposide) are generally well under 50%, especially if patients with poorly differentiated adenocarcinoma, who have a higher response rate, are excluded; complete responses are rare. Regimens containing mitomycin C are associated with the risk of hemolytic uremic syndrome. In some series, patients with a good performance status whose disease is limited to soft tissue sites or extends only above the diaphragm have shown a better rate of response to therapy. While patients whose disease responds to treatment seem to have better survival than those whose disease does not respond, the difference may be related to inherent characteristics of the tumor rather than to a beneficial effect of chemotherapy.

Before combination chemotherapy is attempted in a patient withCUPS, the potential benefits must be weighed carefully against the certainty of toxicity. While some randomized studies have reported a benefit of one form of therapy over another, these reports are generally plagued by small numbers of patients and inadequate control of potential prognostic variables. Depending on motivation, eligibility, and availability, patients with CUPS may be candidates for evaluation of new (phase I) therapies.

100. PARANEOPLASTIC SYNDROMES - *Bruce E. Johnson*

ENDOCRINE SYNDROMES

Paraneoplastic syndromes are caused by factors produced by cancer cells that often act at a distance from both the primary cancer site and its metastases. The accurate documentation of a paraneoplastic endocrine syndrome requires (1) demonstration of mRNA expression and protein production by the tumor tissue, (2) biochemical and clinical resolution of the syndrome following successful surgical resection, (3) elevated levels of the hormone in the peripheral blood, (4) a tenfold or greater concentration gradient in the blood before and after it passes through the cancer, and (5) normal or suppressed endogenous hormone production.

The three major classes of hormones are steroids, monoamines, and peptides/proteins. Production of steroid hormones by malignant tumors is rare; lymphomas may produce 1,25-dihydroxyvitamin D from circulating 1-hydroxyvitamin D, but most other steroid-producing tumors are benign tumors of the glands that normally secrete the steroid. Monoamines such as norepinephrine and epinephrine are secreted by pheochromocytomas (Chap. 332), but they are not secreted ectopically by malignant tumor cells.

Most hormonal syndromes in patients with cancer are related to the production of peptide or protein hormones. The most common of these endocrine syndromes are listed inTable 100-1, together with the protein hormones that mediate them and the tumors that most commonly produce the hormones. A peptide hormone generally is encoded by an mRNA that is translated into a larger prohormone molecule, which undergoes a number of posttranslational modifications, including cleavage, glycosylation, and/or other steps. For example, pro-opiomelanocortin can be cleaved to yield adrenocorticotropic hormone (ACTH), lipotropin, endorphin, melanocyte-stimulating hormone, and/or enkephalin, with different cell types producing different products. In addition, some cells use alternatively spliced forms of the message to produce different proteins (e.g., calcitonin vs. calcitonin gene-related peptide).

Tumor cells of nonendocrine organs often lack certain components of the pathway that leads from prohormone to biologically active hormone to secreted product. Generally, as a result of defects in protein processing or post-translational changes, tumor cells may produce proteins that are structurally related to but biologically less active than the normal hormones. Thus, cancer patients may have elevated levels of immunoreactive hormones in plasma in the absence of clinical syndromes of hormone excess.

The severity of paraneoplastic endocrine syndromes often parallels the clinical course of the cancer. However, with some benign or slowly growing tumors, the hormone syndrome can be the major cause of morbidity. Despite their production by tumor cells, hormones are not very good tumor markers. Human chorionic gonadotropin (hCG) is a reliable tumor marker in some forms of testicular cancer, but no other hormone is used to quantitate tumor mass.

Most endocrine cancer syndromes occur with tumors derived from neuroendocrine or neural crest tissue (small cell lung cancer, carcinoid tumors). The genetic mechanisms

that account for the production of a hormone by a cell that does not usually produce it are not clear. Oncogenes may activate other cellular genes (including genes that encode hormones) that normally are silent. Alternatively, demethylation of normally methylated inactive genes may permit expression in rapidly dividing cells.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia of malignancy, the most common paraneoplastic endocrine syndrome, is responsible for approximately 40% of all hypercalcemia (Chap. 341). Hypercalcemia with cancer is classified as humoral hypercalcemia of malignancy (HHM), which is caused by circulating hormones, or local osteolytic hypercalcemia (LOH), which is caused by local paracrine factors secreted by cancers within bone. Parathyroid hormone-related peptide (PTHrP) causes nearly all cases of HHM, while the mediators of LOH in bone are heterogeneous.

Pathogenesis Eighty percent of patients with hypercalcemia of malignancy haveHHM.PTHrP is composed of 139 to 173 amino acids; 8 of the first 13 amino acids at the amino-terminal end are identical to the amino-terminal portion of parathyroid hormone (PTH). PTHrP binds to PTH receptors in the bone and kidney and causes increased bone resorption, decreased bone formation, increased renal tubular reabsorption of calcium, increased phosphaturia, and increased urinary levels of cyclic adenosine monophosphate, leading to hypercalcemia. PTHrP is detected in the plasma in ~80% of cancer patients with hypercalcemia. Rare patients have been reported to have hypercalcemia caused by ectopically produced authentic PTH. HHM in lymphoma may be caused by the production of 1,25-dihydroxyvitamin D by the tumor.

Twenty percent of patients with hypercalcemia haveLOH, in which hypercalcemia is caused by the local production of hormones or cytokines by cancers that have spread to the bone or bone marrow; such factors increase bone resorption in the area around the cancer. The ectopically produced hormones that may play a role in LOH include transforming growth factorsa and b, interleukin (IL)-1, IL-6, prostaglandins, and tumor necrosis factor.

Clinical Manifestations The initial symptoms and signs of hypercalcemia (calcium level[3] 2.6 mmol/L)

[1]Calcium measurements given in millimoles per liter can be multiplied by 4 to convert to milligrams per deciliter or by 2 to convert to milliequivalents per liter. include malaise, fatigue, confusion, anorexia, bone pain, polyuria, polydipsia, weakness, constipation, nausea, and vomiting. Neurologic symptoms and signs in profound hypercalcemia (>3.5 mmol/L) include confusion, lethargy, coma, and death. The cancers associated withHHM are non-small cell lung cancer and cancers of the breast, kidney, head and neck, and bladder. HHM is particularly common in patients with cancers of squamous cell histology. Hypercalcemia is uncommon at presentation (<1% of patients) but becomes more common as the cancer progresses and is present in 10 to 20% of patients near the time of death.LOH is responsible for hypercalcemia in patients with breast cancer, myeloma, lymphoma, and leukemia. Among hypercalcemic patients with breast cancer, approximately half have HHM and half have LOH.

Diagnosis The patient with cancer who develops hypercalcemia should be evaluated for other causes of hypercalcemia, including use of thiazide diuretics, vitamin D, or lithium, hyperthyroidism, and sarcoidosis. If the underlying cancer is controlled, elevation of serumPTH as measured by immunoassay suggests primary hyperparathyroidism, which may be responsible for as many as 10% of cases of hypercalcemia of cancer and which should be treated like other cases of hyperparathyroidism (Chap. 341). A normal PTH level and a low serum phosphorus level in the absence of bone metastases support the diagnosis ofHHM, while a normalPTHrPlevel and normal phosphorus in a patient with bone metastases suggestLOH.

TREATMENT

The median survival of patients with hypercalcemia of malignancy is only 1 to 3 months. Intervention to reverse hypercalcemia should be undertaken when the cancer is likely to be controlled with appropriate systemic or local treatment.

The treatment ofHHM andLOH is similar (Chap. 341). Patients with mild to moderate hypercalcemia (2.7 to 3.5 mmol/L) can be treated with 2 to 4 L of saline hydration per day and furosemide to prevent intravascular volume overload. The bisphosphonate pamidronate (90 mg intravenously) decreases osteoclastic bone resorption. Combined administration of diuretics and pamidronate reduces the serum calcium to normal values in 90% of patients within 7 days. Doses may be repeated as needed. In patients with LOH, glucocorticoids may inhibit the production of cytokines that promote bone resorption. Severe hypercalcemia [>3.50 mmol/L (>14 mg/dL)] with alteration of mental status can be treated with all of the above plus salmon calcitonin, 4 to 8 U/kg, administered intramuscularly or subcutaneously every 12 h. Calcitonin administration will decrease the serum calcium within 24 h, and its hypocalcemic effect can be prolonged in patients with LOH by adding glucocorticoids. If these agents are not effective in reducing the serum calcium, plicamycin and gallium nitrate may be added.

HYPONATREMIA OF MALIGNANCY

Hyponatremia of malignancy (Na^+ level<130 mmol/L) is usually due to the inappropriate secretion of arginine vasopressin (AVP) and is termed the *syndrome of inappropriate antidiuretic hormone secretion* (SIADH). In rare cases, atrial natriuretic peptide produces hyponatremia.

Pathogenesis Small cell lung cancer is the malignancy chiefly responsible for producing ectopicAVP. AVP mRNA is expressed and translated, and the product is processed into the nonapeptide AVP, which is secreted into the circulation. The ectopically produced AVP binds to receptors in the kidney, causing retention of free water with resulting hypoosmolality in the plasma and hyperosmolality in urine (Chap. 329).

About 15% of cancer patients withSIADH do not have evidence of ectopic production ofAVP. In some of these patients, tumors secrete atrial natriuretic peptide. This hormone inhibits sodium reabsorption in the proximal tubule and inhibits release of renin and aldosterone. How atrial natriuretic peptide leads to hyponatremia is not clear.

Clinical Manifestations SIADH is commonly recognized as asymptomatic hyponatremia on routine serum chemistry examination. It is present at the time of diagnosis in 15% of patients with small cell lung cancer, 3% of patients with head and neck cancer, and<1% of patients with non-small cell lung cancer. Hyponatremia may also occur with primary brain tumors, hematologic malignancies, melanoma, sarcoma, and gynecologic, gastrointestinal, breast, prostate, and bladder cancers. The symptoms of mild hyponatremia (>120 mmol/L) include difficulty focusing attention, fatigue, nausea, vomiting, anorexia, weakness, and headache. Profound hyponatremia (<120 mmol/L) can cause confusion, lethargy, coma, seizures, and death.

Diagnosis (See also Chap. 329) SIADH is suspected in patients with hyponatremia (serum sodium<130 mmol/L) and a concentrated urine (osmolality>300 mosm/kg). Patients are euvolemic, are not using diuretics, and have normal thyroid and adrenal function. Polydipsia is excluded by the urine osmolality. Pseudohyponatremia can be present if serum glucose, triglyceride, or protein levels are high. Conditions other than cancer that can cause SIADH include central nervous system disorders, pulmonary infections, positive-pressure breathing, pneumothorax, asthma, and a wide array of drugs, including chemotherapeutic agents (vincristine, vinblastine, cisplatin, cyclophosphamide, melphalan), thiazide diuretics, carbamazepine, antidepressants, nicotine, and narcotics.

TREATMENT

Treatment should be directed at the underlying cancer. Patients whose tumors have not been or cannot be controlled are candidates for restriction of fluid intake to 500 mL/d. Such restriction corrects hyponatremia within 7 days in most patients, but it is difficult and uncomfortable for patients to maintain fluid restriction for extended periods. Oral demeclocycline (600 to 1200 mg/d) may be useful in blocking the effects of AVP but can cause renal insufficiency. Other agents that may be used for the treatment of hyponatremia include dilantin and lithium.

Rare patients develop profound hyponatremia and altered mental status. These patients should be treated with normal saline hydration and furosemide diuresis. If that is not effective, 3% saline can be administered via a central line together with furosemide diuresis to prevent hypervolemia. Hypertonic saline is rarely required and must be given slowly; fluid balance and electrolytes should be monitored several times per day, and the increase in sodium should be limited to 0.5 mmol/L per hour to prevent pontine lysis (Chap. 329).

ECTOPIC ACTH SYNDROME

Ectopic production of ACTH by cancer cells is responsible for ~15% of all cases of Cushing's syndrome and for most cases of Cushing's syndrome that occur in cancer patients (Chaps. 328,331). In rare patients, Cushing's syndrome is caused by ectopically produced corticotropin-releasing hormone (CRH), which stimulates pituitary ACTH release.

Pathogenesis When pro-opiomelanocortin mRNA is expressed in cancer cells, the

241-amino-acid prohormone is translated and processed into a variety of molecules, including, in some cases, the 39-amino-acid hormoneACTH, which can be secreted into the circulation. The ectopically produced ACTH causes excessive secretion of glucocorticoids and mineralocorticoids by the adrenals.

Clinical Manifestations Women make up 50% of patients with ectopicACTHsyndrome and 90% of patients with pituitary Cushing's disease. Therefore, Cushing's syndrome in men is more likely to be caused by ectopic ACTH than by a pituitary tumor. Because of mineralocorticoid excess, patients with ectopic Cushing's syndrome usually have hypokalemic alkalosis at presentation, a rare finding in patients with Cushing's disease. Other common manifestations of ectopic ACTH syndrome include weakness, hypertension, and hyperglycemia. Ectopic ACTH syndrome in patients with slow-growing cancers (e.g., carcinoids) may develop typical features of central obesity, moon facies, hyperpigmentation, and hirsutism in addition to the metabolic abnormalities.

EctopicACTHsyndrome is most commonly due to small cell lung cancer (50% of cases), bronchial carcinoid tumors (10%), thymic carcinoid tumors or thymomas (10%), pancreatic islet cell tumors (10%), pheochromocytoma or other neural crest tumors (5%), or medullary carcinoma of the thyroid (5%). About 2% of patients with small cell lung cancer and bronchial carcinoids have ectopic ACTH syndrome at the time of diagnosis. Patients with small cell lung cancer and ectopic ACTH syndrome have shorter survival rates than patients without the syndrome and are more likely to develop opportunistic infections.

Diagnosis (See alsoChaps. 328,331) EctopicACTHsyndrome is usually characterized by elevated levels of urinary free cortisol that do not decrease after administration of high doses of dexamethasone (8 mg/d). However, in 20 to 30% of patients with ectopic ACTH syndrome, urinary cortisol levels decrease by >50% after administration of high-dose dexamethasone. The plasma levels of ACTH are markedly elevated in more than half of patients. If these tests do not provide definitive evidence of ectopic ACTH syndrome, bilateral inferior petrosal vein sampling will show an elevated ACTH level in petrosal vein blood that does not increase after administration ofCRH.

TREATMENT

Treatment of the ectopicACTHsyndrome should be directed at the underlying cancer: chemotherapy for small cell lung cancer; surgical resection or radiation therapy for carcinoids. Some patients with ectopic Cushing's syndrome have no evidence of tumor after extensive evaluation. These patients should be treated symptomatically and followed closely with periodic imaging studies, because they may have slow-growing tumors amenable to surgical resection.

Agents that inhibit steroidogenesis in the adrenal gland include ketoconazole (400 to 1200 mg/d), which reduces urinary cortisol excretion by more than half in two-thirds of patients, and metyrapone (1 to 4 g/d), which also reduces urinary cortisol excretion. Patients who are in good condition and whose manifestations are not controlled by drugs may be considered for adrenalectomy.

ECTOPIC ACROMEGALY

Ectopic production of growth hormone-releasing hormone (GHRH) is the predominant cause of ectopic acromegaly (Chap. 328).

PathogenesisGHRH is processed into 40- and 44-amino-acid peptides and binds to receptors in the pituitary, increasing production of growth hormone that increases insulin-like growth factor (IGF)-1 production in peripheral tissues. Rare cases of ectopic acromegaly are due to ectopic production of growth hormone itself by tumors.

Clinical Manifestations The symptoms and signs of ectopic acromegaly develop over several years and include increasing glove and shoe size, facial disfigurement, arthralgias, amenorrhea-galactorrhea or impotence, hypertension, muscle weakness, and diabetes mellitus. Ectopic acromegaly has been reported in fewer than 100 patients and accounts for 1% or less of all cases of acromegaly. The cancers associated with ectopic acromegaly include carcinoid tumors of the bronchus, pancreatic islet cell tumors, and cancers of the lung, breast, colon, and adrenal glands.

Diagnosis If a clinical diagnosis of acromegaly is suspected in a patient with cancer, the serum levels of GHRHandIGF-1 and the glucose-suppressed growth hormone (GH) serum level should be measured (Chap. 328). Patients with elevated GHRH levels and acromegaly have ectopic acromegaly. Patients without evidence of cancer who have elevated GHRH levels should undergo imaging of the central nervous system, chest, and abdomen to look for an occult cancer. Patients with cancer, low GHRH levels, high GH levels, and elevated IGF-1 levels should undergo magnetic resonance imaging of the pituitary and hypothalamus. If no pituitary tumor is detected, GH may be secreted directly by the known tumor. Not all GH -secreting tumors of the pituitary are demonstrable by imaging techniques, however.

TREATMENT

The therapy of ectopic acromegaly should be directed at the underlying cancer and should consist of surgical resection or radiation therapy for patients with carcinoid and islet cell tumors. Medical control of ectopic acromegaly is obtained by using octreotide (100 to 250 ug every 8 h), which inhibits pituitary secretion of growth hormone. Octreotide produces symptomatic improvement in approximately two-thirds of patients.

GYNECOMASTIA

Ectopic production ofhCG or estrogens by tumors such as cancers of the lung and testis is responsible for approximately 3% of cases of gynecomastia detected in men (Chap. 337). Ectopic production of hCG is the most common cause of paraneoplastic gynecomastia; the hCG acts by stimulating the Leydig cells of the testis to produce increased amounts of estrogen. Alternatively, on rare occasions, a tumor (such as a hepatoma or a germ cell tumor with choriocarcinoma elements) contains aromatase enzyme activity that converts circulating androgens to estrogen. Leydig cell or Sertoli cell tumors may also secrete estradiol. In all cases, the increased ratio of estrogen to testosterone leads to the proliferation of breast tissue and gynecomastia. Other tumors rarely associated with ectopic gynecomastia include carcinoid tumors of the bronchus,

intestine, and small cell lung cancer.

About 5% of men with testicular choriocarcinoma present with an enlarging breast mass. In the absence of an obvious cancer, men presenting with gynecomastia should have a careful examination of the testes and measurement of serumhCG. Patients with a testicular mass should undergo an inguinal orchiectomy for diagnosis and treatment. If no testicular mass is found by physical examination, the testes should be examined with ultrasound. Patients with an elevated hCG level and no testicular mass should undergo evaluation for an extragonadal germ cell tumor.

TREATMENT

The therapy of tumor-associated gynecomastia should be directed at the underlying cancer: chemotherapy is used for testicular cancers, and surgical resection or radiation therapy for carcinoids and islet cell tumors. In patients with successfully treated testicular cancer, gynecomastia completely resolves in three-fourths of cases.

NON-ISLET CELL TUMOR HYPOGLYCEMIA

Hypoglycemia that is not caused by the ectopic production of insulin (as in patients with islet cell tumors of the pancreas) can occur with large, slow-growing sarcomas, mesotheliomas, and hepatomas (Chap. 334). Ectopic production ofIGF-2 is responsible for hypoglycemia in most patients with non-islet cell tumors. The ectopically produced IGF-2 inhibits glycogenolysis and gluconeogenesis in the liver, suppresses lipolysis, and increases peripheral glucose utilization, thereby causing hypoglycemia. IGF-2 may also act as an autocrine growth factor for the tumor.

Patients with large sarcomas (1 to 10 kg) may develop hypoglycemia, particularly with fasting. Headache, fatigue, confusion, or seizures may occur. Patients with a large sarcoma and hypoglycemia are likely to have non-islet cell tumor hypoglycemia. AlthoughIGF-2 protein or mRNA is detectable in tumor tissue, the diagnosis is usually made on clinical grounds, because the plasma levels of IGF-2 are typically not elevated. Levels of IGF binding proteins may be increased.

TREATMENT

The therapy of non-islet cell hypoglycemia should be directed at the underlying cancer: surgical resection or radiation therapy. Patients whose tumors cannot be successfully resected or irradiated can be treated with frequent oral feedings or constant intravenous administration of glucose.

HEMATOLOGIC SYNDROMES

The elevation of granulocyte, platelet, and eosinophil counts in most patients with myeloproliferative disorders is caused by the proliferation of the myeloid elements due to the underlying disease rather than a paraneoplastic syndrome. The paraneoplastic hematologic syndromes in patients with solid tumors are less well characterized than the endocrine syndromes, because the ectopic hormone(s) or cytokines responsible have not been identified in most of these tumors (Table 100-2). The severity of the

paraneoplastic syndromes parallels the course of the cancer.

ERYTHROCYTOSIS

Ectopic production of erythropoietin by cancer cells causes most paraneoplastic erythrocytosis. The ectopically produced erythropoietin stimulates the production of red blood cells in the bone marrow and raises the hematocrit. Other lymphokines and hormones produced by cancer cells may stimulate erythropoietin release but have not been proven to cause erythrocytosis.

Most patients with erythrocytosis have an elevated hematocrit (>52% in men; >48% in women) that is detected on a routine blood count. Approximately 3% of patients with renal cell cancer, 10% of patients with hepatoma, and 15% of patients with cerebellar hemangioblastomas have erythrocytosis. In most cases the erythrocytosis is asymptomatic.

Patients with erythrocytosis due to a renal cell cancer, hepatoma, or central nervous system cancer should have measurement of red cell mass. If the red cell mass is elevated, the serum erythropoietin level should then be measured. Patients with an appropriate cancer, elevated erythropoietin levels, and no other explanation for erythrocytosis (e.g., a hemoglobinopathy that causes increased O_2affinity, Chap. 106) have the paraneoplastic syndrome.

TREATMENT

Successful resection of the cancer usually resolves the erythrocytosis. If the tumor neither can be resected nor treated effectively with radiation therapy or chemotherapy, phlebotomy may control any symptoms related to erythrocytosis.

GRANULOCYTOSIS

Approximately 30% of patients with solid tumors have granulocytosis (granulocyte count>8000/uL). In about half of patients with granulocytosis and cancer, the granulocytosis has an identifiable nonparaneoplastic etiology (infection, tumor necrosis, glucocorticoid administration, etc.). The other patients have proteins in urine and serum that stimulate the growth of bone marrow cells. Tumors and tumor cell lines from patients with lung, ovarian, and bladder cancers have been documented to produce granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and/orIL-6. However, the etiology of granulocytosis has not been characterized in most patients.

Patients with granulocytosis are nearly all asymptomatic, and the differential white blood cell count does not have a shift to immature forms of neutrophils. Granulocytosis occurs in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast cancer, 30% of patients with brain tumors and ovarian cancers, and 10% of patients with renal cell carcinoma. Patients with advanced-stage disease are more likely to have granulocytosis than those with early-stage disease.

Paraneoplastic granulocytosis does not require treatment. The granulocytosis resolves

when the underlying cancer is successfully treated.

THROMBOCYTOSIS

Thirty-five percent of patients with thrombocytosis (platelet count>400,000/uL) have an underlying diagnosis of cancer.IL-6, a candidate molecule for the etiology of paraneoplastic thrombocytosis, stimulates the production of platelets in vitro and in vivo. Some patients with cancer and thrombocytosis have elevated levels of IL-6 in plasma. Another candidate molecule is thrombopoietin, a peptide hormone that stimulates megakaryocyte proliferation and platelet production. The etiology of thrombocytosis has not been established in most cases.

Patients with thrombocytosis are nearly all asymptomatic. Thrombocytosis is not clearly linked to thrombosis in patients with cancer. Thrombocytosis is present in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast, endometrial, and ovarian cancers, and 10% of patients with lymphoma. Patients with thrombocytosis are more likely to have advanced-stage disease and have a poorer prognosis than patients without thrombocytosis. Paraneoplastic thrombocytosis does not require treatment.

EOSINOPHILIA

Eosinophilia is present in ~1% of patients with cancer. Tumors and tumor cell lines from patients with lymphomas or leukemia may produceIL-5, which stimulates eosinophil growth. Activation of IL-5 transcription in lymphomas and leukemias may involve translocation of the long arm of chromosome 5, to which the genes for IL-5 and other cytokines map.

Patients with eosinophilia are typically asymptomatic. Eosinophilia is present in 10% of patients with lymphoma, 3% of patients with lung cancer, and occasional patients with cervical, gastrointestinal, renal, and breast cancer. Patients with markedly elevated eosinophil counts (>5000/uL) can develop shortness of breath and wheezing. A chest radiograph may reveal diffuse pulmonary infiltrates from eosinophil infiltration and activation in the lungs.

TREATMENT

Definitive treatment is directed at the underlying malignancy: tumors should be resected or treated with radiation or chemotherapy. In most patients who develop shortness of breath related to eosinophilia, symptoms resolve with the use of oral or inhaled glucocorticoids.

THROMBOPHLEBITIS

Deep venous thrombosis and pulmonary embolism are the most common thrombotic conditions in patients with cancer. Migratory or recurrent thrombophlebitis may be the initial manifestation of cancer. Approximately 15% of patients who develop deep venous thrombosis or pulmonary embolism have a diagnosis of cancer (Chap. 117). The coexistence of peripheral venous thrombosis with visceral carcinoma, particularly

pancreatic cancer, is called *Trousseau's syndrome*.

Pathogenesis Patients with cancer are predisposed to thromboembolism because they are often at bedrest or immobilized, and tumors may obstruct or slow blood flow. In addition, clotting may be promoted by release of procoagulants or cytokines from tumor cells or associated inflammatory cells, or by platelet adhesion or aggregation. The specific molecules that mediate the increased risk of thromboembolism have not been identified.

Clinical Manifestations Patients with cancer who develop deep venous thrombosis usually develop swelling or pain in the leg, and physical examination reveals tenderness, warmth, and redness. Patients who present with pulmonary embolism develop dyspnea, chest pain, and syncope, and physical examination shows tachycardia, cyanosis, and hypotension. Approximately 5% of patients with no history of cancer who have a diagnosis of deep venous thrombosis or pulmonary embolism will have a diagnosis of cancer within 1 year. The most common cancers associated with thromboembolic episodes include lung, pancreatic, gastrointestinal, breast, ovarian, and genitourinary cancers, lymphomas, and brain tumors. Patients with cancer who undergo surgical procedures requiring general anesthesia have a 20 to 30% risk of deep venous thrombosis.

Diagnosis The diagnosis of deep venous thrombosis in patients with cancer is made by impedance plethysmography or bilateral compression ultrasonography of the leg veins. Patients with a noncompressible venous segment have deep venous thrombosis. If compression ultrasonography is normal and a high clinical suspicion exists for deep venous thrombosis, venography should be done to look for a luminal filling defect. Elevation of D-dimer is not as predictive of deep venous thrombosis in patients with cancer as in patients without cancer.

Patients with symptoms and signs suggesting a pulmonary embolism should be evaluated with a chest radiograph, electrocardiogram, arterial blood gas analysis, and ventilation-perfusion scan. Patients with mismatched segmental perfusion defects have a pulmonary embolus. Patients with equivocal ventilation-perfusion findings should be evaluated as described above for deep venous thrombosis in their legs. If deep venous thrombosis is detected, they should be anticoagulated. If deep venous thrombosis is not detected, they should be considered for a pulmonary angiogram.

Patients without a diagnosis of cancer who present with an initial episode of thrombophlebitis or pulmonary embolus need no additional tests for cancer other than a careful history and physical exam. In light of the many possible primary sites, diagnostic testing in asymptomatic patients is wasteful. However, if the clot is refractory to standard treatment or is in an unusual site, or if the thrombophlebitis is migratory or recurrent, efforts to find an underlying cancer are indicated.

TREATMENT

Patients with cancer and a diagnosis of deep venous thrombosis or pulmonary embolism should be treated initially with intravenous unfractionated heparin or low molecular weight heparin for at least 5 days and coumadin started within 1 or 2 days.

The coumadin dose should be adjusted so the INR is 2 to 3. Patients with proximal deep venous thrombosis and a relative contraindication to heparin anticoagulation (hemorrhagic brain metastases or pericardial effusion) should be considered for placement of a filter in the inferior vena cava (Greenfield filter) to prevent pulmonary embolism. Coumadin should be administered for 3 to 6 months. Patients with cancer who undergo a major surgical procedure should be considered for heparin prophylaxis or pneumatic boots. Breast cancer patients undergoing chemotherapy and patients with implanted catheters should be considered for prophylaxis (1 mg coumadin per day).*Cutaneous paraneoplastic syndromes are discussed in Chap. 57. Neurologic paraneoplastic syndromes are discussed in Chap. 101. More extensive discussion of functional endocrine tumors is given in Chap. 93.*

(Bibliography omitted in Palm version)

101. PARANEOPLASTIC NEUROLOGIC SYNDROMES - *Muhammad T. Al-Lozi*, *Alan Pestronk*

GENERAL PRINCIPLES

A paraneoplastic neurologic syndrome (PNNS) is a neurologic disorder that is associated with a neoplasm but lies anatomically remote from it. Paraneoplastic disorders are caused by immune or other mechanisms and are not due to direct effects of the tumor itself, metastases, opportunistic infections, complications of drug or radiation therapy, or malnutrition. Clinical features of a PNNS are often distinctive. Onset can be dramatic, arising subacutely over weeks or even days to produce neurologic symptoms that may be profoundly disabling.

PNNSassociated with autoantibodies can be grouped into (1) disorders in which the neoplasm contains a surface antigen or intracellular protein that is the antigenic target, and (2) monoclonal gammopathy syndromes associated with secretion of an antibody by the neoplasm. Each subgroup has typical clinical, pathologic, and immune characteristics (Table 101-1). Some PNNS, including lymphoma-associated motor neuropathy, subacute necrotic myopathy, dermatomyositis, and necrotizing myopathy, have no currently identified antibody or target antigen and are not yet classifiable in this scheme.

The temporal relationship of aPNNS to the associated neoplasm is variable. The PNNS may precede or follow the identification of a neoplasm by weeks, months, or occasionally years. The strength of the association between neoplasms and PNNS varies with different syndromes, different neoplasms, and the clinical context. In some PNNS, such as the sensory neuronopathy associated with anti-Hu antibodies, the association with neoplasm is very strong. By contrast, the Lambert-Eaton myasthenic syndrome (LEMS) is associated with neoplasm in approximately 50% of cases only; the relationship is probably stronger in older individuals who have a history of cigarette smoking. Disorders that are clinically identical to most PNNS also occur in the absence of cancer. Nonetheless, the development of a PNNS in a previously healthy individual should in most circumstances prompt a thorough search for its associated neoplasms.

PNNS-associated neoplasms vary considerably in terms of malignancy. Tumors associated with subacute necrotic myelopathy are often severe and unresponsive to therapy. In other syndromes, the tumor either remains small or can be effectively treated; in such cases, the long-term prognosis is determined by the effectiveness of management of the paraneoplastic syndrome. Thymoma associated with myasthenia gravis is an example of a tumor in this category. In some PNNS, such as those associated with small cell lung cancer (SCLC) and anti-Hu antibodies, it has been suggested that the presence of the autoantibodies may confer a more favorable prognosis by inhibiting tumor growth.

As outlined inTable 101-2, certain syndromes are associated with particular types of tumors, and more than one syndrome may occur with a given neoplasm. For example,SCLCsare associated with a variety ofPNNS, including limbic encephalitis, cerebellar ataxia, opsoclonus-myoclonus, necrotic myelopathy, sensory neuronopathy, autonomic neuropathy, andLEMS.

Prevalence estimates vary with the particular syndrome. Tumors that are most often associated withPNNS are cancers of the lung, stomach, breast, ovary, and colon. Some 30% of patients with thymoma also develop myasthenia gravis as a paraneoplastic syndrome. A poorly characterized neuromyopathy with proximal weakness and distal sensory loss is very common in patients who have lost more than 15% of their body weight. In contrast, most of the well-defined PNNS are rare, with estimated prevalence rates of <1% of the population with cancer.

The diagnosis of aPNNSdepends primarily on (1) the presence of a recognized clinical paraneoplastic syndrome; (2) careful exclusion of other cancer-related disorders; and (3) appropriate confirmatory studies, including measurement of specific antibodies and neurophysiologic studies to define the anatomic distribution of the disease process.

PNNS OF THE CENTRAL NERVOUS SYSTEM

LIMBIC ENCEPHALITIS

Limbic encephalitis is a feature of several paraneoplastic syndromes. It occurs in isolation or overlaps with syndromes that also involve the brainstem, cerebellum, spinal cord, and posterior root ganglia. Patients present with seizures, confusion, psychiatric symptoms (agitation, hallucinations, depression, anxiety, and changes in personality), or severe short-term memory loss. Seizures are commonly complex-partial in type, with or without secondary generalization, and may be intractable and refractory to treatment. Other features can include vertigo, ataxia, nystagmus, numbness/paresthesias, and symmetric or asymmetric weakness. Limbic encephalitis typically progresses over a period of weeks before stabilizing. Exacerbations may occur, and remissions are rare, with or without treatment. The onset of symptoms may precede or follow the discovery of tumor. Limbic encephalitis is most commonly associated withSCLC; less frequently with testicular cancer; and occasionally with thymoma, Hodgkin's disease, non-SCLC, breast, colon, and bladder cancer. Some cases are not associated with cancer.

Magnetic resonance imaging (MRI) suggests that paraneoplastic limbic encephalitis is often a relatively widespread disease of the central nervous system. The T2 signal may be increased not only in the temporal lobes but also in the cortex or brainstem. Approximately 75% of patients show electroencephalographic abnormalities that may include focal slowing and/or paroxysmal sharp waves and spikes. Cerebrospinal fluid (CSF) often shows elevated protein, mild mononuclear pleocytosis, oligoclonal bands, or increased IgG synthesis but may be normal.

Neuropathologic features of limbic encephalitis include neuronal loss in the hippocampus, cingulate gyrus, orbital frontal lobe, brainstem, and posterior root ganglia. Additionally, there may be scattered gliosis, microglial nodules, and/or perivascular lymphocytic cuffing.

Anti-Hu antibodies (Table 101-2) are detected in the serum andCSF in the majority of patients with paraneoplastic limbic encephalitis. Most patients with anti-Hu antibodies haveSCLC; however, breast and prostate cancer and neuroblastoma are also described. Approximately 20% of patients with SCLC without neurologic symptoms have

low titers of anti-Hu antibodies. Anti-Hu antibodies are strongly (>90%) associated with neoplasms; patients with positive antibody titers but a negative initial malignancy workup should have a search for neoplasm repeated every 6 to 12 months. Immunotherapy [plasma exchange, intravenous immunoglobulin (IVIg), cyclophosphamide, or glucocorticoids] and/or resection of primary tumor are only rarely associated with improvement in the limbic encephalitis.

Patients with limbic and/or brainstem encephalitis and testicular cancer may have serum IgG antibodies that bind to Ma2, a 40-kD cytoplasmic and nuclear protein. Ma2 is expressed in both brain tissue and testicular tumors. Occasional patients in this subgroup have improved after treatment of the primary neoplasm.

BRAINSTEM ENCEPHALITIS

Paraneoplastic brainstem encephalitis is usually associated with disease elsewhere in the central or peripheral nervous system. Symptoms of brainstem encephalitis relate to the distribution of the disease process. The predominant symptoms are due to medullary involvement producing nausea, vomiting, nystagmus, vertigo, and ataxia. A rare syndrome of marked dysarthria and dysphagia is associated with pontine involvement. Mesencephalic inflammation and neuronal loss result in nuclear or internuclear eye movement abnormalities; diplopia and oscillopsia may be disabling. Rostral midbrain and nigral involvement may cause rigidity. Other rare disorders are deafness and hypoventilation.

PARANEOPLASTIC CEREBELLAR DEGENERATION (PCD)

Approximately 90% of PCD occurs withSCLC, Hodgkin's lymphoma, or breast or ovarian cancer. Patients usually present with the subacute onset of a pancerebellar disorder consisting of nystagmus, oculomotor ataxia, dysarthric speech, and limb and gait ataxia (Chaps. 22 and364). In many patients, especially those with the anti-Yo antibody syndrome, signs are restricted to cerebellar dysfunction. However, symptoms of more widespread central (lethargy, cognitive abnormalities) and peripheral (weakness, sensory changes, and dry mouth) nervous system involvement may be present. Symptoms usually progress over weeks and eventually stabilize, leaving the patient severely disabled.

MRIusually reveals cerebellar atrophy. TheCSF may be normal or show mildly elevated protein, mononuclear pleocytosis, increased IgG index, and/or oligoclonal bands. The most consistent neuropathologic feature is a diffuse loss of Purkinje cells. Neuronal loss in the granular cell layer and deep cerebellar nuclei may also occur. Perivascular cuffing has been observed in the cerebellum and leptomeninges.

PCDmay be associated with polyclonal IgG anti-Yo, anti-Tr, or anti-glutamate receptor (mGluR1) antibodies in the serum andCSF. Anti-Yo antibodies are commonly associated with breast or ovarian cancer. The Yo autoantigens are proteins that are prominently expressed in Purkinje cell cytoplasm (Golgi) and proximal dendrites but not in the nucleus. Anti-Tr and anti-mGluR1 antibodies occur with Hodgkin's lymphoma. Clinical features in the three antibody groups are similar. PCD syndromes rarely improve after treatment; however, occasional anti-Tr patients improve after treatment of

Hodgkin's lymphoma. Reappearance or exacerbation of the PCD may indicate recurrence of the tumor.

PARANEOPLASTIC OPSOCLONUS-MYOCLONUS (POM)

This disorder is also known as the "dancing eyes-dancing feet" syndrome. Opsoclonic eye movements are involuntary, high-amplitude, arrhythmic, multidirectional, conjugate saccades. They are often nearly continuous and persist with the eyes closed and during sleep. Opsoclonus is associated with blinking and myoclonus and increases with visual pursuit and voluntary ocular refixation. The syndrome may occur in isolation or as a component of otherPNNS, including limbic or brainstem encephalitis. POM occurs in 2% of young children with neuroblastoma and may precede or follow the discovery of the neoplasm; 50% of children with POM harbor neuroblastoma. Patients may also manifest ataxia, irritability, and vomiting. Antibodies directed against neurofilaments have been described. In the pediatric population, POM may improve following treatment with adrenocorticotropic hormone (ACTH), glucocorticoids, orIVIg, but residual central nervous system signs are frequent.

In adults, opsoclonus/myoclonus syndromes may develop in association with neoplasms of the lung (anti-Hu antibodies), breast (anti-Ri antibodies), thymus, lymphoid cells, ovaries, uterus, and bladder. Anti-Ri antibodies bind to neuronal nuclear antigens, including NOVA-1, a protein that regulates RNA splicing or metabolism in a subset of developing neurons. Remissions may occur spontaneously or following treatment of the underlying tumor. Clonazepam and/or valproate may be useful for symptomatic control of opsoclonus and myoclonus.

CARCINOMA-ASSOCIATED RETINOPATHY (CAR)

The chief complaint in CAR is unilateral or bilateral, symmetric or asymmetric, loss of vision. Night blindness may be the presenting symptom. The visual loss occurs either gradually or in a stepwise pattern over weeks to months. Other symptoms may include visual shimmering, sparkling, or distortions. Examination shows poor visual acuity, impaired color vision, and an afferent pupillary defect. Visual field defects most commonly consist of central and/or ring scotomas. CAR occurs mainly withSCLC(90%) but may also occur with melanoma and gynecologic neoplasms. CAR visual loss frequently precedes the discovery of SCLC. CAR associated with melanoma usually follows the discovery of cancer, with an interval of up to 10 years. Histologically, there is severe loss of the inner and outer segments of the rods and cones, with widespread degeneration of the outer nuclear layer. The electroretinogram is usually flat due to loss of the rod and cone cells. Polyclonal IgG antibodies in SCLC/CAR are directed against recoverin, a 23-kD retinal photoreceptor-specific calcium-binding protein. Other autoantigens include retinal enolase, the S-antigen, and tubby-like protein 1 (TULP1) which is a molecule expressed in synaptic terminals of photoreceptor cells. Treatment with glucocorticoids (prednisone) produces mild to moderate improvement in most patients.

PARANEOPLASTIC MYELOPATHY

Paraneoplastic myelopathy is a rare disorder that presents as acute spinal shock

manifest as flaccid paraparesis with a sensory level and sphincter disturbances (Chap. 368). Spinal cord dysfunction is rapidly progressive and ascending. The prognosis is poor. TheCSF is often cellular with a high protein.MRI may show T2 signal changes in the spinal cord, with cord swelling and involvement of both white and gray matter structures. The onset of the syndrome may precede or follow detection of a neoplasm, typically lymphoma, leukemia, or lung cancer.

STIFF-PERSON SYNDROME (SPS)

SPS is characterized by stiffness and painful spasms, especially in axial and proximal limb muscles, due to hyperexcitability of motor neurons (Chap. 22). The stiffness produces lumbar hyperlordosis. Muscle spasms are triggered by stretching, emotion, and sensory stimulation. A small minority of SPS occurs in association with neoplasms such as breast cancer,SCLC, thymoma, Hodgkin's disease, and colon cancer. IgG polyclonal antibodies directed against amphiphysin, a 125-kD synaptic vesicle-associated protein, have been detected in sera of some SPS patients, primarily those with breast cancer. Some patients respond to glucocorticoids or tumor resection. Treatment with diazepam, clonazepam, lioresal, or sodium valproate may produce symptomatic improvement.

PNNS OF THE NEUROMUSCULAR SYSTEM

Paraneoplastic neuromuscular syndromes may selectively involve nerve cell bodies (anterior horn or dorsal root ganglia), peripheral nerves (myelin or motor, sensory, or autonomic axons), the neuromuscular junction, or muscle. Some neuromuscularPNNS, including sensory neuronopathy with anti-Hu antibodies, are almost always associated with cancer. Other syndromes, such as myasthenia gravis, are statistically associated with neoplasms but in up to 90% of patients a neoplasm is never found. Some neuromuscular PNNS have protean clinical manifestations that are not distinctive; correct diagnosis may rely upon serologic testing for specific autoantibodies (Tables 101-2 and101-3).

NEURONOPATHIES

Neuronopathies, indicating damage to the cell body of the neuron, are typically asymmetric and produce proximal as well as distal involvement early in their clinical course. They are generally poorly responsive to treatment.

Subacute sensory neuronopathy (SSN) presents with numbness and pain that evolves in a progressive fashion over 1 to 8 weeks. A history of smoking is found in >95% of patients. Examination shows asymmetric sensory loss that may involve the face and trunk and proximal as well as distal regions of the upper and lower extremities. All sensory modalities are affected. Patients may become disabled by severe sensory ataxia and pseudoathetosis resulting from the deafferentation. Strength is usually normal. Tendon reflexes are diffusely diminished or absent. Nerve conduction studies show diminished or absent sensory responses with normal motor studies. SSN may occur in isolation but is often associated with central nervous system signs, ranging from mild nystagmus to severe encephalopathy.CSFcommonly shows a mild pleocytosis and elevated protein levels. Serum IgG antibodies that bind to the Hu family

of 35- to 40-kDa nuclear proteins are characteristic of SSN and are a useful diagnostic test. Hu proteins are neuron-specific but are also found inSCLCcells. Although anti-Hu antibodies have strong specificity for SSN and otherPNNS, there is no evidence that the antibodies play a pathogenic role. Morphologically there is neuronal loss with perivascular inflammatory infiltrates in the dorsal root ganglia. SSN with anti-Hu antibodies is almost always associated with a neoplasm, especially SCLC, but neoplasm is found at initial evaluation in only 50% of patients. As noted above, the presence of anti-Hu antibodies is associated with a lower degree of malignancy of the SCLC, suggesting that the antibodies may inhibit tumor growth. The differential diagnosis of SSN includes Sjogren's syndrome and drug toxicity from cisplatin or pyridoxine. Treatment consists of therapy for the associated neoplasm. There is almost never improvement in the SSN itself; however, physical therapy may allow the patient, over time, to partially compensate for the sensory loss.

Motor neuronopathy is a rare syndrome that begins subacutely and then reaches a plateau. Patients have asymmetric weakness that may involve the arms more than the legs. The bulbar muscles are spared. Sensation is normal. Motor neuronopathy often manifests after the detection of a neoplasm, typically lymphoma.CSFshows elevated protein levels and oligoclonal bands in 60% of cases.

PERIPHERAL NEUROPATHY

These disorders typically present with distal symptoms and signs in the limbs. They may be axonal, demyelinating, or a combination of the two types. The presence of circulating paraproteins or serologic markers often helps to define paraneoplastic neuropathy syndromes (Table 101-2).

Polyneuropathies associated with circulating paraproteins include: (1) chronic inflammatory demyelinating polyneuropathy (CIDP); (2) demyelinating neuropathy with serum IgM binding to antimyelin-associated glycoprotein (MAG); (3) multifocal motor neuropathy; (4) POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy or edema, *M* protein, and *s*kin changes); and (5) primary acquired amyloidosis.**For further discussion of polyneuropathies associated with circulating paraproteins, see Chap. 378.*

An *axonal sensorimotor neuropathy* is frequently associated with neoplasms. This syndrome is especially common in patients with longstanding cancer and substantial weight loss (>15% of baseline weight). The neuropathy is characterized by distal, symmetric sensory loss and paresthesias, which may be painful, and by weakness and muscle wasting, which is especially prominent in the distal legs. Pathologically there is noninflammatory degeneration of axons and mild myelin loss, presumably secondary to the axonopathy. An accompanying myopathy with atrophy of type II muscle fibers may produce proximal muscle weakness. Axonal loss, with low-amplitude sensory and motor amplitudes and normal conduction velocities, is seen on electrophysiologic studies. This neuromyopathy has been described in association with a variety of solid tumors (lung, breast, stomach), lymphoma, and plasma cell dyscrasia. Successful treatment of the neoplasm may result in improvement or stabilization of the neuromyopathy.

Other axonal neuropathies may bePNNS, but their associations with neoplasms are less clearly established. *Peripheral nerve vasculitis*, producing mononeuritis multiplex or

asymmetric sensorimotor polyneuropathy, has been reported with lymphomas or carcinoma of the lung, prostate, kidney, or stomach. *Polyneuropathy*, presenting with either a subacute mononeuritis multiplex or a slowly progressive distal symmetric sensorimotor polyneuropathy, occurs in approximately 20% of patients with cryoglobulinemia. *Guillain-Barre syndrome* (Chap. 378) may be associated with Hodgkin's disease; it is characterized by subacute motor weakness; sensory loss, which is often mild in comparison with the motor deficits; areflexia; and a characteristic elevation of spinal fluid protein concentration without pleocytosis. *Enteric autonomic neuropathy* with anti-Hu antibodies, commonly presenting as intestinal pseudoobstruction, has been described in association withSCLC.

NEUROMUSCULAR JUNCTION

Lambert-Eaton myasthenic syndrome is a disorder of the presynaptic component of neuromuscular transmission. Common symptoms in LEMS are weakness, fatigue, and dryness of the mouth. Some patients complain of paresthesias, myalgia, or impotence. Weakness is symmetric, proximal, and most prominent in the lower limbs. Strength can decrease with rest and improve with exercise. Ocular (diplopia and ptosis) and bulbar (dysphagia and dysarthria) symptoms may occur in some patients. Respiratory muscle weakness is rare. Tendon reflexes are either diminished or absent at rest but may increase after exercise. About 50% of patients have an associated neoplasm, most commonlySCLC and less often a lymphoproliferative disorder. About 3% of patients with SCLC haveLEMS. Almost all patients with both SCLC and LEMS have a smoking history. LEMS may precede the detection of cancer by 2 to 3 years.

The most useful diagnostic test for LEMS is repetitive nerve stimulation, specifically the finding of compound muscle action potential (CMAP) amplitudes that are small at rest but increase by at least 100% after rapid repetitive nerve stimulation (30 to 50 Hz) or maximal muscle contraction sustained for at least 10 s. LEMS is believed to be an autoimmune disorder associated with diminished quantal release of acetylcholine. IgG antibodies directed against P/Q voltage-gated calcium channels (VGCC) in the motor nerve terminal are found in the sera of ~90% of patients with LEMS and in nearly 100% when LEMS is associated with neoplasm. False-positive findings occur with hypergammaglobulinemia, chronic liver disorders, and (in<3% of normal individuals) infection. Ultrastructurally, the number of active zones, which represent the P/Q VGCC in the presynaptic nerve terminal membrane, is decreased in LEMS. This humoral immune response to P/Q VGCC may be stimulated by similar VGCC expressed by the tumor cells. Edrophonium chloride (Tensilon) generally does not improve strength. Treatment of LEMS is directed at tumor resection, enhancing the release of acetylcholine from the presynaptic terminal, and modulating the autoimmune response. Treatment modalities directed at improving neuromuscular transmission include 3,4-diaminopyridine, guanidine, and pyridostigmine. Immunomodulation may include plasmapheresis, glucocorticoids, azathioprine, and cyclosporine.

Myasthenia gravis (MG) is associated with thymoma in 10 to 15% of patients, especially those who present at ³30 years. Fatigable weakness may involve the ocular, facial, bulbar, and/or limb muscles. Anti-acetylcholine receptor antibodies are detected in about 85% of cases. Slow repetitive nerve stimulation (5 Hz) of proximal or facial muscles produces a decrement of³10% in 70% of patients. Single-fiber

electromyography is a sensitive but not specific confirmatory test in difficult cases.**Myasthenia gravis is discussed in Chap. 380.*

MYOPATHY

Mild proximal muscle weakness with type II muscle fiber atrophy is commonly encountered in patients with cancer, especially when weight loss of>15% is present. Muscle wasting is more prominent than muscle weakness in this syndrome. Inflammatory myopathy, especially dermatomyositis in older females, may occur in association with a variety of neoplasms (Chap. 382).

Necrotizing myopathy presents with a subacute onset of weakness that is typically proximal and ranges from mild to severe. Some patients experience myalgia in addition to muscle weakness. The serum creatine kinase levels are very high. Muscle fiber necrosis is the predominant finding in muscle biopsy. Necrotizing myopathy is most commonly seen with adenocarcinoma and non-small cell cancer of the lung but may also be associated with a variety of other neoplasms. The overall prognosis depends on the malignancy of the associated neoplasm. Weakness may improve following tumor resection or glucocorticoid treatment.

Chronic proximal myopathies have been described with an IgM M-protein binding to decorin; scleromyxedema with IgG or IgA M-proteins; a rippling muscle disease has been reported to occur with thymoma. Hormone-secreting (ACTH or parathyroid hormone-like) tumors may also be associated with proximal myopathies.

102. ONCOLOGIC EMERGENCIES - *Rasim Gucalp*, *Janice Dutcher*

Emergencies in patients with cancer may be classified into three groups: pressure or obstruction caused by a space-occupying lesion, metabolic or hormonal problems (paraneoplastic syndromes, Chap. 100), and complications arising from the effects of treatment.

STRUCTURAL-OBSTRUCTIVE ONCOLOGIC EMERGENCIES

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome (SVCS) is the clinical manifestation of superior vena cava (SVC) obstruction, with severe reduction in venous return from the head, neck, and upper extremities. Malignant tumors, such as lung cancer, lymphoma, and metastatic tumors, are responsible for more than 90% of all SVCS cases. Lung cancer, particularly of small-cell and squamous-cell histologies, accounts for approximately 85% of all cases of malignant origin. Metastatic cancers to the mediastinum, such as testicular and breast carcinomas, account for a small proportion of cases. Other causes include benign tumors, aortic aneurysm, thyroid enlargement, thrombosis, and fibrosing mediastinitis caused by prior irradiation or histoplasmosis.

Patients withSVCSusually present with neck and facial swelling (especially around the eyes), dyspnea, and cough. Other symptoms include hoarseness, tongue swelling, headaches, nasal congestion, epistaxis, hemoptysis, dysphagia, pain, dizziness, syncope, and lethargy. Bending forward or lying down may aggravate the symptoms. The characteristic physical findings are dilated neck veins, an increased number of collateral veins covering the anterior chest wall, cyanosis, and edema of the face, arms, and chest. More severe cases include proptosis, glossal and laryngeal edema, and obtundation. The clinical picture is milder if the obstruction is located above the azygos vein.

The diagnosis ofSVCS is a clinical one. The most significant chest radiographic finding is widening of the superior mediastinum, most commonly on the right side. Pleural effusion occurs in only 25% of patients, often on the right side. However, a normal chest radiograph is still compatible with the diagnosis if other characteristic findings are present. Computed tomography (CT) provides the most reliable view of the mediastinal anatomy. The diagnosis of SVCS requires diminished or absent opacification of central venous structures with prominent collateral venous circulation. Magnetic resonance imaging (MRI) has no advantages over CT. Invasive procedures, including bronchoscopy, percutaneous needle biopsy, mediastinoscopy, and even thoracotomy, can be performed by a skilled clinician without any major risk of bleeding. For patients with a known cancer, a detailed workup usually is not necessary, and appropriate treatment may be started after obtaining a CT scan of the thorax. For those with no history of malignancy, a detailed evaluation is absolutely necessary to rule out benign causes and determine a specific diagnosis to direct the appropriate therapy.

TREATMENT

The one potentially life-threatening complication of a superior mediastinal mass is

tracheal obstruction. Upper airway obstruction demands emergent therapy. Diuretics with a low salt diet, head elevation, and oxygen may produce temporary symptomatic relief.

Radiation therapy is the primary treatment forSVCScaused by non-small cell lung cancer and other metastatic solid tumors. Chemotherapy is effective when the underlying cancer is small cell carcinoma of the lung or lymphoma. Recurrent SVCS occurs in 10 to 30% of patients after initial therapy; it may be palliated with the use of intravascular self-expanding stents (Fig. 102-1). Surgery may provide immediate relief for patients in whom a benign process is the cause.

Clinical improvement occurs in most patients, although this improvement may be due to the development of adequate collateral circulation. The mortality associated withSVCSdoes not relate to caval obstruction, but rather to the underlying cause.

SVCS and Central Venous Catheters in Adults The use of long-term central venous catheters has become common practice in patients with cancer. Major vessel thrombosis may occur. In these cases, catheter removal should be combined with anticoagulation to prevent embolization. SVCS in this setting, if detected early, can be treated successfully by fibrinolytic therapy without sacrificing the catheter. Warfarin (1 mg/d) reduces the incidence of thrombosis without altering coagulation tests.

PERICARDIAL EFFUSION/TAMPONADE

Malignant pericardial disease is found at autopsy in 5 to 10% of patients with cancer, most frequently with lung cancer, breast cancer, leukemias, and lymphomas. Cardiac tamponade as the initial presentation of extrathoracic malignancy is rare. The origin is not malignancy in about 50% of cancer patients with symptomatic pericardial disease, but can be related to irradiation, drug-induced pericarditis, hypothyroidism, idiopathic pericarditis, infection, or autoimmune diseases. Two types of radiation pericarditis have been described: an acute inflammatory, effusive pericarditis occurring within months of irradiation, which usually resolves spontaneously, and a chronic effusive pericarditis that may appear up to 20 years after radiotherapy and is accompanied by a thickened pericardium.
