Most patients with pericardial metastasis are asymptomatic. However, the common symptoms are dyspnea, cough, chest pain, orthopnea, and weakness. Pleural effusion, sinus tachycardia, jugular venous distension, hepatomegaly, peripheral edema, and cyanosis are the most frequent physical findings. Relatively specific diagnostic findings, such as paradoxical pulse, diminished heart sounds, pulsus alternans (pulse waves alternating between those of greater and lesser amplitude with successive beats), and friction rub are less common than with nonmalignant pericardial disease. Chest radiographs and ECG reveal abnormalities in 90% of patients, but half of these abnormalities are nonspecific. Echocardiography is the most helpful diagnostic test. Pericardial fluid may be serous, serosanguineous, or hemorrhagic, and cytologic examination of pericardial fluid is diagnostic in most patients. False negative cytology may occur in patients with lymphoma and mesothelioma.

TREATMENT

Pericardiocentesis with or without the introduction of sclerosing agents, the creation of a pericardial window, complete pericardial stripping, cardiac irradiation, or systemic chemotherapy are effective treatments. Acute pericardial tamponade with life-threatening hemodynamic instability requires immediate drainage of fluid. This can be quickly achieved by pericardiocentesis. Alternatively, subxyphoid pericardiotomy can be performed in 45 min under local anesthesia.

INTESTINAL OBSTRUCTION

Intestinal obstruction and reobstruction are common problems in patients with advanced cancer, particularly colorectal or ovarian carcinoma. However, other cancers, such as lung or breast cancer and melanoma, can metastasize within the abdomen, leading to intestinal obstruction. Typically, obstruction occurs at multiple sites. Intestinal pseudoobstruction is caused by infiltration of the mesentery or bowel muscle by tumor, involvement of the celiac plexus, or paraneoplastic neuropathy in patients with small cell lung cancer. Paraneoplastic neuropathy is associated with IgG antibodies reactive to neurons of the myenteric and submucosal plexuses of the jejunum and stomach. Ovarian cancer can lead either to authentic luminal obstruction or to pseudoobstruction that results when circumferential invasion of a bowel segment arrests the forward progression of peristaltic contractions.

The onset of obstruction is usually insidious. Pain is the most common symptom and is usually colicky in nature. Pain can also be due to abdominal distention, tumor masses, or hepatomegaly. Vomiting can be intermittent or continuous. Patients with complete obstruction usually have constipation. Physical examination may reveal abdominal distention with tympany, ascites, visible peristalsis, high-pitched bowel sounds, and tumor masses. Erect plain abdominal films may reveal multiple air-fluid levels and dilation of the small or large bowel. Acute cecal dilation to more than 12 to 14 cm is considered a surgical emergency because of the high likelihood of rupture. The overall prognosis for the patient with cancer who develops intestinal obstruction is poor; median survival is 3 to 4 months. About one-fourth to one-third of patients are found to have intestinal obstruction due to causes other than cancer. Adhesions from previous operations are a common benign cause. Ileus induced by vincristine is another reversible cause.

TREATMENT

The management of intestinal obstruction in patients with advanced malignancy depends on the extent of the underlying malignancy and the functional status of the major organs. The initial management should include surgical evaluation. Operation is not always successful and may lead to further complications with a substantial mortality rate (10 to 20%). Self-expanding metal stents placed in the gastric outlet, duodenum, proximal jejunum, colon, or rectum may palliate obstructive symptoms at those sites without major surgery. Patients known to have advanced intraabdominal malignancy should receive a prolonged course of conservative management, including nasogastric decompression. Treatment with antiemetics, antispasmodics, and analgesics may allow patients to remain outside the hospital. The somatostatin analogue octreotide may relieve obstructive symptoms through its inhibitory effect on gastrointestinal secretion.

URINARY OBSTRUCTION

Urinary obstruction may occur in patients with prostatic or gynecologic malignancies, particularly cervical carcinoma, or metastatic disease from other primary sites. Radiation therapy to pelvic tumors may cause fibrosis and subsequent ureteral obstruction. Bladder outlet obstruction is usually due to prostate and cervical cancers and may lead to bilateral hydronephrosis and renal failure.

Flank pain is the most common symptom. Persistent urinary tract infection, persistent proteinuria, or hematuria in patients with a cancer should raise suspicion of ureteral obstruction. Total anuria and/or anuria alternating with polyuria may occur. A slow, continuous rise in the serum creatinine level necessitates immediate evaluation in patients with cancer. Renal ultrasound examination is the safest and cheapest way to identify hydronephrosis. The function of an obstructed kidney can be evaluated by a nuclear scan.CT can be helpful in identifying a retroperitoneal mass or retroperitoneal adenopathy.

TREATMENT

Obstruction associated with flank pain, sepsis, or fistula formation is an indication for immediate palliative urinary diversion. There are many newer techniques by which internal ureteral stents can be placed under local anesthesia. Percutaneous nephrostomy offers an alternative approach for drainage. In the case of bladder outlet obstruction due to malignancy, a suprapubic cystostomy can be used for urinary drainage.

MALIGNANT BILIARY OBSTRUCTION

This common clinical problem can be caused by a primary carcinoma arising in the pancreas, ampulla of Vater, bile duct, or liver or by metastatic disease to the periductal lymph nodes or liver parenchyma. The most common metastatic tumors causing biliary obstruction are gastric, colon, breast, and lung cancers. Jaundice, light-colored stools, dark urine, pruritus, and weight loss due to malabsorption are usual symptoms. Pain and secondary infection are uncommon in malignant biliary obstruction. Ultrasound,CT, or percutaneous transhepatic or endoscopic retrograde cholangiography will identify the site and nature of the biliary obstruction.

TREATMENT

Palliative intervention is indicated only in patients with disabling pruritus resistant to medical treatment, severe malabsorption, or infection. Stenting under radiographic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. The choice of modality should be based on the site of obstruction (proximal versus distal), the type of tumor (sensitive to radiotherapy, chemotherapy, or neither), and the general condition of the patient. In the absence of pruritus, biliary obstruction may be a largely asymptomatic cause of death.

SPINAL CORD COMPRESSION

Spinal cord compression occurs in 5 to 10% of patients with cancer. Epidural tumor is the first manifestation of malignancy in about 10% of patients. The underlying cancer is usually identified during the initial evaluation; lung cancer is most commonly the primary malignancy.

Metastatic tumor involves the vertebral column more often than any other part of the bony skeleton. Lung, breast, and prostate cancer are the most frequent offenders. Multiple myeloma also has a high incidence of spine involvement. The thoracic spine is the most common site (70%), followed by the lumbosacral spine (20%) and the cervical spine (10%). Involvement of multiple sites is most frequent in patients with breast and prostatic carcinoma. Cord injury develops when metastases to the vertebral body or pedicle enlarge and compress the underlying dura. Another cause of cord compression is direct extension of a paravertebral lesion through the intervertebral foramen. These cases usually involve a lymphoma, myeloma, or pediatric neoplasm. Parenchymal spinal cord metastasis due to hematogenous spread is rare.

The most common initial symptom in patients with spinal cord compression is localized back pain and tenderness due to involvement of vertebrae by tumor. Pain is usually present for days or months before other neurologic findings appear. It is exacerbated by movement and by coughing or sneezing. It can be differentiated from the pain of disk disease by the fact that it worsens when the patient is supine. Radicular pain is less common than localized back pain and usually develops later. Radicular pain in the cervical or lumbosacral areas may be unilateral or bilateral. Radicular pain from the thoracic roots is often bilateral and is described by patients as a feeling of tight, band-like constriction around the thorax and abdomen. Typical cervical radicular pain radiates down the arm; in the lumbar region, the radiation is down the legs. Loss of bowel or bladder control may be the presenting symptom, but usually occurs late in the course.

On physical examination, pain induced by straight leg raising, neck flexion, or vertebral percussion may help to determine the level of cord compression. Patients develop numbness and paresthesias in the extremities or trunk. Loss of sensibility to pinprick is as common as loss of sensibility to vibration or position. The upper limit of the zone of sensory loss is often one or two vertebrae below the site of compression. Motor findings include weakness, spasticity, and abnormal muscle stretching. The presence of an extensor plantar reflex reflects significant compression. Deep tendon reflexes may be brisk. Motor and sensory loss usually precede sphincter disturbance. Patients with autonomic dysfunction may present with decreased anal tonus, decreased perineal sensibility, and a distended bladder. The absence of the anal wink reflex or the bulbocavernosus reflex confirms cord (conus or cauda equina) involvement. In doubtful cases, evaluation of post-voiding urinary residual volume can be helpful. A residual volume of more than 150 mL suggests bladder dysfunction. Autonomic dysfunction is an unfavorable prognostic factor. Patients with progressive neurologic symptoms should have frequent neurologic examinations and rapid therapeutic intervention.

Patients with cancer who develop back pain should be evaluated for spinal cord compression as quickly as possible (Fig. 102-2). Treatment is more often successful in patients who are ambulatory and still have sphincter control at the time treatment is

initiated. Patients should have a neurologic examination and plain films of the spine. Those whose physical examination suggests cord compression should receive dexamethasone (24 mg intravenously every 6 h), starting immediately.

Erosion of the pedicles (the "winking owl" sign) is the earliest radiologic finding of vertebral tumor. Other radiographic changes include increased intrapedicular distance, vertebral destruction, lytic or sclerotic lesions, scalloped vertebral bodies, and vertebral body collapse. Vertebral collapse is not a reliable indicator of the presence of tumor; about 20% of cases of vertebral collapse, particularly those in older patients and postmenopausal women, are due not to cancer but to osteoporosis. Also, a normal appearance on plain films of the spine does not exclude the diagnosis of cancer. The role of bone scans in the detection of cord compression is not clear; this method is sensitive but less specific than spinal radiography.

The full-length image of the cord provided byMRI is useful. On T1-weighted images, good contrast is noted between the cord, cerebrospinal fluid, and extradural lesions. Owing to their sensitivity in demonstrating the replacement of bone marrow by tumor, MRI can show which parts of a vertebra are involved by tumor (the body, pedicle, lamina, spinous process). MRI also visualizes intraspinal extradural masses compressing the cord. T2-weighted images are most useful for the demonstration of intramedullary pathology. Gadolinium-enhanced MRI can help to characterize and delineate intramedullary disease. MRI is as good as or better than myelography plus postmyelogramCT in detecting metastatic epidural disease with cord compression. Myelography should be reserved for patients who have poor MR images or who cannot undergo MRI promptly. CT in conjunction with myelography enhances the detection of small areas of spinal destruction.

In patients with spinal cord compression and an unknown primary tumor, a simple workup including chest radiography, mammography, measurement of prostate-specific antigen, and abdominalCTusually reveals the underlying malignancy.

TREATMENT

The treatment of patients with spinal cord compression is aimed at relief of pain and restoration of neurologic function (Fig. 102-2).

Radiation therapy plus glucocorticoids is generally the initial treatment of choice for spinal cord compression. Up to 75% of patients treated when still ambulatory remain ambulatory, but only 10% of patients with paraplegia recover walking capacity. Indications for surgical intervention include unknown etiology, failure of radiation therapy, a radioresistant tumor type (e.g., melanoma or renal cell cancer), pathologic fracture dislocation, and rapidly evolving neurologic symptoms. Until recently, laminectomy was the standard operation for metastatic spinal cord compression, although results were poor. At present, laminectomy should be used only for tissue diagnosis and for the removal of posteriorly localized epidural deposits in the absence of vertebral disease. Because most cases of epidural spinal cord compression are due to anterior or anterolateral extradural disease, resection of the anterior vertebral body along with the tumor, followed by spinal stabilization, has achieved good results and low mortality rate. Chemotherapy may have a role in patients with chemosensitive tumors

who have had prior radiation therapy to the same region and who are not candidates for surgery.

The histology of the tumor is an important determinant of both recovery and survival. Rapid onset and quick progression are poor prognostic features.

INCREASED INTRACRANIAL PRESSURE

About 25% of patients with cancer die with intracranial metastases. The cancers that most often metastasize to the brain are lung and breast cancers and melanoma. Brain metastases often occur in the presence of systemic disease, and they frequently cause major symptoms, disability, and early death.

The signs and symptoms of a metastatic brain tumor are similar to those of other intracranial expanding lesions: headache, nausea, vomiting, behavioral changes, seizures, and focal, progressive neurologic changes. Occasionally the onset is abrupt, resembling a stroke, with the sudden appearance of headache, nausea, vomiting, and neurologic deficits. This picture is usually due to hemorrhage into the metastasis. Melanoma, germ cell tumors, and renal cell cancers have a particularly high incidence of intracranial bleeding. The tumor mass and surrounding edema may cause obstruction of the circulation of cerebrospinal fluid, with resulting hydrocephalus. Patients with increased intracranial pressure may have papilledema with visual disturbances and neck stiffness. As the mass enlarges, brain tissue may be displaced through the fixed cranial openings, producing various herniation syndromes.

CTand MRIare equally effective in the diagnosis of brain metastases. CT with contrast should be used as a screening procedure. The CT scan shows brain metastases as multiple enhancing lesions of various sizes with surrounding areas of low-density edema. If a single lesion or no metastases are visualized by contrast-enhanced CT, MRI of the brain should be performed. Gadolinium-enhanced MRI is more sensitive than CT at revealing small lesions, particularly in the brainstem or cerebellum.

TREATMENT

If signs and symptoms of brain herniation (particularly headache, drowsiness, and papilledema) are present, the patient should be intubated and hyperventilated to maintain P_{CO_2}between 25 and 30 mmHg and should receive infusions of mannitol (1 to 1.5 g/kg) every 6 h. Dexamethasone is the best initial treatment for all symptomatic patients with brain metastases (see above). Patients with multiple lesions should receive whole-brain radiation therapy. Patients with a single brain metastasis and with controlled extracranial disease may be treated with surgical excision followed by whole-brain radiation therapy, especially if they are younger than 60 years. Radioresistant tumors should be resected if possible. Stereotactic radiosurgery is an effective treatment for inaccessible or recurrent lesions. With a gamma knife or linear accelerator, multiple small, well-colimated beams of ionizing radiation destroy lesions seen onMRI. Some patients with increased intracranial pressure associated with hydrocephalus may benefit from shunt placement.

NEOPLASTIC MENINGITIS

Tumor involving the leptomeninges is a complication of both primary tumors of the central nervous system (CNS) and tumors that metastasize to the CNS. The incidence is estimated at 3 to 8% of patients with cancer. Melanoma, breast and lung cancer, lymphoma (including AIDS-associated), and acute leukemia are the most common causes.

Patients typically present with multifocal neurologic signs and symptoms including headache, gait abnormality, mental changes, nausea, vomiting, seizures, back or radicular pain, and limb weakness. Signs include cranial nerve palsies, extremity weakness, paresthesia, and decreased deep tendon reflexes.

Diagnosis is made by demonstrating malignant cells in the cerebrospinal fluid (CSF); however, up to 40% of patients may have false negative CSF cytology. An elevated CSF protein level is nearly always present (except in HLTV-1-associated adult T cell leukemia). Patients with neurologic signs and symptoms consistent with neoplastic meningitis who have a negative CSF cytology but an elevated CSF protein level should have the spinal tap repeated at least three times for repeated cytologic examination before the diagnosis is rejected.MRI may show hydrocephalus or smooth or nodular enhancement of the meninges.

The development of neoplastic meningitis usually occurs in the setting of uncontrolled cancer outside theCNS; thus, prognosis is poor (median survival 10 to 12 weeks). However, treatment of the neoplastic meningitis may successfully alleviate symptoms and control the CNS spread.

TREATMENT

Intrathecal chemotherapy, usually methotrexate, cytarabine, or thiotepa, is delivered by lumbar puncture or by an intraventricular reservoir (Ommaya) three times a week until theCSF is free of malignant cells. Then injections are given twice a week for a month and then weekly for a month. An extended release preparation of cytarabine (Depocyte) has a longer half-life and is more effective than regular formulations. Among solid tumors, breast cancer responds best to therapy. Patients with neoplastic meningitis from either acute leukemia or lymphoma may be cured of theirCNSdisease if the systemic disease can be eliminated.

SEIZURES

Seizures occurring in a patient with cancer can be caused by the tumor itself, by metabolic disturbances, by radiation injury, by cerebral infarctions, by chemotherapy-related encephalopathies, or byCNSinfections. Metastatic disease to the CNS is the most common cause of seizures in patients with cancer. Seizures are a presenting symptom of CNS metastasis in 6 to 29% of cases. Approximately 10% of patients with CNS metastasis eventually develop seizures. The presence of frontal lesions correlates with early seizures, and the presence of hemispheric symptoms increases the risk for late seizures. Both early and late seizures are uncommon in patients with posterior fossa lesions. Seizures are also common in patients with CNS metastases from melanoma. Very rarely, cytotoxic drugs such as etoposide, busulfan,

and chlorambucil cause seizures.

TREATMENT

Patients in whom seizures due toCNSmetastases have been demonstrated should receive anticonvulsive treatment with diphenylhydantoin. Prophylactic anticonvulsant therapy is not recommended unless the patient is at a high risk for late seizures. In those patients, serum diphenylhydantoin levels should be monitored closely and the dosage adjusted accordingly.

INTRACEREBRAL LEUKOCYTOSTASIS

Intracerebral leukocytostasis (Ball's disease) is a potentially fatal complication of acute leukemia (particularly myelogenous leukemia) that can occur when the peripheral blast cell count is greater than 100,000/uL. At such high blast cell counts, blood viscosity is increased and blood flow is slowed, and the primitive leukemic cells are capable of invading through endothelium and causing hemorrhage into the brain. Patients may experience stupor, dizziness, visual disturbances, ataxia, coma, or sudden death. Administration of 600 cGy of whole-brain irradiation can protect against this complication and can be followed by rapid institution of antileukemic therapy. This complication is not a feature of the high white cell counts associated with chronic lymphocytic leukemia or chronic myelogenous leukemia.

HEMOPTYSIS

Hemoptysis may be caused by nonmalignant conditions, but lung cancer accounts for a large proportion of cases. Up to 20% of patients with lung cancer have hemoptysis some time in their course. Endobronchial metastases from carcinoid tumors, breast, colon, kidney cancer, and melanoma may also cause hemoptysis. The volume of bleeding is often difficult to gauge. Massive hemoptysis is defined as more than 600 mL of blood produced in 48 h. When respiratory difficulty occurs, hemoptysis should be treated emergently. Often patients can tell where the bleeding is occurring. They should be placed bleeding side down, given supplemental oxygen, and subjected to emergency bronchoscopy. If the site of the lesion is detected, either the patient undergoes a definitive surgical procedure or the lesion is treated with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The surgical option is preferred. Bronchial artery embolization may control brisk bleeding in 75 to 90% of patients, permitting the definitive surgical procedure to be done more safely. Embolization without definitive surgery is associated with rebleeding in 20 to 50% of patients.

Pulmonary hemorrhage with or without hemoptysis in hematologic malignancies is often associated with fungal infections, particularly *Aspergillus* sp. After granulocytopenia resolves, the lung infiltrates in aspergillosis may cavitate and cause massive hemoptysis. Thrombocytopenia and coagulation defects should be corrected, if possible.

AIRWAY OBSTRUCTION

Generally, *airway obstruction* refers to a blockage at the level of the mainstem bronchi

or above. It may result either from intraluminal tumor growth or from extrinsic compression of the airway. If the obstruction is proximal to the larynx, a tracheostomy may be life-saving. For more distal obstructions, particularly intrinsic lesions incompletely obstucting the airway, bronchoscopy with laser treatment, photodynamic therapy, or stenting can produce immediate relief in most patients. However, radiation therapy (either external-beam irradiation or brachytherapy) given together with glucocorticoids may also open the airway. Symptomatic extrinsic compression may be palliated by stenting.

METABOLIC EMERGENCIES

HYPERCALCEMIA

Hypercalcemia is the most common paraneoplastic syndrome (Chaps. 100 and341), occurring in about 10% of patients with advanced cancer. It is associated most often with cancers of the lung, breast, head and neck, and kidney and with multiple myeloma and some B and T cell lymphomas.

Increased release of calcium from bone is the main factor leading to hypercalcemia. Bone resorption is increased dramatically through stimulation of the proliferation and activity of osteoclasts, and bone formation is not stimulated in parallel. The kidney may play an important role through an increase in the reabsorption of calcium in the distal tubule. Parathormone-related protein (PTHrP) produced by tumors has a central role as a mediator of hypercalcemia in cancer. PTHrP shares 80% homology with the first 13 amino acids of parathormone (PTH), which are in the region responsible for binding to the PTH receptor. PTHrP acts via the PTH hormone receptors on osteoblasts and renal tubular cells to stimulate bone resorption and renal calcium conservation, leading to hypercalcemia. Elevated plasma PTHrP levels are also found in most hypercalcemic patients with bone metastases, whose hypercalcemia has traditionally been explained by local osteolysis due to the production of osteolytic factors by tumors. Transforming growth factors, cytokines (interleukins 1 and 6), and other unknown factors could play a contributory role. True "ectopic" PTH production by malignant tumors is rare. In lymphoma, a vitamin D-related product of the tumor may also increase calcium absorption in the gut.

The clinical features of hypercalcemia in patients with cancer are nonspecific and include fatigue, anorexia, constipation, polydipsia, muscle weakness, nausea, and vomiting. They may easily be attributed to the malignancy itself or to its treatment. Laboratory assessment should include measurement of serum electrolytes, calcium, phosphate, and albumin. Hypoalbuminemia is common in malignancy and affects the total serum concentration of calcium. If the ionized calcium level cannot be obtained, then the corrected serum calcium concentration should be calculated with the following formula:

Most patients with hypercalcemia of malignancy have obvious evidence of malignancy, and their serumPTHlevels are suppressed. Measurements ofPTHrPand serum 1,25-dihydroxyvitamin D are not indicated. Routine serum chemistry evaluations are not

able to distinguish between malignant and nonmalignant causes of hypercalcemia.

TREATMENT

Not all patients with moderate to severe hypercalcemia (corrected calcium³12 mg/dL) should be treated. The decision to treat will depend on the patient's quality of life, the current symptoms, and the prospect for further cancer treatment. Treatment directed at hypercalcemia only extends life in patients for whom effective cancer treatment is available. Nonetheless, therapy may be indicated to reduce symptoms and improve the quality of life. Treatment of symptomatic hypercalcemia begins with intravenous saline to restore the depleted intravascular volume, which may be 4 to 8 L below normal at presentation. Rehydration usually has little effect on calcium levels, producing a median decrease of only 1 mg/dL. Antiresorptive agents are essential to decrease osteoclastic activity and control hypercalcemia. Bisphosphonates, which are potent inhibitors of bone resorption, are easy to administer, virtually free of side effects, and rapidly effective in lowering the serum calcium level. Pamidronate is the most effective of the commercially available bisphosphonates. The recommended dose of pamidronate is 60 mg for moderate hypercalcemia (corrected calcium 12 to 13.5 mg/dL) and 90 mg for severe hypercalcemia (corrected calcium >13.5 mg/dL). The dose is given as a single infusion over 4 or 24 h.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE (SIADH)

SIADH is attributed to production of arginine vasopressin by the tumor cells and is characterized by hyponatremia, urine osmolarity inappropriately higher than plasma osmolarity, and high urinary sodium excretion in the absence of volume depletion. Renal, adrenal, and thyroid insufficiency must be excluded, because these disorders can also present with hyponatremia and impaired urinary dilution. Low serum levels of urea and uric acid are useful in distinguishing SIADH from conditions associated with renal hypoperfusion (Chaps. 100 and329).

A broad spectrum of malignant tumors have been reported to causeSIADH. Ectopic vasopressin secretion may occur in some 38% of small cell carcinomas of the lung; often adrenocorticotropic hormone is also produced. The presence of hyponatremia in patients with small cell lung cancer confers a poor prognosis. SIADH may also be caused by various other conditions, such as CNS and pulmonary disorders and some surgical procedures. A variety of drugs have also been shown to produce SIADH, including antidepressants, angiotensin converting-enzyme inhibitors, and cytotoxic drugs such as vincristine, vinorelbine, ifosfamide, cyclophosphamide, cisplatin, levamisole, and melphalan.

Most patients withSIADHare asymptomatic. The severity of symptoms and signs is related to the degree of hyponatremia and the rapidity with which it develops. Early changes include anorexia, depression, lethargy, irritability, confusion, muscle weakness, and marked personality changes. When the plasma sodium level falls below 110 mEq/L, extensor plantar responses, areflexia, and pseudobulbar palsy may be noted; and further reductions may cause coma, convulsions, and death.

TREATMENT

The optimal therapy forSIADH is to treat the underlying malignancy. If that is not possible, other therapeutic approaches are available, such as water restriction or the administration of demeclocycline (900 to 1200 mg per os bid), urea, or lithium carbonate (300 mg per os tid). Demeclocycline is usually used first. Demeclocycline and lithium inhibit the effects of vasopressin on the distal renal tubule. Patients with seizure or coma from hyponatremia may require normal saline infusion plus furosemide to enhance free water clearance. The rate of sodium correction should be slow [0.5 to 1 (mEq/L)/h] to prevent rapid fluid shifts and central pontine myelinolysis. The serum calcium level should be monitored closely to avoid hypocalcemia.

LACTIC ACIDOSIS

Lactic acidosis is a rare and potentially fatal metabolic complication of cancer. Lactic acidosis associated with sepsis and circulatory failure is a common preterminal event in many malignancies. Lactic acidosis in the absence of hypoxemia may occur in patients with leukemia, lymphoma, or solid tumors. Extensive involvement of the liver by tumor is present in most cases. Alteration of liver function may be responsible for the lactate accumulation. Tachypnea, tachycardia, change of mental status, and hepatomegaly may be seen. The serum level of lactic acid may reach 10 to 20 meq/L (90 to 180 mg/dL). Treatment is aimed at the underlying disease. The danger from lactic acidosis is from the acidosis, not the lactate. Sodium bicarbonate should be added if acidosis is very severe or if hydrogen ion production is very rapid and uncontrolled. The prognosis is poor.

HYPOGLYCEMIA

Persistent hypoglycemia occasionally is associated with tumors other than pancreatic islet cell tumors. Usually these tumors are large, and often they are of mesenchymal origin or are hepatomas or adrenocortical tumors. Mesenchymal tumors are usually located in the retroperitoneum or thorax. In these patients, obtundation, confusion, and behavioral aberrations occur in the postabsorptive period and may precede the diagnosis of the tumor. Hypoglycemia is due to tumor overproduction of insulin-like growth factor, a peptide hormone with structural homology to proinsulin but having only about 1% of its biologic effects. Additionally, the development of hepatic dysfunction from liver metastases and increased glucose consumption by the tumor can contribute to hypoglycemia. If the tumor cannot be resected, treatment of the hypoglycemia has generally been relief of symptoms, with the administration of glucose, glucocorticoids, or glucagon.

Hypoglycemia can be artifactual; hyperleukocytosis from leukemia, myeloproliferative diseases, leukemoid reactions, or colony stimulating factor treatment can increase glucose consumption in the test tube after blood is drawn, leading to pseudohypoglycemia.

ADRENAL INSUFFICIENCY

In patients with cancer, adrenal insufficiency may go unrecognized because the

symptoms, such as nausea, vomiting, anorexia, and orthostatic hypotension, are nonspecific and may be mistakenly attributed to progressive cancer or to cancer therapy. Primary adrenal insufficiency may develop owing to replacement of both glands by metastases (lung, breast, colon, or kidney cancer, lymphoma), to removal of both glands, or to hemorrhagic necrosis in association with sepsis or anticoagulation. Impaired adrenal steroid synthesis occurs in patients being treated for cancer with mitotane, ketoconazole, aminoglutethimide, or the investigational agent suramin or in those undergoing rapid reduction in glucocorticoid therapy. Rarely, metastatic replacement causes primary adrenal insufficiency as the first manifestation of an occult malignancy. Metastasis to the pituitary or hypothalamus is found at autopsy in up to 5% of patients with cancer, but associated secondary adrenal insufficiency is rare. Patients abruptly discontinuing megestrol acetate therapy (for cancer cachexia) may develop Addisonian crisis from central suppression of the pituitary-adrenal axis with decreased serum levels of cortisol and adrenocorticotropic hormone.

Acute adrenal insufficiency is potentially lethal. Treatment of suspected adrenal crisis is initiated after the sampling of serum cortisol and ACTH levels (Chap. 331).

TREATMENT-RELATED EMERGENCIES

TUMOR LYSIS SYNDROME

Tumor lysis syndrome is a well-recognized clinical entity that is characterized by various combinations of hyperuricemia, hyperkalemia, hyperphosphatemia, lactic acidosis, and hypocalcemia and is caused by the destruction of a large number of rapidly proliferating neoplastic cells. Frequently, acute renal failure develops as a result of the syndrome.

Tumor lysis syndrome is most frequently associated with the treatment of Burkitt's lymphoma, acute lymphoblastic leukemia, and other high-grade lymphomas, but it also may be seen with chronic leukemias and, rarely, with solid tumors. This syndrome has been seen in patients with chronic lymphocytic leukemia after treatment with fludarabine and cladribine. Tumor lysis syndrome usually occurs during or shortly (1 to 5 days) after chemotherapy. Rarely, spontaneous necrosis of malignancies causes tumor lysis syndrome.

Hyperuricemia may be present at the time of chemotherapy. Effective treatment accelerates the destruction of malignant cells and leads to increased serum uric acid levels from the turnover of nucleic acids. Owing to the acidic local environment, uric acid can precipitate in the tubules, medulla, and collecting ducts of the kidney, leading to renal failure. Lactic acidosis and dehydration may contribute to the precipitation of uric acid in the renal tubules. The finding of uric acid crystals in the urine is strong evidence for uric acid nephropathy. The ratio of urinary uric acid to urinary creatinine is >1 in patients with acute hyperuricemic nephropathy and<1 in patients with renal failure due to other causes.

Hyperphosphatemia, which can be caused by the release of intracellular phosphate pools by tumor cell lysis, produces a reciprocal depression in serum calcium, which causes severe neuromuscular irritability and tetany. Deposition of calcium phosphate in the kidney and hyperphosphatemia may cause renal failure. Potassium is the principal

intracellular cation, and massive destruction of malignant cells may lead to hyperkalemia. Hyperkalemia in patients with renal failure may rapidly become life-threatening. Hyperkalemia can cause ventricular arrhythmias and sudden death.

The likelihood that the tumor lysis syndrome will occur in patients with Burkitt's lymphoma is related to the tumor burden and renal function. Hyperuricemia and high serum levels of lactate dehydrogenase LDH (>1500 U/L), both of which correlate with total tumor burden, also correlate with the risk of tumor lysis syndrome. In patients at risk for tumor lysis, pretreatment evaluations should include a complete blood count, serum chemistry evaluation, and urine analysis. High leukocyte and platelet counts may artificially elevate potassium levels ("pseudohyperkalemia") due to lysis of these cells after the blood is drawn. In these cases, plasma potassium instead of serum potassium should be followed. In pseudohyperkalemia, no electrocardiographic abnormalities are present. In patients with abnormal baseline renal function, the kidneys and retroperitoneal area should be evaluated by sonography and/orCT. Urine output should be watched closely.

Recognition of risk and prevention are the most important steps in the management of this syndrome (Fig. 102-3). Despite aggressive prophylaxis, tumor lysis syndrome and/or oliguric or anuric renal failure may occur. Dialysis is often necessary and should be considered early in the course. Hemodialysis is preferred. The prognosis is excellent, and renal function recovers after the uric acid level is lowered to <10 to 20 mg/dL.

HUMAN ANTIBODY INFUSION REACTIONS

The initial infusion of human or humanized antibodies (e.g., rituximab) is associated with fever, chills, nausea, asthenia, and headache in up to half of treated patients. Bronchospasm and hypotension occur in 1% of patients. The pathogenesis is thought to be activation of immune effector processes (cells and complement). In the presence of high levels of circulating tumor cells, thrombocytopenia, a rapid fall in circulating tumor cells, and mild tumor lysis syndrome may also occur. Diphenhydramine and acetaminophen can often prevent or suppress the symptoms. If they occur, the infusion should be stopped and restarted at half the initial infusion rate after the symptoms have abated.

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome (HUS) and, less commonly, thrombotic thrombocytopenic purpura (TTP) occurring after treatment with antineoplastic drugs have been described. Mitomycin is by far the most common agent causing this peculiar syndrome. Other chemotherapeutic agents, including cisplatin, bleomycin, and gemcitabine, have also been reported to be associated with this syndrome. It occurs most often in patients with gastric, colorectal, and breast carcinoma. In one series, 35% of patients were without evident cancer at the time this syndrome appeared. Secondary HUS/TTP has also been reported as a rare but sometimes fatal complication of bone marrow transplantation.

HUSusually has its onset 4 to 8 weeks after the last dose of chemotherapy, but it is not rare to detect it several months later. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Dyspnea, weakness, fatigue,

oliguria, and purpura are also common initial symptoms and findings. Systemic hypertension and pulmonary edema frequently occur. Severe hypertension, pulmonary edema, and rapid worsening of hemolysis and renal function may occur after a blood transfusion. Cardiac findings include atrial arrhythmias, pericardial friction rub, and pericardial effusion. Raynaud's phenomenon is part of the syndrome in patients treated with bleomycin.

Laboratory findings include severe to moderate anemia associated with red blood cell fragmentation and numerous schistocytes on peripheral smear. Reticulocytosis, decreased plasma haptoglobin, and an elevated lactic dehydrogenase (LDH) level document hemolysis. The serum bilirubin level is usually normal or slightly elevated. The Coombs test is negative. The white cell count is usually normal, and thrombocytopenia (<100,000/uL) is almost always present. Most patients have a normal coagulation profile, although some have mild elevations in thrombin time and in level of fibrin degradation products. The serum creatinine level is elevated at presentation and shows a pattern of subacute worsening within weeks of the initial azotemia. The urinalysis reveals hematuria, proteinuria, and granular or hyaline casts; and circulating immune complexes may be present.

The basic pathologic lesion appears to be deposition of fibrin in the walls of capillaries and arterioles, and these deposits are similar to those seen inHUS due to other causes. These microvascular abnormalities involve mainly the kidneys and rarely occur in other organs. The pathogenesis of chemotherapy-related HUS is unknown. Immune complexes have been proposed but not confirmed to be etiologic.

The case fatality rate is high; most patients die within a few months. Plasmapheresis and plasma exchange may normalize the hematologic abnormalities, but renal failure is not reversed in most patients. Immunoperfusion over a staphylococcal protein A column is the most successful treatment. About half of the patients treated with immunoperfusion respond with resolution of thrombocytopenia, improvement in anemia, and stabilization of renal failure. Treatment is well tolerated. It is not clear how the treatment works.

NEUTROPENIA AND INFECTION

These remain the most common serious complications of cancer therapy.**They are covered in detail in Chap. 85.*

PULMONARY INFILTRATES

Patients with cancer may present with dyspnea associated with diffuse interstitial infiltrates on chest radiographs. Such infiltrates may be due to progression of the underlying malignancy, treatment-related toxicities, infection, and/or unrelated diseases. The cause may be multifactorial; however, most commonly they occur as a consequence of treatment. Infiltration of the lung by malignancy has been described in patients with leukemia, lymphoma, and breast and other solid cancers. Pulmonary lymphatics may be involved diffusely by neoplasm (pulmonary lymphangitic carcinomatosis), resulting in a diffuse increase in interstitial markings on chest radiographs. The patient is often mildly dyspneic at the onset, but pulmonary failure

develops over a period of weeks. In some patients, dyspnea precedes changes on the chest radiographs and is accompanied by a nonproductive cough. This syndrome is characteristic of solid tumors. In patients with leukemia, diffuse microscopic neoplastic peribronchial and peribronchiolar infiltration is frequent but may be asymptomatic. However, some patients present with diffuse interstitial infiltrates, an alveolar capillary block syndrome, and respiratory distress. In these situations, glucocorticoids can provide symptomatic relief, but specific chemotherapy should always be started promptly.

In addition, accumulation of leukemic blasts in the pulmonary capillary system may cause pulmonary distress and failure in patients with acute myelogenous leukemia. This complication is strongly related to high peripheral blast counts (>100,000/uL) and a short tumor cell doubling time. Some patients with pulmonary leukostasis may have nodular and/or floccular, diffuse infiltrates on chest radiographs. In addition to dyspnea, patients may develop dizziness, confusion, tinnitus, ataxia, visual blurring, and retinal abnormalities due to leukostasis in cerebral vessels. Leukapheresis and/or chemotherapy should be started without delay. Pulmonary irradiation may reduce symptoms.

Several cytotoxic agents, such as bleomycin, methotrexate, busulfan, and the nitrosoureas, may cause pulmonary damage. The most frequent presentations are interstitial pneumonitis, alveolitis, and pulmonary fibrosis. Some cytotoxic agents, including methotrexate and procarbazine, may cause an acute hypersensitivity reaction. Cytosine arabinoside has been associated with noncardiogenic pulmonary edema. Administration of multiple cytotoxic drugs, as well as radiation therapy and preexisting lung disease, may potentiate the pulmonary toxicity. Supplemental oxygen may potentiate the effects of drugs and radiation injury. Patients should always be managed with the lowest FI_{O2} that is sufficient to maintain hemoglobin saturation.

The onset of symptoms may be insidious, with symptoms including dyspnea, nonproductive cough, and tachycardia. Patients may have bibasilar crepitant rales, end-inspiratory crackles, fever, and cyanosis. The chest radiograph generally shows an interstitial and sometimes an intraalveolar pattern that is strongest at the lung bases and may be symmetric. A small effusion may occur. Hypoxemia with decreased carbon monoxide diffusing capacity is always present. Glucocorticoids may be helpful in patients in whom pulmonary toxicity is related to radiation therapy or to chemotherapy. Treatment is otherwise supportive.

Radiation pneumonitis and/or fibrosis is a relatively frequent side effect of thoracic radiation therapy when the dosage exceeds 40 Gy; it may be acute or chronic. It has its onset usually from 2 to 6 months after completion of radiation therapy. The clinical syndrome, which varies in severity, consists of dyspnea, cough with scanty sputum, low-grade fever, and an initial hazy infiltrate on chest radiographs. The infiltrate and tissue damage generally are confined to the radiation field. The patients subsequently may develop a patchy alveolar infiltrate and air bronchograms, which may progress to acute respiratory failure that is sometimes fatal. A lung biopsy may be necessary to make the diagnosis. Asymptomatic infiltrates found incidentally after radiation therapy need not be treated. However, prednisone should be administered to patients with fever or other symptoms. The dosage should be tapered slowly after the resolution of

radiation pneumonitis, as abrupt withdrawal of glucocorticoids may cause an exacerbation of pneumonia. Delayed radiation fibrosis may occur years after radiation therapy and is signaled by dyspnea on exertion. Often it is mild, but it can progress to chronic respiratory failure. Therapy is supportive.

Classical radiation pneumonitis that leads to pulmonary fibrosis is due to radiation-induced production of local cytokines such as platelet-derived growth factor b, tumor necrosis factor, and transforming growth factorb in the radiation field. An immunologically mediated sporadic radiation pneumonitis occurs in about 10% of patients; bilateral alveolitis mediated by T cells results in infiltrates outside the radiation field. This form of radiation pneumonitis usually resolves without sequelae.

Pneumonia is a common problem in patients undergoing treatment for cancer. Bacterial pneumonia typically causes a localized infiltrate on chest radiographs. Therapy is tailored to the causative organism. When diffuse interstitial infiltrates appear in a febrile patient, the differential diagnosis is extensive and includes pneumonia due to infection with *Pneumocystis carinii*, cytomegalovirus, or intracellular pathogens such as mycoplasma and *Legionella*; effects of drugs or radiation; tumor progression; nonspecific pneumonitis; and fungal disease. Patients with cancer who are neutropenic and have fever and local infiltrates on chest radiograph should be treated with a third generation cephalosporin perhaps together with an aminoglycoside or imipenem. A new or persistent focal infiltrate not responding to broad spectrum antibiotics argues for initiation of empiric antifungal therapy. When diffuse bilateral infiltrates develop in patients with febrile neutropenia, broad spectrum antibiotics plus trimethoprim-sulfamethoxazole with or without erythromycin should be initiated. The empiric administration of trimethoprim-sulfamethoxazole plus erythromycin to patients without neutropenia and these antibiotics plus ceftazidime to patients with neutropenia covers nearly every treatable diagnosis (except tumor progression) and gives as good overall survival as a strategy based on early invasive intervention with bronchoalveolar lavage or open lung biopsy. If the patient does not improve in 4 days, open lung biopsy is the procedure of choice. Bronchoscopy with bronchoalveolar lavage may be used in patients who are poor candidates for surgery.

In patients with pulmonary infiltrates who are afebrile, heart failure and multiple pulmonary emboli form part of the differential diagnosis.

TYPHLITIS

Neutropenic enterocolitis (typhlitis) is a necrosis of the cecum and adjacent colon that may complicate the treatment of acute leukemia. The patient develops right lower quadrant abdominal pain, often with rebound tenderness and a tense, distended abdomen, in a setting of fever and neutropenia. Watery diarrhea (often containing sloughed mucosa) and bacteremia are common, and bleeding may occur. Plain abdominal films are generally of little value in the diagnosis;CT scan may show marked bowel wall thickening, particularly in the cecum, with bowel wall edema. Rapid institution of broad-spectrum antibiotic coverage and nasogastric suction may reverse the disease. Surgical intervention should be considered if there is no improvement by 24 h after the start of antibiotic treatment. If the localized abdominal findings become diffuse, the prognosis is poor.

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis can develop in patients receiving cyclophosphamide or ifosfamide. Both drugs are metabolized to acrolein, which is a strong chemical irritant that is excreted in the urine. Prolonged contact or high concentrations may lead to bladder irritation and hemorrhage. Symptoms include gross hematuria, frequency, dysuria, burning, urgency, incontinence, and nocturia. The best management is prevention. Maintaining a high rate of urine flow minimizes exposure. In addition, 2-mercaptoethanesulfonate (mesna) detoxifies the metabolites and can be coadministered with the instigating drugs. Mesna usually is given three times on the day of ifosfamide administration in doses that are each 20% of the total ifosfamide dose. If hemorrhagic cystitis develops, the maintenance of a high urine flow may be sufficient supportive care. If conservative management is not effective, irrigation of the bladder with an 0.37 to 0.74% formalin solution for 10 min stops the bleeding in most cases. *N*-acetylcysteine may also be an effective irrigant. Prostaglandins (carboprost tromethamine) can inhibit the progress. In extreme cases, ligation of the hypogastric arteries, urinary diversion, or cystectomy may be necessary.

In summary, the diagnosis of cancer and its treatment carry risk of a multitude of medical problems. Knowledge of both the disease process and the potential hazards of the treatment is required to anticipate and treat these emergent complications.

(Bibliography omitted in Palm version)

103. LATE CONSEQUENCES OF CANCER AND ITS TREATMENT - *Michael C. Perry*, *Dan L. Longo*

The 5-year survival rate of all patients diagnosed with cancer is now 59%. This year alone, nearly 700,000 survivors will be added to the 7 million already considered cured. Virtually all of these survivors will bear some mark of their diagnosis and its therapy, and many will experience long-term complications, including medical problems, psychosocial disturbances, sexual dysfunction, and inability to find employment or insurance.

Problems may be related to the cancer itself (for example, patients with primary cancers of the head and neck are at increased risk for subsequent lung cancer) or to the normal aging process (surviving one cancer does not necessarily alter the risk of other common tumors that increase in frequency with age). However, many of the problems affecting cured patients are related to the treatments. Large numbers of individuals carefully followed for periods up to 30 years have taught us the spectrum of problems that can be encountered. Because of heterogeneity in treatment details and in completeness of follow-up, some treatment-related problems went undetected for many years. However, studies of long-term survivors of childhood cancers, acute leukemia, Hodgkin's disease, lymphomas, testicular cancer, and localized solid tumors have identified the features of cancer treatment that are associated with later morbidity and mortality. We have been somewhat slow to act in changing those aspects of primary treatment that contribute to these late problems. This reticence is due to the uncertainty associated with changing a treatment that is known to work before having a replacement that works as well.

The first task is always to eradicate the diagnosed malignancy. Late problems occurring in cured patients reflect the success of treatment. Such problems never develop in those who do not survive the cancer. Morbidity and mortality from iatrogenic disease should be avoided, if possible. However, the risk of late complications should not lead to the failure to apply potentially curative treatment. The challenge is to preserve or augment the cure rate while decreasing the risk of serious treatment-related illness.

The mechanisms of damage vary. Surgical procedures can create abnormal physiology (such as blind loops leading to malabsorption) or interfere with normal organ function (splenectomy leading to impaired immune response). Radiation therapy can damage organ function directly (salivary gland toxicity leading to dry mouth and dental caries), act as a carcinogen (second solid tumors in radiation ports), or promote accelerated aging-associated changes (atherosclerosis). Cancer chemotherapy can produce damage to the bone marrow and immune system and induce a spectrum of organ dysfunctions. Therapy may produce subclinical damage that may only become recognized in the presence of a second inciting factor (such as the increased incidence of melanoma in patients with dysplastic nevus syndrome treated for Hodgkin's disease with radiation therapy). Finally, although the mechanisms are not elucidated, cancer and its treatment are associated with psychosocial problems that can impair the survivor's ability to adapt to life after cancer.

Late effects by treatment modality are shown in Table 103-1.**Toxicities associated with drugs are discussed in Chap. 84; radiation toxicity is discussed in Chap 394.*

CONSEQUENCES BY ORGAN SYSTEM

Cardiovascular Dysfunction Most anthracyclines damage the heart muscle. A dose-dependent dropout of myocardial cells is seen on endomyocardial biopsy, and eventually ventricular failure ensues. About 5% of patients who receive>550 mg/m_2 of doxorubicin will develop congestive heart failure (CHF). Coexisting cardiac disease, hypertension, advanced age, and concomitant therapy with thoracic radiation therapy or mitomycin may hasten the onset of CHF. Anthracycline-induced CHF is not readily reversible; mortality is as high as 50%, thus, prevention is the best approach. Mitoxantrone is a related drug that has less cardiac toxicity. Administration of doxorubicin by continuous infusion or encapsulated in liposomes appears to decrease the risk of heart damage. Dexrazoxane, an intracellular iron chelator, may protect the heart against anthracycline toxicity by preventing iron-dependent free-radical generation.

Mediastinal radiation therapy that includes the heart can induce acute pericarditis, chronic constrictive pericarditis, myocardial fibrosis, or accelerated premature coronary atherosclerosis. The incidence of acute pericarditis is 5 to 13%; patients may be asymptomatic or have dyspnea on exertion, fever, chest pain. Onset is insidious with a peak about 9 months after treatment. Pericardial effusion may be present. Chronic constrictive pericarditis can develop 5 to 10 years after treatment and usually presents with dyspnea on exertion. Myocardial fibrosis may present as unexplainedCHF with diagnostic evaluation showing restrictive cardiomyopathy. Patients may have aortic insufficiency from valvular thickening or mitral regurgitation from papillary muscle dysfunction. Patients who receive mantle field radiation therapy have a three-fold increased risk of *fatal* myocardial infarction. Similarly, radiation of the carotids is associated with premature atherosclerosis of the carotids and can produce central nervous system (CNS) embolic disease.

At very high doses, cyclosphosphamide can produce a hemorrhagic myocarditis. Patients receiving bleomycin may develop Raynaud's phenomenon. The symptoms range from mild to debilitating; up to 40% of patients receiving bleomycin for testicular cancer report this problem.

Pulmonary Dysfunction Pulmonary fibrosis from bleomycin is dose-related, with potential exacerbation by age, preexisting lung disease, thoracic radiation, high concentrations of inhaled oxygen, and the concomitant use of other chemotherapeutic agents. Several other chemotherapy agents and radiation therapy can cause pulmonary fibrosis, and at least five can cause pulmonary venoocclusive disease, especially following high-dose therapy such as that involved in stem cell/bone marrow transplantation.

Liver Dysfunction Clinically significant long-term damage to the liver from standard dose chemotherapy is relatively infrequent, and mostly confined to patients who have received chronic methotrexate for maintenance therapy of acute lymphoblastic leukemia. Radiation doses to the liver exceeding 1500 cGy can produce liver dysfunction. Although rarely seen with standard dose chemotherapy, hepatic venoocclusive disease is more common with high-dose therapy, such as that given to prepare patients for autologous or allogeneic stem cell transplantation. Endothelial damage is probably the inciting event.

Renal/Bladder Dysfunction Reduced renal function may be produced by cisplatin and is usually asymptomatic, but may also render the patient that much more susceptible to other renal insults. Cyclophosphamide cystitis may eventually lead to the development of bladder cancer. Ifosfamide produces cystitis and a proximal tubular defect, a Fanconi-like syndrome that is usually, but not always, reversible.

Endocrine Dysfunction Long-term survivors of childhood cancer who received cranial irradiation are shorter, more likely to be obese, and have reductions in strength, exercise tolerance, and bone mineral density. The obesity may be related to alterations in leptin biology. Growth hormone deficiency is the most common hormone deficiency.

Thyroid disease is common in patients who have received radiation therapy to the neck, such as patients with Hodgkin's disease, with an incidence of up to 62% at 26 years post-therapy. Hypothyroidism is the most common abnormality, followed by Graves' disease, thyroiditis, and cancer. Such patients should have frequent thyroid-stimulating hormone (TSH) levels to detect hypothyroidism early and suppress the TSH drive, which may contribute to thyroid cancer.

Nervous System Dysfunction Although many patients experience peripheral neuropathy during chemotherapy, only a few have chronic problems, perhaps because they have other co-existing diseases such as diabetes mellitus. High doses of cisplatin can produce severe sensorimotor neuropathy. Vincristine may produce permanent numbness and tingling in the fingers and toes.

Neurocognitive sequelae from intrathecal chemotherapy, with or without radiation therapy, are recognized complications of the successful therapy of childhood acute lymphoblastic leukemia. Cognitive decline has been attributed to radiating the brain in the treatment of a variety of tumor types. In addition, cognitive decline can follow the use of adjuvant chemotherapy in women being treated for breast cancer. Because the agents are given at modest doses and are not thought to cross the blood-brain barrier, the mechanism of the cognitive decline is not defined.

Many patients suffer intrusive thoughts about cancer recurrence for many years after successful treatment. Adjustment to normal expectations can be difficult. Cancer survivors may often have more problems holding a job, staying in a stable relationship, and coping with the usual stresses of daily life.

A dose-related hearing loss can occur with the use of cisplatin, usually with doses in excess of 400 mg/m_2. This is irreversible and patients should be screened with audiometric exams periodically during such therapy.

Eyes Cataracts may be caused by chronic glucocorticoid use, radiation therapy to the head, and, rarely, by tamoxifen.

Sexual and Reproductive Dysfunction Reversible azoospermia can be caused by many chemotherapy agents. The gonads may also be permanently damaged by radiation therapy or by chemotherapeutic agents, particularly the alkylating agents. The extent of the damage depends upon the patient's age and the total dose administered.

As a woman nears menopause, smaller amounts of chemotherapy will produce ovarian failure. In men, chemotherapy may produce infertility, but hormone production is not usually affected. Women, however, commonly lose both fertility and hormone production. The premature induction of menopause in a young woman can have serious medical and psychological consequences. Hormone replacement therapy is controversial, but most evidence supports its use. Paroxetine may be useful in controlling hot flashes.

Musculoskeletal Dysfunction Late consequences of radiation therapy on the musculoskeletal system occur mostly in children and are related to the radiation dose, volume of tissue irradiated, and the age of the child at the time of therapy. Damage to the microvasculature of the epiphyseal growth zone may result in leg length discrepancy, scoliosis, and short stature.

Oral Complications Radiation therapy can damage the salivary glands, producing dry mouth. Without saliva, dental caries develop and many patients have poor dentition. In rare patients, taste can be adversely affected and appetite can be suppressed.

SECOND MALIGNANCIES

Second malignancies are a major cause of death for those cured of cancer. Second malignancies can be grouped into three categories: those associated with the primary cancer, those caused by radiation therapy, and those caused by chemotherapy.

Primary cancers increase the risk of secondary cancers in a number of settings. Patients with head and neck cancers are at increased risk of developing a lung cancer, and vice versa, probably because of shared risk factors, especially tobacco abuse. Patients with breast cancer are at increased risk of a second breast cancer in the contralateral breast. Patients with Hodgkin's disease are at increased risk of non-Hodgkin's lymphoma. Patients with genetic syndromes, such as MEN 1 or Lynch syndrome, are at increased risk of second cancers of specific types. In none of these examples does it appear that treatment of primary cancer is the cause of the secondary cancer, but a role for treatment is difficult to exclude. These predispositions should result in heightened surveillance in persons at risk. Patients with head and neck cancer may have a reduced risk of developing lung cancer with retinoic acid treatment. Other cancer preventions have not been proved effective.

Patients treated with radiation therapy have an increasing and apparently life-long risk of developing second solid tumors, usually in or adjacent to the radiation field. The risk is modest in the first decade after treatment but reaches 1% per year in the second decade, such that populations followed for 25 years or more have a³25% chance of developing a second treatment-related tumor. Some organs differ in their susceptibility to radiation carcinogenesis with age; women receiving chest radiation therapy after age 30 have a small increased risk of breast cancer, but those under 30 have a 128-fold increased risk. The chances of curing the second malignancies hinge on early diagnosis. Patients who were treated with radiation therapy should be carefully examined on an annual basis and evaluated for any abnormalities in organs and tissues that were in the radiation field. Symptoms in a patient cured of cancer should not be dismissed as they may be an early sign of second cancers.

Chemotherapy produces two clinical syndromes that can be fatal: myelodysplasia and acute myeloid leukemia. Two types of acute leukemia have been described. The first occurs in patients treated with alkylating agents, especially over a protracted period. The malignant cells frequently carry genetic deletions in chromosomes 5 or 7. The lifetime risk is about 2%; the risk is increased by the addition of radiation therapy and is about 3 times higher in people treated over age 40. It peaks in incidence 4 to 6 years after treatment; the risk returns to baseline if no disease has developed within 10 years of treatment. The second type of acute leukemia occurs after exposure to topoisomerase II inhibitors such as doxorubicin or etoposide. It is morphologically indistinguishable from the first but contains a characteristic chromosome translocation involving 10q23. The incidence is <1%, and it usually occurs 1 1/2 to 3 years after treatment. Both forms of acute leukemia are highly refractory to treatment, and no preventive strategy has been developed.

Hormonal manipulations can also cause second tumors. Tamoxifen induces endometrial cancer in about 1 to 2% of women taking it 5 years or longer. Usually these tumors are found at early stage; mortality from endometrial cancer is very low compared to the benefit from tamoxifen use as adjuvant therapy in women with breast cancer.

CONSEQUENCES BY CANCER TYPE

Pediatric Cancers Quality of life is often excellent, although the majority have at least one late effect. About one-third of long-term survivors have moderate to severe problems. Cognitive function may be impaired. Late effects are worse for those with poor socioeconomic status. Functional impairments in the cardiovascular system due to radiation therapy and anthracyclines, and in the lungs due to radiation therapy, are rare. Scoliosis and/or delayed growth due to radiation of the skeleton is more common. Many have psychosocial and sexual problems. Second malignant neoplasms are a significant cause of death.

Hodgkin's Disease The patient cured of Hodgkin's disease remains subject to long-term medical problems such as thyroid dysfunction, premature coronary artery disease, gonadal dysfunction, postsplenectomy sepsis, and second malignancies. The second malignancies encountered include myelodysplasia and acute myeloid leukemia, non-Hodgkin's lymphomas, breast cancer, lung cancer, and melanoma. The major risk factor for hematologic malignancies is treatment with alkylating agents, while solid tumors are more likely to be seen with the use of radiation therapy. Patients cured of Hodgkin's disease seem to have greater fatigue, more psychosocial and sexual problems, and report a poorer quality of life than patients cured of acute leukemia.

Non-Hodgkin's Lymphomas The patient cured of a non-Hodgkin's lymphoma may be at increased risk of myelodysplasia and acute leukemia if high doses or prolonged alkylating agents were used. Chronic exposure to cyclophosphamide increases the risk of bladder cancer. Patients cured of lymphoma report a very good quality of life.

Acute Leukemia The late effects of anti-leukemic therapy include second malignancies (hematologic and solid tumors), neuropsychiatric difficulties, subnormal growth, thyroid abnormalities, and infertility.

Head and Neck Cancer Patients frequently have poor dentition, dry mouth, trismus, difficulty in eating, and poor nutrition. Those with nasopharyngeal cancer report the poorest long-term quality of life, possibly related to the volume of disease that is radiated.

Stem Cell Transplantation Cured patients are at risk of second cancers, especially if radiation therapy was part of the treatment. They are also subject to gonadal damage and infertility. Graft-versus-host disease is the leading factor contributing to the morbidity and mortality from allogeneic bone marrow transplantation, with an immune-mediated attack against the skin, liver, and gut epithelium. About half of patients report psychosexual problems.

Breast Cancer Patients treated with adjuvant chemotherapy and/or hormonal therapy for breast cancer are at risk for endometrial cancer from the use of tamoxifen. Those patients who have received chemotherapy may be at risk from doxorubicin or radiation-induced cardiomyopathy and acute leukemia. The development of premature ovarian failure from chemotherapy may cause hormone-deficient symptoms (hot flashes, decreased vaginal secretions, dyspareunia) and places women at risk for osteoporosis and cardiovascular deaths. Patients commonly report intrusive thoughts of cancer and psychological distress.

Testicular Cancer Depending on the modalities used for therapy, patients cured of testicular cancer can anticipate Raynaud's phenomena, renal and/or pulmonary damage from chemotherapy, and ejaculatory dysfunction from retroperitoneal lymph node dissection. Sexual dysfunction is reported by 15% of patients cured of testicular cancer.

Colon Cancer To date the major threat to patients with colorectal cancer treated with chemotherapy and or radiation therapy remains the risk of a second colorectal cancer. Quality of life is reported as high in long-term survivors.

Prostate Cancer Radical surgical treatment is often accompanied by impotence and about 10 to 15% develop some urine incontinence. Use of radiation therapy increases the risk of second cancers.

The challenge for the future is to integrate new chemotherapy and biologic agents and newer techniques of delivering radiation therapy in a fashion that increases cure rates and lowers the late effects of treatment. Additional populations at risk for late effects include those with cancers where therapy is becoming more effective, such as ovarian cancer, and cancers where chemotherapy and radiation therapy are used together in an organ-sparing approach, such as bladder cancer, anal cancer, and laryngeal cancer. Patients who have been cured of a cancer represent an important resource for cancer prevention studies.

SECTION 2 -DISORDERS OF HEMATOPOIESIS

104. HEMATOPOIESIS - *Peter J. Quesenberry*, *Gerald A. Colvin*

Hematopoiesis is the production of blood cells. It is a tightly regulated system exquisitely responsive to functional demands. The level of neutrophils, eosinophils, and basophils are maintained in discrete ranges with rapid adjustments when demands such as bacterial infection, parasitic infection, or allergic reaction are imposed. Similarly, lymphocytes, monocytes, platelets, and red cells, while maintained in normal ranges, respond rapidly to demands -- lymphocytes to immune challenge, monocytes to various infections, platelets to hemorrhage or inflammation, and red cells to tissue hypoxia from many causes. Derangements in marrow function can lead to an excess of white cells, such as leukemia or leukemoid reactions, or an inadequate number of cells, such as anemia, thrombocytopenia, or leukopenia. Kinetics of cytopenia induction after marrow injury with drugs, radiation, or infections reflect the life span of these cells in peripheral blood. The first lineage to drop are the neutrophils with a blood life span of 6 to 8 h, followed by platelets with a 10-day life span. Anemia develops over a longer time in the absence of blood loss, reflecting the 120-day life span of red blood cells. All of these cell types are produced by primitive cells termed *stem cells*, which are present in the bone marrow of adult mammals.

The production of all the cell types except lymphocytes is usually very efficient, and production is controlled largely by negative feedback. When demand for production of cells of a particular lineage increases or peripheral levels of the cells fall, stimulatory cytokines are released and generate new cells with a time delay of a few days, or the time required for maturation from stem cell precursors. By contrast, production of lymphocytes is highly inefficient. Each day many more cells are generated than are required in the periphery. Most lymphocytes are destroyed during development; this is due at least in part to the destruction of cells that express antigen receptors specific for self antigens.

HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells are characterized by extensive proliferation and differentiation capacity, with the ability to self-renew on a population basis (Fig. 104-1). They also express a variety of cell-surface proteins and have the ability to rapidly "home" to bone marrow after intravenous injection. Human stem cells lack markers of lineage commitment (i.e., lineage-negative) and express c-Kit, c-mpl, and usually cluster of differentiation determinant-34 (CD34); a small subset of stem cells may be CD34-negative. Murine cells are also lineage-negative and express c-Kit, CD34, c-mpl, and Ly6A or Sca. The most primitive cells are characterized by low-level expression of a relatively large number of cytokine receptors and by relative exclusion (or pumping out) of the dyes rhodamine and Hoechst. These cells express a variety of adhesion proteins presumptively involved in marrow homing, including alpha$_4$, alpha$_5$, alpha$_6$, L-selectin, and platelet/endothelial cell adhesion molecule (PECAM) (Fig. 104-2). Another characteristic of the stem cell is a functional plasticity in response to cytokines as it transits the cell cycle (Fig. 104-3). Engraftment capacity is good in G_1 but virtually lost in late S and early G_2.

The stem cell is also a highly mobile cell with the capacity to evolve rapidly or involute pseudopodial extensions. The gold standard for defining the stem cell has been in vivo repopulation and long-term reconstitution of lethally irradiated mice. In vivo repopulation studies using unique radiation-induced chromosomal abnormalities or retroviral markers have shown that one or, at most, a few stem cells are capable of reconstituting the entire lymphohematopoietic system of a mouse; they also have defined classes of stem cells with short, medium, or long-term repopulating capacity. These are cell types that differ in the kinetics of hematopoietic reconstitution. Short-term cells repopulate in the first few weeks after transplantation but are not long-lasting; long-term cells account for long-lived reconstitution beginning a few months after reconstitution and lasting the entire life span; medium-term cells bridge the time between short- and long-term cells. When relatively small numbers of marked stem cells -- obtained by limiting dilution of sorted marrow cells -- are transplanted, lymphohematopoiesis may be clonal or oligoclonal, initially. Normal polyclonal lymphohematopoiesis derives from a relatively large number of clones. Both competitive marrow repopulation and mathematical studies support the model of polyclonal hematopoiesis. The most primitive long-term repopulating cells on activation with cytokines can rapidly alter phenotype and become short-term repopulating cells.

While stable multilineage chimerism has been documented in humans after clinical marrow transplantation, no assay system exists for human stem cell activity. A number of surrogate assays are used for the long-term, multilineage-repopulating cell in both humans and mice. These include the multifactor-responsive, high-proliferative potential colony-forming cells (HPP-CFC) and variations of stromal-based assays including the cobblestone-forming cell, long-term culture-initiating cell (LTC-IC) or LTC-IC-extended (LTC-IC-e). The adequacy of these assays is still the subject of debate. In addition, the NOD-SCID immunodeficient mouse has become a surrogate model for assaying human hematopoietic stem cells, although lineage skewing and variability of engraftment undermine its reliability.

LINEAGE PLASTICITY OF STEM CELLS

Tissue stem cells are capable of producing a wide variety of differentiated cell lineages, depending on intrinsic cell programming and the microenvironmental signals. Marrow cells may differentiate into mesenchymal, myocyte, endothelial, hematopoietic, and neural cells. Neural muscle and hepatic stem cells have been reported to give rise to hematopoiesis in transplanted mice. The regulation of stem cell plasticity and life span remains incompletely understood. However, once a particular set of transcription factors has been induced, either through an intrinsic program or from extracellular signals, reversibility is limited. The sequentially ordered activation of transcription factors leads to lineage commitment.

MICROENVIRONMENT

Nonhematopoietic tissues exert major influences on hematopoiesis, both short- and long-range. The nonhematopoietic tissues immediately abutting hematopoietic tissue have been termed the hematopoietic microenvironment, and the cells that comprise the environment influence hematopoiesis. For example, a surface location of adoptively transferred murine stem cells in the spleen of lethally irradiated mice favored

erythropoiesis, while an intrasplenic trabecular location was biased toward granulocyte production. In both human and murine species, various cell types have been identified in stroma, including hematopoietically derived macrophages and nonhematopoietic preadipocytic fibroblasts, endothelial cells, and vascular smooth muscle. This system appears capable of supporting the most primitive stem cells and controlling their proliferation and self-renewal. Most stem cells are resting under normal physiologic conditions but can be recruited into the cell cycle by demands of increased terminally differentiated hematopoietic cells. Cell-cell contact is critical in determining the microenvironment stimulus. Stem cells and primitive cells bind tightly to the stroma, while maturing precursors and terminally differentiated cells are nonadherent. Blocking interactions between stem cells and stromal cells with antibodies to vascular cell adhesion molecule (VCAM)-1 on stromal cells or its ligand, VLA-4, on stem cells block the interaction. Cytokine receptors binding to membrane-associated cytokines like stem cell factor, or to extracellular matrix-bound ligands, contribute other adhesive interactions.

PROGENITORS

Bone marrow stem cells can be induced to proliferate and differentiate into a wide variety of mature cell types in vitro in the presence of an appropriate colony-stimulating factor (CSF). Cells that give rise to mature colonies of granulocytes and macrophages are called granulocyte-macrophage colony-forming units (CFU-GM) (Fig. 104-4). The particular hematopoietic growth factor that stimulates the development of these colonies is called granulocyte-macrophage colony-stimulating factor (GM-CSF). Distinct culture conditions and supplemental growth factors, alone and in combination, are capable of producing a range of cell expansions from multilineage colonies that include lymphocytes to single-lineage clones. The different stem/progenitor clones are summarized in Table 104-1. Progenitor cells in general are found to have a higher proliferative rate and more lineage restriction than stem cells. They are also responsive to smaller numbers of cytokines. Thus, they are defined by expression of a limited variety of cytokine receptors.

The size of the colonies denotes the activity of cells at different stages of differentiation. Terminally acting cytokines produce smaller colonies called CFU (colony-forming units). When progenitors are stimulated with mixtures of early- and late-acting cytokines and are cultured for longer periods of time, the colonies are larger and multiple lineages are represented. Primitive multifactor-responsive erythroid colonies are termed burst-forming unit erythroid (BFU-E) while even more primitive colonies with great proliferative potential are termed HPP-CFC.

CYTOKINES

The lymphohematopoietic stem/progenitor populations and their progeny are largely defined by their cytokine responsiveness and cytokine receptor phenotype. Major efforts to define the regulators of granulocyte, erythroid, and platelet production have culminated in the definitions of a variety of glycoproteins. Acting through cell surface receptors at very low concentrations, these glycoproteins control the production of stem cells in vivo. Most prominent have been erythropoietin for red blood cells,GM-CSFfor granulocytes and macrophages, granulocyte-CSF (G-CSF) for granulocytes, and

thrombopoietin for platelets. In addition, macrophage-CSFor CSF-1, was defined as a primary regulator of macrophage-monocyte production and function. These cytokines exert prominent actions on specific cell lineages, but all exert actions on different cell lineages or on cells that have the potential to differentiate along more than one lineage.

In addition to the more lineage-restricted cytokines, a large number (perhaps up to 70) act broadly on multiple lineages and at multiple stages of lymphohematopoiesis. They exert effects on renewal, proliferation, survival, and differentiation; these effects may be stimulatory or inhibitory, and the cytokines usually show additive or synergistic effects with other cytokines. The cytokines also modulate intrinsic functions of early stem cells (migration and cell adherence) and promote the effector functions of their terminally differentiated progeny.G-CSFprimes neutrophils to undergo oxidative metabolism in response to formyl-methionyl-leucyl-phenylalanine (fMLF) and enhances cell migration, while interleukin (IL) 3 activates basophils, mast cells, and eosinophils.CSF-1 at low levels supports survival of murine marrow macrophages and at higher levels stimulates protein synthesis, cell division, and various macrophage functions, including antitumor activity, secretion of products of oxygen reduction, and plasminogen activator. CSF-1 also induces secretion of IL-1 from macrophages. Many of the hematopoietically active cytokines induce secretion of other cytokines, either inhibitory or stimulatory, creating multiple cytokine regulatory loops. Transforming growth factor b(TGF-b) is an inhibitory cytokine but also an autocrine factor supporting survival of pluripotent hematopoietic stem cells by blocking G1 to S phase transition. TGF-b conversely shows stimulatory effects on progenitors. Cytokines also modulate adhesion protein and integrin expression on multiple cell types. They exert their effects by interacting with surface-based receptors and initiating second-messenger cascades (see below).

The lymphohematopoietic cytokines can be broadly divided into colony-stimulating factors, erythropoietin, thrombopoietin, the interleukins, the inhibitory cytokines, chemokines that regulate cell migration and activation, and a variety of other hematopoietically active cytokines. A noninclusive overview of these cytokines emphasizing their primary, highlighted, or first-described action is presented in Tables 104-2,104-3and104-4. The general characteristics of cytokines are summarized inTable 104-5.

CYTOKINE RECEPTORS, SIGNAL TRANSDUCTION, AND TRANSCRIPTION FACTORS

Cytokines induce their effects through cell-surface membrane receptors. Several cytokine receptor families have been identified. The hematopoietic receptor family includesIL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9,G-CSF,GM-CSF, and erythropoietin. Common characteristics of this family include four conserved cysteine residues and a WSXWS motif (X is a variable, nonconserved amino acid). Some also have immunoglobulin-like structures in their extracellular domains. Receptors frequently consist of multiple chains, and dimerization on cytokine binding is a usual feature of receptor biology. These receptors have no intrinsic signaling capacity and transmit signals by attaching to intracellular signaling molecules, such as the src family and the JAK family kinases. GM-CSF, IL-3, and IL-5 receptors have low-affinity alpha chains and a common high-affinity beta chain. The common beta chain may play a role in the competitive binding of these ligands.

Receptors for FLT-3 ligand, c-kit, platelet-derived growth factor (PDGF),CSF-1, and thrombopoietin constitute the tyrosine kinase receptor family. These receptors have conserved cysteines in the extracellular domain, with tyrosine kinase activity in the cytoplasmic domain, an immunoglobulin-like structure involved in ligand, and binding. Chemokine receptors are seven-transmembrane (serpin) G-protein linked receptors that signal cell activation and migration.

Cytokines typically cause receptor oligomerization on hematopoietic cells, followed by activation of intrinsic (receptor) or extrinsic tyrosine kinases, phosphorylation of the receptor and recruitment of Src-homology (SH2), and phospho-tyrosine binding (PT3) domain proteins to the receptor. Subsequent steps vary with different cytokines but essentially represent a series of phosphorylation-dephosphorylation events, with the final activation or nuclear translocation of a protein or protein complex that binds specific regions of DNA and initiates various genetic programs (i.e., acts as a transcription factor).

The complexity of these second-messenger signaling systems is illustrated by signaling through theGM-CSF,IL-3, and IL-5 receptors, which share a common beta chain. The beta chain does not have kinase activity but induces tyrosine phosphorylation of itself and a number of cytoplasmic proteins, including kinases, such as P1-3 kinase; adapters illustrated by Grb2; the insulin receptor-substrate 2 Cbl and Shc; guanine nucleotide exchange factors such as Vav; phosphastases such asSH2-domain protein tyrosine phosphatase-2 and SH2-containing inositol phosphatase; and transcription factors such as STAT 5.

Receptor phosphorylation is mediated by receptor-associated kinases, such as JAK2 (Janus family kinase 2, named Janus for the Roman god who guards the gates and looks in two directions; original Janus kinases were felt to have both tyrosine and serine kinase activity) and Src-family kinases. These sequential protein interactions lead to the evolution of proteins or protein complexes, termed *transcription factors*, that bind to specific regions of DNA to initiate genetic programs determining survival, proliferation, differentiation, and function.

As with second messengers, the transcription factor field is complex and evolving, but a number of transcription factors associated with specific stem cell levels or differentiation pathways have been described. Transcription factors that act at the earliest stem cell levels include c-myb, p45-NF-E2, GATA-2, AML-1 and tal-1/SCL, while Ikaros and PU-1 may act at the earliest lymphoid level. GATA-1 influences erythroid, mast cell, and megakaryocyte lineages, while FOG (friend of GATA-1) acts in concert with GATA-1. PU-1 appears to influence granulocyte and monocyte differentiation, P45-NF-E2 affects megakaryocyte lineages, and PAX-5 B lymphoid development. These transcription factors usually act in complexes with specific conformations binding to particular DNA sequences.

MIGRATION HOMING AND ADHESION PROTEINS

The process of stem cell homing to the marrow is complex and involves a number of adhesion proteins. Very late antigen (VLA) 4, VLA-5, VLA-6,PECAM, P- and E-selectin,

CD44, CXCR, and a receptor for ligand-bearing galactosyl and mannosyl residues have been shown to be expressed by hematopoietic stem/progenitor cells and implicated in marrow homing. The integrins α_4 and/or α_5 are expressed on immature blasts, erythroid progenitors, monocytes, and CD34+ cells; in general, expression of α_4 appears to decrease with maturation. Hematopoietic cells also bind differentially to different extracellular matrix components: erythroid cells to fibronectin, CFU-GM and BFU-E to collagen.

Antibody to VLA-4 given in vivo causes mobilization of hematopoietic progenitors in normal or cytokine-treated primates and/or mice. Stem cell mobilization by cytokines involves down regulation of adhesion protein expression on hematopoietic stem cells. The cell-cycle related fluctuations in engraftment appear to be based on alterations on different surface adhesion proteins. The stem cells are highly motile and move in a direction of cytokine or chemokine gradients with steel factor and stromal-derived factor 1 (SDF-1) being active. Adhesion proteins act not only for motility/adhesion, but also serve a regulatory role that is similar in some cases to traditional cytokines.

PHYSIOLOGY OF HEMATOPOIESIS AND SOURCES OF CYTOKINES

Erythropoietin is produced largely by the kidney in response to tissue hypoxia. The regulation of granulocyte and monocyte production is more complex, but appears to be in response to various infectious or noxious agents, such as gram-negative bacteria, the endotoxin in the cell wall of these bacteria, and antigen stimulation. All of these interact with peripheral tissue cells to generate a variety of cytokine messages, resulting in increase production in specific cell types. Parasitic infections appear to elicit IL-5, which modulates the eosinophilia and mast cell lineages. Viral infections have specific effects on lymphocyte classes; typically bacterial infections stimulate granulocyte production. Tuberculosis or other mycobacterial infections predominantly induce increased monocyte production. All of these biologic affects appear to be mediated by the selective evolution of cytokine complexes from tissue endothelial cells, fibroblasts, macrophages, and lymphocytes. Most cells produce a large variety of cytokines, but the key is the relative levels, combinations, and timing of the production of these cytokines (Fig. 104-5).

HEMATOPOIETIC STEM CELL AND CYTOKINE DISEASES

The classic stem cell disease is *chronic myeloid leukemia*. Here a specific genetic translocation between chromosomes 9 and 22 at the stem cell level leads to excess production of granulocytes, monocytes, basophils, frequently platelets, and less frequently red cells. Other lymphohematopoietic clonal stem cell diseases include polycythemia vera, myelofibrosis with myeloid metaplasia, paroxysmal nocturnal hemoglobinuria, and acute myeloid leukemia. Out of the scope of this chapter, but relevant to these discussions, is the fact that many lymphoid neoplasms are clonal diseases at early stages of development, but probably not at the mature stage suggested by the tumor cell-surface phenotype. The vast majority of peripheral B cell and T cell malignancies have genetic lesions associated with receptor gene rearrangements, which occur early in lymphoid cell development. Aplastic anemia appears to be a disease characterized by a defective number of hematopoietic stem cells. Cyclic hematopoiesis is another disease of hematopoietic stem cells. In gray collie

dogs with this disorder, levels of platelets, reticulocytes, monocytes, and granulocytes cycle. This disease can be cured or transmitted by marrow transplantation. The human disease, cyclical neutropenia -- or cyclic hematopoiesis in which blood cells oscillate with a 21-day period -- is caused by missense and splicing mutations in the gene encoding neutrophil elastase, thus implicating this inflammatory chymotryptic serine protease in the oscillatory timing of hematopoiesis. The stem cell diseases are summarized inTable 104-6.

A number of cytokine disorders or diseases have now been defined. The best characterized is the anemia of renal failure, an erythropoietin deficiency state that can be corrected by the administration of erythropoietin. Various tumors, particularly lung cancer, increase peripheral granulocyte counts secondary to the production ofG-CSF. The IL-6 family of cytokines appears to be prominently involved in a number of inflammatory states, causes the systemic symptoms associated with Castleman's disease and atrial myxoma, and may be an etiologic factor in multiple myeloma. IL-6 may also be a major cause of symptoms in various lymphomas. Abnormalities of the c-Kit receptor may underlie a number of mast cell diseases in humans; IL-5 production is the proximate cause of a number of eosinophilic states. A deficiency of IL-1 is a feature of aplastic anemia. Mutations in the G-CSF receptor in chronic congenital neutropenia (Kostmann's syndrome) may be a causative factor in the evolution of acute myeloid leukemia in some of these patients.

THERAPEUTIC IMPLICATIONS OF STEM CELLS AND CYTOKINES

Stem Cells Stem cell transplantation was first established as an effective therapy for relapsed acute myeloid leukemia and aplastic anemia. It is now a mainstay of therapy for virtually all leukemias and some relapsed lymphomas. Application of this treatment to a number of solid tumors has been disappointing. Major expectations with regard to its potential in breast cancer have not yet been fulfilled, although it appears to be effective in relapsed testicular cancer. The rationale is the use of very high doses of drugs or radiation designed to kill all tumor cells, but at levels where marrow toxicity would be lethal. Marrow damage is the dose-limiting toxicity for many chemotherapeutic agents. If marrow function is replaced by transplant, it might be possible to increase the dose of chemotherapy substantially before another organ toxicity becomes dose-limiting.

The strategy is somewhat different in intrinsic marrow diseases, such as aplastic anemia, where marrow function is restored without the need for killing tumor cells, or in genetic marrow diseases such as thalassemia and sickle cell anemia, where replacement of the abnormal marrow with normal marrow corrects the disease state. Aggressive autoimmune diseases are also being treated with marrow replacement. Stem cells can come from a related or unrelated allogeneic source or directly from the patient. The sources of the stem cells also vary. Initially, marrow aspirate was the predominant source, but now apheresed peripheral blood stem cells are the most utilized. In addition, umbilical vein cord blood, especially in pediatric patients, appears effective. Numbers of cells are sometimes limiting for adult recipients (Chap 115).

Cytokines Demonstration that hematopoietic cytokines could modulate red blood cell and white cell production in humans has been useful in some clinical settings.

Erythropoietin treatment improves hematocrit and quality of life in patients with chronic renal failure. Erythropoietin has been tried in myelodysplastic syndromes (MDS), a group of clonal stem cell disorders. Meta-analysis shows an overall response rate of only 13%; the actual overall clinical benefit was exceedingly small. In addition, the best results were seen in patients receiving daily injections. Prohibitive costs and often poor response limits use to those patients with serum EPO levels lower than 500 mU/L, and less than 5% myeloblasts. The utilization of erythropoietin in other settings than renal failure remains controversial and its use may relate more to effective marketing than to the science.

These concerns are multiplied for the use of the myeloid growth factors,G-CSF, andGM-CSF. These agents elevate neutrophil and monocyte counts, and under very selective conditions they can result in a reduced toxicity of various chemotherapeutic regimens (Table 104-7). Unfortunately, they save about the same amount of money in hospitalizations for febrile neutropenia as they cost, and their use has not increased survival rate. Virtually all of the G-CSF and GM-CSF trials in cancer patients have been flawed by design; they involve escalation of drugs to toxic levels and reversal of toxicity without addressing the question of whether the patient's survival is affected by the treatment. GM-CSF and G-CSF are grossly overutilized; they are often used in settings where their efficacy has not been shown (e.g., patients with a low probability of neutropenia). Their use should still be considered experimental, and they should continue to be studied in a protocol setting but not used routinely. G-CSF is useful in mobilization of stem cells, and it is also effective in treatment of various chronic neutropenias, in particular cyclic neutropenia and Kostmann's syndrome. G-CSF may be involved in the evolution to acute myeloid leukemia in some patients, but overall it appears to be an effective intervention in these seriously ill patients. G-CSF may also aid in healing of diabetic skin ulcers.

IL-11 and thrombopoietin can elevate platelet counts in experimental animals, but their place in clinical practice is unclear. IL-11 has been approved for use in chemotherapy-induced thrombocytopenia, but its effects are small. Use of pegylated recombinant human megakaryocyte growth and development factor -- the truncated version of thrombopoietin -- has resulted in production of neutralizing antithrombopoietin antibodies and thrombocytopenia. Recombinant human thrombopoietin does not commonly elicit neutralizing antithrombopoietin antibodies. Clinical benefit (or cost effectiveness) has not yet been shown with thrombopoietin. Surrogate values of platelet counts or number of platelet transfusions are not valid criteria for clinical benefit. Thrombopoietin may eventually find a role as an expander of early stem cells in vitro. Active research in this important area continues.

Gene Therapy Hematopoietic stem cells provide an ideal vehicle for various gene therapy approaches. These cells can be easily induced into the cell cycle for retroviral integration. Long-term expression of introduced genes is currently being obtained in animal models. Initial clinical application has been disappointing, but success has been obtained in Gaucher's disease, suggesting that gene therapy will eventually become a successful approach to a number of hematopoietic diseases.

ACKNOWLEDGEMENT

Dr. Francis Ruscetti and Dr. Jonathan Keller contributed this chapter in the 14th

edition and portions of their chapter have been retained here.

105. IRON DEFICIENCY AND OTHER HYPOPROLIFERATIVE ANEMIAS - *John W. Adamson*

Anemias associated with normocytic and normochromic red cells and an inappropriately low reticulocyte response (reticulocyte index <2.5) are *hypoproliferative anemias*. This category includes early iron deficiency (before hypochromic microcytic red cells develop), acute and chronic inflammation (including many malignancies), renal disease, hypometabolic states such as protein malnutrition and endocrine deficiencies, and anemias from marrow damage. Marrow damage states are discussed in Chap. 109. Hypoproliferative anemias are the most common anemias and anemia associated with acute and chronic inflammation is the most common of these. The anemia of acute and chronic inflammation, like iron deficiency, is related in part to abnormal iron metabolism. The anemias associated with renal disease, inflammation, cancer, and hypometabolic states are characterized by an abnormal erythropoietin response to anemia.

IRON METABOLISM

Iron is a critical element in the function of all cells, although the amount of iron required by individual tissues varies during development. At the same time, the body must protect itself from free iron, which is highly toxic in that it participates in chemical reactions that generate free radicals such as singlet O_2 or OH^-. Consequently, elaborate mechanisms have evolved that allow iron to be made available for critical physiologic functions while at the same time conserving this element and handling it in such a way that toxicity is avoided.

The major role of iron in mammals is to carry O_2 as part of the heme protein that, in turn, is part of hemoglobin. O_2 also is bound by a heme protein in muscle, myoglobin. Iron also is a critical element in iron-containing enzymes, including the cytochrome system in mitochondria. Iron distribution in the body is shown in Table 105-1. Without iron, cells lose their capacity for electron transport and energy metabolism; in erythroid cells hemoglobin synthesis is impaired, resulting in anemia and reduced O_2 delivery to tissue.

THE IRON CYCLE IN HUMANS

Figure 105-1 outlines the major pathways of internal iron exchange in humans. Iron absorbed from the diet or released from stores circulates in the plasma bound to *transferrin*, the iron transport protein. Transferrin is a bilobed glycoprotein with two iron binding sites. Transferrin that carries iron exists in two forms -- *monoferric* (one iron atom) or *diferric* (two iron atoms). The turnover (half-clearance time) of transferrin-bound iron is very rapid -- typically 60 to 90 min. Because the overwhelming majority of iron transported by transferrin is delivered to the erythroid marrow, the clearance time of transferrin-bound iron from the circulation is affected most by the plasma iron level and the activity of the erythroid marrow. When erythropoiesis is markedly stimulated, the pool of erythroid cells requiring iron increases and the clearance time of iron from the circulation decreases. The half-clearance time of iron in the presence of iron deficiency is as short as 10-15 min; this value reflects the limits of iron delivery as a function of the cardiac output going to the bone marrow. With suppression of the erythroid marrow, the plasma iron level typically is increased and the half-clearance time is prolonged to as much as several hours. Normally, the iron bound

to transferrin turns over 10 to 20 times per day. Assuming a normal plasma iron level of 80 to 100 ug/dL, the amount of iron passing through the transferrin pool is 20 to 24 mg/d.

The iron-transferrin complex circulates in the plasma until the iron-carrying transferrin interacts with specific *transferrin receptors* on the surface of marrow erythroid cells. Diferric transferrin has the highest affinity for transferrin receptors; apotransferrin (transferrin not carrying iron) has very little affinity. While transferrin receptors are found on cells in many tissues within the body -- and all cells at some time during development will display transferrin receptors -- the cell having the greatest number of receptors (300,000 to 400,000/cell) is the developing erythroblast.

Once the iron-bearing transferrin interacts with its receptor, the iron-transferrin-receptor complex is internalized via clathrin-coated pits and transported to an acidic endosome, where the iron is released at the low pH. The iron is then made available for heme synthesis while the transferrin-receptor complex is recycled to the surface of the cell, where the bulk of the transferrin is released back into the circulation and the transferrin receptor reanchors into the cell membrane. At this point a certain amount of the transferrin receptor protein may be released into circulation. Within the erythroid cell, iron that is in excess of the amount needed for hemoglobin synthesis binds to a storage protein, *apoferritin*, forming *ferritin*. This mechanism of iron exchange also takes place in other cells of the body expressing transferrin receptors, especially liver parenchymal cells where the iron can be incorporated into heme-containing enzymes or stored. The iron incorporated into hemoglobin subsequently enters the circulation as new red cells are released from the bone marrow. The iron is then part of the red cell mass and will not become available for reutilization until the red cell dies.

In a normal individual, the average red cell life span is 120 days. Thus, 0.8 to 1.0% of red cells turn over each day. At the end of its life span, the red cell is recognized as senescent by the cells of the *reticuloendothelial (RE) system*, and the cell undergoes phagocytosis. Once within the RE cell, the hemoglobin from the ingested red cell is broken down, the globin and other proteins are returned to the amino acid pool, and the iron is shuttled back to the surface of the RE cell, where it is presented to circulating transferrin. The "harvesting" of iron from senescent red cells is both efficient and rapid, with newly recycled iron appearing in the circulation within 10 min of ingestion of the red cell. It is the efficient and highly conserved recycling of iron from senescent red cells that supports steady state (and even mildly accelerated) erythropoiesis.

Since each milliliter of red cells contains 1 mg of elemental iron, the amount of iron needed to replace those red cells lost through senescence amounts to 16 to 20 mg/day (assuming an adult with a red cell mass of 2 L). Any additional iron required for daily red cell production comes from the diet. Normally, an adult male will need to absorb at least 1 mg of elemental iron daily to meet needs, while females in the childbearing years will need to absorb an average of 1.4 mg/d. However, to achieve a maximum proliferative erythroid marrow response to anemia, additional iron must be available. With markedly stimulated erythropoiesis, demands for iron are increased by as much as six- to eightfold. With hemolytic anemias, the rate of red cell destruction is increased, but the iron recovered from the red cells is efficiently reutilized for hemoglobin synthesis. In contrast, with blood loss anemia the rate of red cell production is limited by the amount

of iron that can be mobilized from ferritin and hemosiderin stores. Typically, the rate of mobilization under these circumstances will not support red cell production more than 2.5 to 3 times normal. If the delivery of iron to the stimulated marrow is suboptimal, the marrow's proliferative response is blunted and normal hemoglobin synthesis is impaired. The result is a hypoproliferative marrow accompanied by microcytic, hypochromic anemia.

While blood loss or hemolysis places a demand for iron to be supplied to the erythroid marrow, other conditions such as inflammation interfere with iron release from stores and can result in a rapid decrease in the serum iron (see below).

NUTRITIONAL IRON BALANCE

The balance of iron metabolism in the organism is tightly controlled and designed to conserve iron for reutilization. There is no excretory pathway for iron, and the only mechanisms by which iron is lost from the body are blood loss (via gastrointestinal bleeding, menses, or other forms of bleeding) and the loss of epidermal cells from the skin and gut. Normally, the only route by which iron comes into the body is via absorption from food (dietary iron intake) or from medicinal iron taken orally. Iron may also enter the body through red cell transfusions or injection of iron complexes. The margin between the amount of iron available for absorption and the requirement for iron in growing infants and the adult female is narrow. The narrowness of this margin accounts for the great prevalence of iron deficiency worldwide -- currently estimated at one-half billion people.

External iron exchange -- the amount of iron required from the diet to replace losses -- averages about 10% of body iron content a year in the male and 15% in women of childbearing age, equivalent to 1.0 and 1.4 mg of elemental iron daily, respectively. Dietary iron content is closely related to total caloric intake (approximately 6 mg of elemental iron per 1000 calories). Iron bioavailability is affected by the nature of the foodstuff with heme iron (e.g., red meat) being most readily absorbed. In the United States, the average iron intake in an adult male is 15 mg/d with 6% absorption; for the average female, the daily intake is 11 mg/d with 12% absorption. An individual with iron deficiency can increase iron absorption to about 20% of the iron present in a meat-containing diet but only 5 to 10% of the iron in a vegetarian diet. As a result, nearly one-third of the female population in the United States has virtually no iron stores. Vegetarians are at an additional disadvantage because certain foodstuffs that include phytates and phosphates reduce iron absorption by about 50%. When ionizable iron salts are given together with food, the amount of iron absorbed is reduced. This is particularly true with iron in the ferric state. When the percentage of iron absorbed from individual food items is compared with the percentage for an equivalent amount of ferrous salt, iron in vegetables is only about one-twentieth as available, egg iron one-eighth, liver iron one-half, and heme iron one-half to two-thirds. Therefore, liver and heme iron are absorbed nearly as well as iron salt added to food, while the iron in vegetables and eggs is much less available.

Infants, children, and adolescents may be unable to maintain normal iron balance because of the demands of body growth and lower dietary intake of iron. In pregnancy during the last two trimesters, daily iron requirements increase to 5 to 6 mg. That is the

reason why iron supplements are almost universally prescribed for pregnant women in developed countries. Enthusiasm for supplementing foods such as bread and cereals with iron has waned in the face of concerns that the very prevalent hemochromatosis gene would result in an unacceptable risk of iron overload.

Iron absorption takes place largely in the proximal small intestine and is a carefully regulated process. For absorption, iron must be taken up by the luminal cell. That process is facilitated by the acidic contents of the stomach, which maintains the iron in solution. At the brush border of the absorptive cell, the ferric iron is converted to the ferrous form by a ferrireductase. Transport across the membrane is accomplished by divalent metal transporter 1 (DMT 1, also known as Nramp 2 or DCT 1). DMT 1 is a general cation transporter. Once iron is inside the gut cell, the iron may be stored as ferritin or transported through the cell to be released at the basolateral surface to plasma transferrin. It is likely another transporter acts here in concert with hephaestin, another ferroxidase. Hephaestin is similar to ceruloplasmin, the copper-carrying protein.

Iron absorption is influenced by a number of physiologic states. Erythroid hyperplasia, for example, stimulates iron absorption, even in the face of normal or increased iron stores. Patients with anemias associated with high levels of ineffective erythropoiesis absorb excess amounts of dietary iron. Over time, this may lead to iron overload and tissue damage. In iron deficiency iron is much more efficiently absorbed from a given diet while the contrary is true in the presence of iron overload. This is possibly mediated through signals that become fixed before the jejunal crypt cell migrates up the villus to become an absorptive cell. The normal individual can reduce iron absorption in situations of excessive intake or medicinal iron intake; however, while the percent of iron absorbed goes down, the absolute amount goes up. This accounts for the acute iron toxicity occasionally seen when children ingest large numbers of iron tablets. Under these circumstances, the amount of iron absorbed exceeds the transferrin binding capacity of the plasma, resulting in free iron that affects critical organs such as cardiac muscle cells.

IRON DEFICIENCY ANEMIA

STAGES OF IRON DEFICIENCY

Iron deficiency anemia is the condition in which there is anemia and clear evidence of iron deficiency. However, it is worthwhile to consider the steps by which iron deficiency occurs (Fig. 105-2). These can be divided into three stages. The first stage is *negative iron balance*, in which the demands for (or losses of) iron exceed the body's ability to absorb iron from the diet. This stage can result from a number of physiologic mechanisms including blood loss, pregnancy (in which the demands for red cell production by the fetus outstrip the mother's ability to provide iron), rapid growth spurts in the adolescent, or inadequate dietary iron intake. Most commonly, the growth needs of the fetus or rapidly growing child exceed the individual's ability to absorb the iron necessary for hemoglobin synthesis from the diet. Blood loss in excess of 10 to 20 mL of red cells per day is greater than the amount of iron that the gut can absorb from a normal diet. Under these circumstances the iron deficit must be made up by mobilization of iron fromREstorage sites. During this period measurements of iron stores -- such as the serum ferritin level or the appearance of stainable iron on bone marrow aspirations

-- will decrease. As long as iron stores are present and can be mobilized, the serum iron, total iron-binding capacity (TIBC), and red cell protoporphyrin levels remain within normal limits. At this stage, red cell morphology and indices are normal.

When iron stores become depleted, the serum iron begins to fall. Gradually, theTIBCincreases, as do red cell protoporphyrin levels. By definition, marrow iron stores are absent when the serum ferritin level <15 ug/L. As long as the serum iron remains within the normal range, hemoglobin synthesis is unaffected despite the dwindling iron stores. Once the transferrin saturation falls to 15 to 20%, hemoglobin synthesis becomes impaired. This is a period of *iron-deficient erythropoiesis*. Careful evaluation of the peripheral blood smear reveals the first appearance of microcytic cells, and if the laboratory technology is available, one finds hypochromic reticulocytes in circulation. Gradually, the hemoglobin and hematocrit begin to fall, reflecting *iron deficiency anemia*. The transferrin saturation at this point is 10 to 15%.

When moderate anemia is present (hemoglobin 10-13 g/dL), the bone marrow remains hypoproliferative. With more severe anemia (hemoglobin 7-8 g/dL), hypochromia and microcytosis become more prominent, misshapen red cells (poikilocytes) appear on the blood smear as cigar or pencil-shaped forms and target cells, and the erythroid marrow becomes increasingly ineffective. Consequently, with severe prolonged iron deficiency anemia, erythroid hyperplasia of the marrow develops rather than hypoproliferation.

CAUSES OF IRON DEFICIENCY

Conditions that increase demand for iron, increase iron loss, or decrease iron intake, absorption, or use can produce iron deficiency (Table 105-2).

CLINICAL PRESENTATION OF IRON DEFICIENCY

Certain clinical conditions carry an increased likelihood of iron deficiency. Pregnancy, adolescence, periods of rapid growth, and an intermittent history of blood loss of any kind should alert the clinician to possible iron deficiency. A cardinal rule is that the appearance of iron deficiency in an adult male means gastrointestinal blood loss until proven otherwise. Signs related to iron deficiency depend upon the severity and chronicity of the anemia in addition to the usual signs of anemia -- fatigue, pallor, and reduced exercise capacity. *Cheilosis* (fissures at the corners of the mouth) and *koilonychia* (spooning of the fingernails) are signs of advanced tissue iron deficiency. The diagnosis of iron deficiency is typically based on laboratory results.

LABORATORY IRON STUDIES

Serum Iron and Total Iron-Binding Capacity The serum iron level represents the amount of circulating iron bound to transferrin. TheTIBC is an indirect measure of the circulating transferrin. The normal range for the serum iron is 50 to 150 ug/dL; the normal range for TIBC is 300 to 360 ug/dL. Transferrin saturation, which is normally 25 to 50%, is obtained by the following formula: serum iron ´ 100¸ TIBC. Iron deficiency states are associated with saturation levels below 18%. In evaluating the serum iron, the clinician should be aware that there is a diurnal variation in the value. A transferrin saturation rate of >50% indicates that a disproportionate amount of the iron bound to

transferrin is being delivered to nonerythroid tissues. If this condition persists for an extended time, tissue iron overload may occur.

Serum Ferritin Free iron is toxic to cells, and the body has established an elaborate set of protective mechanisms to bind iron in various tissue compartments. Within cells, iron is stored complexed to protein as ferritin or hemosiderin. Apoferritin binds to free ferrous iron and stores it in the ferric state. As ferritin accumulates within cells of theREsystem, protein aggregates are formed as hemosiderin. Iron in ferritin or hemosiderin can be extracted for release by the RE cells although hemosiderin is less readily available. Under steady state conditions, the serum ferritin level correlates with total body iron stores; thus, the serum ferritin level is the most convenient laboratory test to estimate iron stores. The normal value for ferritin varies according to the age and gender of the individual (Fig. 105-3). Adult males have serum ferritin values averaging about 100 ug/L, while adult females have levels averaging 30 ug/L. As iron stores are depleted, the serum ferritin falls to<15 ug/L. Such levels are virtually always diagnostic of absent body iron stores.

Evaluation of Bone Marrow Iron Stores AlthoughRE cell iron stores can also be estimated from the iron stain of a bone marrow aspirate or biopsy, the measurement of serum ferritin has largely supplanted bone marrow aspirates for determination of storage iron (Table 105-3). The serum ferritin level is a better indicator of iron overload than the marrow iron stain. However, in addition to storage iron the marrow iron stain provides information about the effective delivery of iron to developing erythroblasts. Normally, 40 to 60% of developing erythroblasts -- called *sideroblasts* -- will have visible ferritin granules in their cytoplasm. This represents iron in excess of that needed for hemoglobin synthesis. In states in which release of iron from storage sites is blocked, RE iron will be detectable, and there will be few or no sideroblasts. In the myelodysplastic syndromes, mitochondrial dysfunction occurs, and accumulation of iron in mitochondria appears in a necklace fashion around the nucleus of the erythroblast. Such cells are referred to as *ringed sideroblasts*.

Red Cell Protoporphyrin Levels Protoporphyrin is an intermediate in the pathway to heme synthesis. Under conditions in which heme synthesis is impaired, protoporphyrin accumulates within the red cell. This can reflect an inadequate iron supply to erythroid precursors to support hemoglobin synthesis. Normal values are less than 30 ug/dL of red cells. In iron deficiency, values in excess of 100 ug/dL are seen. The most common causes of increased red cell protoporphyrin levels are absolute or relative iron deficiency and lead poisoning.

Serum Levels of Transferrin Receptor Protein Because erythroid cells have the highest numbers of transferrin receptors on their surface of any cell in the body, and because transferrin receptor protein (TRP) is released by cells into the circulation, serum levels of TRP reflect the total erythroid marrow mass. Another condition in which TRP levels are elevated is absolute iron deficiency. Normal values are 4 to 9 ug/L determined by immunoassay. This laboratory test is becoming increasingly available and has been proposed to measure the serial expansion of the erythroid marrow in response to recombinant erythropoietin therapy.

DIFFERENTIAL DIAGNOSIS

Other than iron deficiency, only three conditions need to be considered in the differential diagnosis of a hypochromic microcytic anemia (Table 105-4). The first is inherited defects in globin chain synthesis: the thalassemias. These are differentiated from iron deficiency most readily by serum iron values, since it is characteristic to have at least normal -- if not increased -- serum iron levels and transferrin saturation with the thalassemias.

The second condition is chronic inflammatory disease with inadequate iron supply to the erythroid marrow. The distinction between true iron deficiency anemia and the anemia associated with chronic inflammatory states is among the most common diagnostic problems encountered by clinicians (see below). Usually the anemia of chronic disease is normocytic and normochromic. Again, the iron values usually make the differential diagnosis clear, as the ferritin level is normal or increased and theTIBC is typically below normal.

Finally, the myelodysplastic syndromes comprise the third condition. Some patients with myelodysplasia have impaired hemoglobin synthesis with mitochondrial dysfunction resulting in impaired iron incorporation into heme. The iron values again reveal normal stores and more than an adequate supply to the marrow, despite the microcytosis and hypochromia.

TREATMENT

The severity and cause of iron deficiency anemia will determine the appropriate approach to treatment. As an example, symptomatic elderly patients with severe iron deficiency anemia and cardiovascular instability may require red cell transfusions. Younger individuals who have compensated for their anemia can be treated more conservatively with iron replacement. The foremost issue for the latter patient is the precise identification of the cause of the iron deficiency.

For the majority of cases of iron deficiency (pregnant women, growing children and adolescents, patients with infrequent episodes of bleeding, and those with inadequate dietary intake of iron), oral iron therapy will suffice. For patients with unusual blood loss or malabsorption, specific diagnostic tests and appropriate therapy take priority. Once the diagnosis of iron deficiency anemia and its cause is made, and a therapeutic approach is charted, there are three major approaches.

Red Cell Transfusion Transfusion therapy is reserved for those individuals who have symptoms of anemia, cardiovascular instability, and continued and excessive blood loss from whatever source, and those who require immediate intervention. The management of these patients is less related to the iron deficiency than it is to the consequences of the severe anemia. Not only do transfusions correct the anemia acutely, but the transfused red cells provide a source of iron for reutilization, assuming they are not lost through continued bleeding. Transfusion therapy will stabilize the patient while other options are reviewed.

Oral Iron Therapy In the patient with established iron deficiency anemia who is asymptomatic, treatment with oral iron is usually adequate. Multiple preparations are

available ranging from simple iron salts to complex iron compounds designed for sustained release throughout the small intestine (Table 105-5). While the various preparations contain different amounts of iron, they are generally all absorbed well and are effective in treatment. Some come with other compounds designed to enhance iron absorption, such as citric acid. It is not clear whether the benefits of such compounds justify their costs. Typically, for iron replacement therapy up to 300 mg of elemental iron per day is given, usually as three or four iron tablets (each containing 50 to 65 mg elemental iron) given over the course of the day. Ideally, oral iron preparations should be taken on an empty stomach, since foods may inhibit iron absorption. Some patients with gastric disease or prior gastric surgery require special treatment with iron solutions, since the retention capacity of the stomach may be reduced. The retention capacity is necessary for dissolving the shell of the iron tablet before the release of iron. A dose of 200 to 300 mg of elemental iron per day should result in the absorption of up to 50 mg of iron per day. This supports a red cell production level of two to three times normal in an individual with a normally functioning marrow and appropriate erythropoietin stimulus. However, as the hemoglobin level rises, erythropoietin stimulation decreases, and the amount of iron absorbed is reduced. The goal of therapy in individuals with iron deficiency anemia is not only to repair the anemia, but also to provide stores of at least 1/2 to 1 g of iron. Sustained treatment for a period of 6 to 12 months after correction of the anemia will be necessary to achieve this.

Of the complications of oral iron therapy, gastrointestinal distress is the most prominent and is seen in 15 to 20% of patients. For these patients, abdominal pain, nausea, vomiting, or constipation often lead to noncompliance. Although small doses of iron or iron preparations with delayed release may help somewhat, the gastrointestinal side effects are a major impediment to the effective treatment of a number of patients.

The response to iron therapy varies, depending upon the erythropoietin stimulus and the rate of absorption. Typically, the reticulocyte count should begin to increase within 4 to 7 days after initiation of therapy and peak at 1 1/2 weeks. The absence of a response may be due to poor adsorption, noncompliance (which is common), or a confounding diagnosis. If iron deficiency persists, it may be necessary to switch to parenteral iron therapy.

Parenteral Iron Therapy Intramuscular or intravenous iron can be given to patients who are unable to tolerate oral iron, whose needs are relatively acute, or who need iron on an ongoing basis, usually due to persistent gastrointestinal blood loss. Currently, the intravenous route is used routinely. Parenteral iron use has been rising rapidly in the last several years with the recognition that recombinant erythropoietin therapy induces a large demand for iron -- a demand that frequently cannot be met through the physiologic release of iron from RE sources. Concern has been raised about the safety of parenteral iron -- particularly iron dextran. The serious adverse reaction rate to intravenous iron dextran is 0.7%. Fortunately, newer iron complexes are becoming available in the United States that are likely to have an even lower rate of adverse effects. The most recently approved preparation is intravenous iron gluconate (Ferrlecit).

There are two approaches to the use of parenteral iron: one is to administer the total dose of iron required to correct the hemoglobin deficit and provide the patient with at least 500 mg of iron stores; the second is to give repeated small doses of parenteral

iron over a protracted period. The latter approach is common in dialysis centers, where it is not unusual for 100 mg of elemental iron to be given weekly for 10 weeks to augment the erythropoietic response to recombinant erythropoietin therapy. The amount of iron needed by an individual patient is calculated by the following formula: body weight (kg) ´ 2.3´ (15 - patient's hemoglobin, g/dL) + 500 or 1000 mg (for stores).

In administering intravenous iron, anaphylaxis is always a concern. Anaphylaxis is less common with the newer preparations. The factors that have correlated with a serious anaphylactic-like reaction include a history of multiple allergies or a prior allergic reaction to dextran (in the case of iron dextran). Generalized symptoms appearing several days after the infusion of a large dose of iron can include arthralgias, skin rash, and low-grade fever. This may be dose-related, but it does not preclude the further use of parenteral iron in the patient. To date, patients with sensitivity to iron dextran have been safely treated with iron gluconate. If a large dose of iron dextran is to be given (>100 mg) the iron preparation should be diluted in 5% dextrose in water or 0.9% NaCl solution. The iron solution can then be infused over a 60 to 90 min period (for larger doses) or at a rate convenient for the attending nurse or physician. While a test dose (25 mg) of parenteral iron is recommended, in reality a slow infusion of a larger dose of parenteral iron solution will afford the same kind of early warning as a separately injected test dose. Early in the infusion of iron, if chest pain, wheezing, a fall in blood pressure, or other systemic manifestations occur, the infusion of iron -- whether as a large solution or a test dose -- should be interrupted immediately.

OTHER HYPOPROLIFERATIVE ANEMIAS

In addition to mild to moderate iron deficiency anemia, the hypoproliferative anemias can be divided into four categories: (1) chronic inflammation/infection; (2) renal disease; (3) endocrine and nutritional deficiencies (hypometabolic states); and (4) marrow damage (Chap. 109). With chronic inflammation, renal disease, or hypometabolism, endogenous erythropoietin production is inadequate for the degree of anemia observed. For the anemia of chronic inflammation (anemia of chronic disease), the erythroid marrow also responds inadequately to stimulation in part due to defects in iron reutilization. As a result of the lack of adequate erythropoietin stimulation, an examination of the peripheral blood smear will disclose only an occasional polychromatophilic (shift) reticulocyte. In the cases of iron deficiency or marrow damage, appropriate elevations in endogenous erythropoietin levels are typically found, and "shift" reticulocytes will be present on the blood smear.

ANEMIA OF ACUTE AND CHRONIC INFLAMMATION/INFECTION (THE ANEMIA OF CHRONIC DISEASE)

The anemia of chronic disease -- which encompasses inflammation, infection, tissue injury, and conditions associated with the release of proinflammatory cytokines (such as cancer) -- is one of the most common forms of anemia seen clinically and is probably the most important in the differential diagnosis of iron deficiency, since many of the features of the anemia are brought about by inadequate iron delivery to the marrow, despite the presence of normal or increased iron stores. This is reflected by a low serum iron, increased red cell protoporphyrin, a hypoproliferative marrow, transferrin saturation in the range of 15 to 20%, and a normal or increased serum ferritin. The serum ferritin

values are often the most distinguishing feature between true iron deficiency anemia and the iron-deficient erythropoiesis associated with inflammation. Typically, serum ferritin values increase three-fold over basal levels in the face of inflammation. All of these changes are due to the effects of inflammatory cytokines at several levels of erythropoiesis (Fig. 105-4). IL-1 directly decreases erythropoietin production in response to anemia. IL-1, acting through accessory cell release of IFN-g, suppresses the response of the erythroid marrow to erythropoietin -- an effect that can be overcome by increased erythropoietin administration in vitro and in vivo. In addition, tumor necrosis factor (TNF), acting through the release of IFN-b by marrow stromal cells, also suppresses the response to erythropoietin; several of these same cytokines, acting in concert, block the release of iron fromREstorage sites. The overall result is a chronic hypoproliferative anemia with classic changes in iron metabolism. The anemia is further compounded by a mild to moderate shortening in red cell survival.

With chronic inflammation/infection, the primary disease will determine the severity and characteristics of the anemia. For instance, many patients with cancer also have anemia that is typically normocytic and normochromic. In contrast, patients with long-standing active rheumatoid arthritis or chronic infections such as tuberculosis will have a microcytic, hypochromic anemia. In both cases, the bone marrow is hypoproliferative, but the differences in red cell indices reflect differences in the availability of iron for hemoglobin synthesis. Occasionally, conditions associated with chronic inflammation are also associated with chronic blood loss. Under these circumstances, a bone marrow aspirate stained for iron may be necessary to rule out absolute iron deficiency. However, the administration of iron in this case will correct the iron deficiency component of the anemia and leave the inflammatory component unaffected.

The anemia associated with acute infection or inflammation is typically mild, but becomes more pronounced over time. Acute infection can produce a fall in hemoglobin levels of 2 to 3 g/dL within 1 or 2 days; this is largely related to the hemolysis of red cells near the end of their natural life span. The fever and cytokines released exert a selective pressure against cells with more limited capacity to maintain the red cell membrane. In most individuals the mild anemia is reasonably well tolerated, and symptoms, if present, are associated with the underlying disease. Occasionally, in patients with preexisting cardiac disease, moderate anemia (hemoglobin 10-11 g/dL) may be associated with angina, exercise intolerance, and shortness of breath. The red cell indices vary from normocytic, normochromic to microcytic, hypochromic. The serum iron values tend to correlate with the red cell indices. The erythropoietic profile that distinguishes the anemia of inflammation from the other causes of hypoproliferative anemias is shown inTable 105-6.

ANEMIA OF RENAL DISEASE

Chronic renal failure is usually associated with a moderate to severe hypoproliferative anemia; the level of the anemia correlates with the severity of the renal failure. Red cells are typically normocytic and normochromic. Reticulocytes are decreased. The anemia is due to a failure to produce adequate amounts of erythropoietin and a reduction in red cell survival. In certain forms of acute renal failure, the correlation between the anemia and renal function is weaker. Patients with the hemolytic-uremic syndrome increase erythropoiesis in response to the hemolysis, despite renal failure requiring dialysis.

Polycystic renal disease also shows a smaller degree of erythropoietin deficiency for a given level of renal failure. By contrast, patients with diabetes have more severe erythropoietin deficiency for a given level of renal failure.

Assessment of iron status provides information to distinguish the anemia of renal disease from the other forms of hypoproliferative anemia (Table 105-6) and to guide management. Patients with the anemia of renal disease usually present with normal serum iron, TIBC, and ferritin levels. However, those maintained on chronic hemodialysis may develop iron deficiency from blood loss through the dialysis procedure. Iron must be replenished in these patients to ensure an adequate response to erythropoietin therapy (see below).

ANEMIA IN HYPOMETABOLIC STATES

Patients who are starving, particularly for protein, and those with a variety of endocrine disorders that produce lower metabolic rates may develop a mild to moderate hypoproliferative anemia. The release of erythropoietin from the kidney is sensitive to the need for O_2, not just O_2 levels. Thus, erythropoietin production is triggered at lower levels of O_2 tension in disease states (such as hypothyroidism and starvation) where metabolic activity and thus O_2 demand is decreased.

Endocrine Deficiency States The difference in the levels of hemoglobin between men and women is related to the effects of androgen and estrogen on erythropoiesis. Testosterone and anabolic steroids augment erythropoiesis; castration and estrogen administration to males decrease erythropoiesis. Patients who are hypothyroid or have deficits in pituitary hormones also may develop a mild anemia. Pathogenesis may be complicated by other nutritional deficiencies as iron and folic acid absorption can be affected by these disorders. Usually, correction of the hormone deficiency reverses the anemia.

Anemia may be more severe in Addison's disease, depending on the level of thyroid and androgen hormone dysfunction; however, anemia may be masked by decreases in plasma volume. Once such patients are given cortisol and volume replacement, the hemoglobin level may fall rapidly. Mild anemia complicating hyperparathyroidism may be due to decreased erythropoietin production as a consequence of the renal effects of hypercalcemia or to impaired proliferation of erythroid progenitors.

Protein Starvation Decreased dietary intake of protein may lead to mild to moderate hypoproliferative anemia; this form of anemia may be prevalent in the elderly. The anemia can be more severe in patients with a greater degree of starvation. In marasmus, where patients are both protein- and calorie-deficient, the release of erythropoietin is impaired in proportion to the reduction in metabolic rate; however, the degree of anemia may be masked by volume depletion and becomes apparent after refeeding. Deficiencies in other nutrients (iron, folate) may also complicate the clinical picture but may not be apparent at diagnosis. Changes in the erythrocyte indices on refeeding should prompt evaluation of iron, folate, and B_{12} status.

Anemia in Liver Disease A mild hypoproliferative anemia may develop in patients with chronic liver disease from nearly any cause. The peripheral blood smear may show burr

cells and stomatocytes from the accumulation of excess cholesterol in the membrane from a deficiency of lecithin cholesterol acyltransferase. Red cell survival is shortened, and the production of erythropoietin is inadequate to compensate. In alcoholic liver disease, nutritional deficiencies can add complexity to the management. Folate deficiency from inadequate intake and iron deficiency from blood loss and inadequate intake can alter the red cell indices.

TREATMENT

Many patients with hypoproliferative anemias experience recovery of normal hemoglobin levels when the underlying disease is appropriately treated. For those in whom such reversals are not possible -- such as patients with end-stage renal failure, cancer, and chronic inflammatory diseases -- symptomatic anemia requires treatment. The two major forms of treatment are transfusions and erythropoietin.

Transfusions Thresholds for transfusion should be altered based on the patient's symptoms. In general, patients without serious underlying cardiovascular or pulmonary disease can tolerate hemoglobin levels above 8 g/dL and do not require intervention until the hemoglobin falls below that level. Patients with more physiologic compromise may need to have their hemoglobin levels kept above 11 g/dL. A typical unit of packed red cells increases the hemoglobin level by 1 g/dL. Transfusions are associated with certain infectious risks (Chap. 114) and chronic transfusions can produce iron overload.

Erythropoietin Erythropoietin is particularly useful in anemias in which endogenous erythropoietin levels are inappropriately low, such as the hypoproliferative anemias. Iron status must be evaluated and iron repleted to obtain optimal effects from erythropoietin. In patients with chronic renal failure, the usual dose of erythropoietin is 50 to 150 U/kg three times a week subcutaneously. The dose needed to correct the anemia in patients with cancer is higher, up to 300 U/kg three times a week. Hemoglobin levels of 10 to 12 g/dL are usually reached within 4 to 6 weeks if iron levels are adequate. Once a target hemoglobin level is reached, the erythropoietin dose can be decreased to 75 U/kg three times a week. A fall in hemoglobin level occurring in the face of erythropoietin therapy usually signifies the development of an infection or iron depletion. Aluminum toxicity and hyperparathyroidism can also compromise the erythropoietin response. When an infection intervenes, it is best to interrupt the erythropoietin therapy and rely on transfusion to correct the anemia until the infection is adequately treated.

106. HEMOGLOBINOPATHIES - *Edward J. Benz, Jr.*

Hemoglobin is critical for normal oxygen delivery to tissues; it is also present in erythrocytes in such high concentrations that it can alter red cell shape, deformability, and viscosity. Hemoglobinopathies are disorders affecting the structure, function, or production of hemoglobin. These disorders are usually inherited and range in severity from asymptomatic laboratory abnormalities to death in utero. Different forms may present as hemolytic anemia, erythrocytosis, cyanosis, or vasoocclusive stigmata.

PROPERTIES OF THE HUMAN HEMOGLOBINS

HEMOGLOBIN STRUCTURE

Different hemoglobins are produced during embryonic, fetal, and adult life (Fig. 106-1). Each consists of a tetramer of globin polypeptide chains: a pair of a-like chains 141 amino acids long and a pair of b-like chains 146 amino acids long. The major adult hemoglobin, HbA, has the structurea_2b_2. HbF (a_2g_2) predominates during most of gestation, and HbA_2(a_2d_2) is a minor adult hemoglobin.

Each globin chain enfolds a single heme moiety, consisting of a protoporphyrin IX ring complexed with a single iron atom in the ferrous state (Fe^{2+}), positioned in a manner optimal for reversible binding of oxygen. Each heme moiety can bind a single oxygen molecule; every molecule of hemoglobin can thus transport up to four oxygen molecules.

The amino acid sequences of the various globins are highly homologous to one another. Each has a highly helical *secondary structure*. Their globular *tertiary structures* cause the exterior surfaces to be rich in polar (hydrophilic) amino acids that enhance solubility and the interior to be lined with nonpolar groups, forming a hydrophobic "pocket" into which heme is inserted. The tetrameric *quaternary structure* of HbA contains twoab dimers. Numerous tight interactions (i.e.,$a_1b_1$contacts) hold the a and bchains together. The complete tetramer is held together by interfaces (i.e.,$a_1b_2$contacts) between the a-like chain of one dimer and the non-a chain of the other dimer.

The hemoglobin tetramer is highly soluble, but individual globin chains are insoluble. Unpaired globin precipitates, forming inclusions (Heinz bodies) that damage the cell. Normal globin chain synthesis is balanced so that each newly synthesizeda or non-a globin chain will have an available partner with which to pair to form hemoglobin.

Solubility and reversible oxygen binding are the key properties deranged in hemoglobinopathies. Both depend most on the hydrophilic surface amino acids, the hydrophobic amino acids lining the heme pocket, a key histidine in the F helix, and the amino acids forming the$a_1b_1$and$a_1b_2$contact points. Mutations in these strategic regions tend to be the ones that alter clinical behavior.

FUNCTION OF HEMOGLOBIN

To support oxygen transport, hemoglobin must bind O_2efficiently at the partial pressure of oxygen (PO_2) of the alveolus, retain it, and release it to tissues at the PO_2 of tissue

capillary beds. Oxygen acquisition and delivery over a relatively narrow range of oxygen tensions depend on a property inherent in the tetrameric arrangement of heme and globin subunits within the hemoglobin molecule called *cooperativity* or *heme-heme interaction*.

At low oxygen tensions, the hemoglobin tetramer is fully deoxygenated (Fig. 106-2). Oxygen binding begins slowly as O_2tension rises. However, as soon as some oxygen has been bound by the tetramer, an abrupt increase occurs in the slope of the curve. Thus, hemoglobin molecules that have bound some oxygen develop a higher oxygen affinity, greatly accelerating their ability to combine with more oxygen. This S-shaped oxygen equilibrium curve, along which substantial amounts of oxygen loading *and unloading* can occur over a narrow range of oxygen tensions, is physiologically more useful than the high-affinity hyperbolic curve of individual monomers.

Oxygen affinity is modulated by several factors. The Bohr effect arises from the stabilizing action of protons on deoxyhemoglobin, which binds protons more readily than oxyhemoglobin because it is a weaker acid. Thus, hemoglobin has a lower oxygen affinity at low pH, facilitating delivery to tissues (Fig. 106-2). The major small molecule that alters oxygen affinity in humans is 2,3-bisphosphoglycerate (2,3-BPG, formerly 2,3-DPG), which lowers oxygen affinity when bound to hemoglobin. HbA has a reasonably high affinity for 2,3-BPG. HbF does not bind 2,3-BPG, so it tends to have a higher oxygen affinity in vivo. Hemoglobin may also bind nitric oxide reversibly, thereby contributing to vascular tone.

To understand hemoglobinopathies, it is sufficient to understand that proper oxygen transport depends on the tetrameric structure of the proteins, the proper arrangement of the charged amino acids, and interaction with low-molecular-weight substances such as protons or2,3-BPG.

DEVELOPMENTAL BIOLOGY

Red cells first appearing at about 6 weeks after conception contain the embryonic hemoglobins Hb Portland (z_2g_2), Hb Gower I (z_2e_2), and Hb Gower II (a_2e_2). At 10 to 11 weeks, fetal hemoglobin (HbF;a_2g_2) becomes predominant. The switch to nearly exclusive synthesis of adult hemoglobin (HbA;a_2b_2) occurs at about 38 weeks (Fig. 106-1). Fetuses and newborns therefore requirea-globin but not b-globin for normal gestation. Small amounts of HbF are produced during postnatal life. A few red cell clones called *F cells* are progeny of a small pool of immature committed erythroid precursors (BFU-e) that retain the ability to produce HbF. Profound erythroid stress, such as that seen in severe hemolytic anemias, after bone marrow transplant, or during chemotherapy, cause more of the "F potent" BFU-e to be recruited. HbF levels thus tend to rise in some patients with sickle cell anemia or thalassemia. This phenomenon is also important because it probably explains the ability of hydroxyurea to increase levels of HbF in adults. Fetal globin genes can also be partially activated after birth by agents such as butyrate, which inhibit histone deacetylase and modify the structure of chromatin.

GENETICS AND BIOSYNTHESIS OF HUMAN HEMOGLOBIN

The human hemoglobins are encoded in two tightly linked gene clusters; thea-like globin genes are clustered on chromosome 16, and the b-like genes on chromosome 11 (Fig. 106-1). The a-like cluster consists of two a-globin genes and a single copy of the z gene. The non-a gene cluster consists of a singlee gene, the Gg and Ag fetal globin genes, and the adultd and bgenes.

Important regulatory sequences flank each gene. Immediately upstream are typical promoter elements needed for the assembly of the transcription initiation complex. Sequences in the 5¢ flanking region of theg and the b genes appear to be crucial for the correct developmental regulation of these genes, while elements that function like classic enhancers and silencers are in the 3¢ flanking regions. The locus control region (LCR) elements located far upstream appear to control the overall level of expression of each cluster. These elements achieve their regulatory effects by interacting with *trans*-acting transcription factors. Some of these factors are ubiquitous (e.g., Sp1 and YY1), while others are more or less limited to erythroid cells (e.g., GATA-1, NFE-2, and EKLF). The latter also appear to modulate genes specifically expressed during erythropoiesis, such as the genes that encode the enzymes of the heme biosynthetic pathway. This is relevant since normal red blood cell (RBC) differentiation also requires the coordinated expression of the globin genes with the genes responsible for heme and iron metabolism.

CLASSIFICATION OF HEMOGLOBINOPATHIES

There are five major classes of hemoglobinopathies (Table 106-1). *Structural hemoglobinopathies* occur when mutations alter the amino acid sequence of a globin chain, altering the physiologic properties of the variant hemoglobins and producing the characteristic clinical abnormalities. The variant hemoglobins relevant to this chapter polymerize abnormally, as in sickle cell anemia, or exhibit altered solubility or oxygen-binding affinity. *Thalassemia syndromes* arise from mutations that impair production or translation of globin mRNA, leading to deficient globin chain biosynthesis. Clinical abnormalities are attributable to the inadequate supply of hemoglobin and the imbalances in the production of individual globin chains, leading to premature destruction of erythroblasts and red cells. *Thalassemic hemoglobin variants* combine features of thalassemia (e.g., abnormal globin biosynthesis) and of structural hemoglobinopathies (e.g., an abnormal amino acid sequence). Hereditary persistence of fetal hemoglobin (HPFH) is characterized by synthesis of high levels of fetal hemoglobin in adult life. *Acquired hemoglobinopathies* include modifications of the hemoglobin molecule by toxins (e.g., acquired methemoglobinemia) and abnormal hemoglobin synthesis (e.g., high levels of HbF production in preleukemia and a-thalassemia in myeloproliferative disorders).

EPIDEMIOLOGY

Hemoglobinopathies are especially common in areas where malaria is endemic. This clustering of hemoglobinopathies is assumed to reflect a selective survival advantage for the abnormal red cells, which presumably provide a less hospitable environment during the obligate intraerythrocytic stages of the parasitic life cycle. Very young children with a-thalassemia are *more* susceptible to infection with the nonlethal *Plasmodium vivax*. Thalassemia might then favor a natural "vaccination" against

infection with the more lethal *P. falciparum*.

Thalassemias are the most common genetic disorders in the world, affecting nearly 200 million people worldwide. About 15% of American blacks are silent carriers for a thalassemia;a-thalassemia trait (minor) occurs in 3% of American blacks and in 1 to 15% of persons of Mediterranean origin.b Thalassemia has a 10 to 15% incidence in individuals from the Mediterranean and Southeast Asia and 0.8% in American blacks. The number of severe cases of thalassemia in the United States is about 1000. Sickle cell disease is the most common structural hemoglobinopathy occurring in heterozygous form in about 8% of American blacks and in homozygous form in 1 in 400. Between 2 and 3% of American blacks carry a hemoglobin C allele.

INHERITANCE AND ONTOGENY

Hemoglobinopathies are autosomal "codominant" traits -- compound heterozygotes that inherit a different abnormal mutant allele from each parent exhibit composite features of each. For example, patients inheriting sickleb thalassemia exhibit features ofb thalassemia and sickle cell anemia. Thea-chain is present in HbA, HBA_2, and HbF; a-chain mutations thus cause abnormalities in all three. The a-globin hemoglobinopathies are symptomatic in utero and after birth because normal function of thea-globin gene is required throughout gestation and adult life. In contrast, infants with b-globin hemoglobinopathies tend to be asymptomatic until 3 to 9 months of age, when HbA has largely replaced HbF.

DETECTION AND CHARACTERIZATION OF HEMOGLOBINOPATHIES -- GENERAL METHODS

Electrophoretic techniques are used for routine hemoglobin analysis. Electrophoresis at pH-8.6 on cellulose acetate membranes is simple, inexpensive, and reliable for initial screening. Hemoglobins S, G, and D have the same mobility at pH-8.6. Agar gel electrophoresis at pH-6.1 in citrate buffer is often used as a complementary method because it detects different variants (S migration differs from G and D). Comparison of results obtained in each system usually allows unambiguous diagnosis, but some important variants are electrophoretically silent. These mutant hemoglobins can usually be characterized by more specialized techniques such as isoelectric focusing and/or high-pressure liquid chromatography (HPLC).

Quantitation of the hemoglobin profile is often desirable. HbA_2 is frequently elevated in b-thalassemia trait and depressed in iron deficiency. HbF is elevated inHPFH, some b thalassemia syndromes, and occasional periods of erythroid stress or marrow dysplasia. For characterization of sickle cell trait, sickle thalassemia syndromes, or hemoglobin SC disease, and for monitoring the progress of exchange transfusion therapy to lower the percentage of circulating HbS, quantitation of individual hemoglobins is also required. In most laboratories, quantitation is performed only if the test is specifically ordered.

Because some variants can comigrate with HbA or HbS (sickle hemoglobin), electrophoretic assessment should always be regarded as incomplete unless functional assays for hemoglobin sickling, solubility, or oxygen affinity are also performed, as dictated by the clinical presentation. The best sickling assays involve measurement of

the degree to which the hemoglobin becomes insoluble, or gelated, as it is deoxygenated (i.e., sickle solubility test). Unstable hemoglobins are detected by their precipitation in isopropanol or after heating to 50°C. High-O_2affinity and low-O_2affinity variants are detected by quantitating the partial pressure of oxygen at which the hemoglobin sample becomes 50% saturated with oxygen (P_{50}test). Direct tests for the percentages of carboxyhemoglobin and methemoglobin, employing spectrophotometric techniques, can readily be obtained from most clinical laboratories on an urgent basis.

Complete characterization, including amino acid sequencing or gene cloning and sequencing, is available from several investigational laboratories around the world. The advent of the polymerase chain reaction (PCR), allele-specific oligonucleotide hybridization, and automated DNA sequencing has made it possible to identify globin gene mutations in a few days.

Diagnosis is best established by recognition of a characteristic history, physical findings, peripheral blood smear morphology, and abnormalities of the complete blood cell count (e.g., profound microcytosis with minimal anemia in thalassemia trait). Laboratory evaluation identifies the specific hemoglobinopathy suspected clinically.

STRUCTURALLY ABNORMAL HEMOGLOBINS

SICKLE CELL SYNDROMES

The sickle cell syndromes are caused by a mutation in the b-globin gene that changes the sixth amino acid from glutamic acid to valine. HbS ($a_2b_{26Glu®Va1}$) polymerizes reversibly when deoxygenated to form a gelatinous network of fibrous polymers that stiffen the erythrocyte membrane, increase viscosity, and cause dehydration due to potassium leakage and calcium influx (Fig. 106-3). These changes also produce the characteristic sickle shape. Sickled cells lose the pliability needed to traverse small capillaries. They possess altered "sticky" membranes (especially reticulocytes) that are abnormally adherent to the endothelium of small venules. These abnormalities provoke unpredictable episodes of microvascular vasoocclusion and premature red cell destruction (hemolytic anemia). Hemolysis occurs because the abnormal erythrocytes are destroyed by the spleen. The rigid adherent cells also clog small capillaries and venules, causing tissue ischemia, acute pain, and gradual end-organ damage. This venoocclusive component usually dominates the clinical course. Prominent manifestations include episodes of ischemic pain (i.e., painful crises) and ischemic malfunction or frank infarction in the spleen, central nervous system, bones, liver, kidneys, and lungs.

The prototype disease, sickle cell anemia, is the homozygous state for HbS (Table 106-2). Several sickle syndromes occur as the result of inheritance of HbS from one parent and another hemoglobinopathy, such as b thalassemia or HbC ($a_2b_{26Glu®Lys}$) from the other parent.

Clinical Manifestations

Sickle Cell Anemia Most patients with sickling syndromes suffer from hemolytic anemia, with hematocrits of 15 to 30%, and significant reticulocytosis. Anemia was once thought

to exert protective effects against vasoocclusion by reducing blood viscosity. Natural history and drug therapy trials suggest that an *increase* in the hematocrit with feedback inhibition of reticulocytosis might be beneficial, even at the expense of increased blood viscosity. The role of adhesive reticulocytes in vasoocclusion might account for these paradoxical effects.

Granulocytosis is common. The white cell count can fluctuate substantially and unpredictably during and between painful crises, infectious episodes, and other intercurrent illnesses.

Vasoocclusion causes protean manifestations; intermittent episodes in connective and musculoskeletal structures produce painful ischemia manifested by acute pain and tenderness, fever, tachycardia, and anxiety. These recurrent episodes, called *painful crises*, are the most common clinical manifestation. Their frequency and severity vary greatly. Pain can develop almost anywhere in the body and may last from a few hours to 2 weeks. Repeated crises requiring hospitalization (more than three per year) correlate with reduced survival in adult life, suggesting that these episodes are associated with accumulation of chronic end-organ damage. Provocative factors include infection, fever, excessive exercise, anxiety, abrupt changes in temperature, hypoxia, or hypertonic dyes.

Repeated microinfarction can destroy tissues having microvascular beds that promote sickling. Thus, the spleen is frequently infarcted within the first 18 to 36 months of life, causing susceptibility to infection, particularly from pneumococci. Acute venous obstruction of the spleen (*splenic sequestration crisis*), a rare occurrence in early childhood, may require emergency transfusion and/or splenectomy to prevent trapping of the entire arterial output in the obstructed spleen. Occlusion of retinal vessels can produce hemorrhage, neovascularization, and eventual detachments. Renal papillary necrosis invariably produces isosthenuria. More widespread renal necrosis leads to renal failure in adults, a common late cause of death. Bone and joint ischemia can lead to aseptic necrosis (especially of the femoral or humeral heads), chronic arthropathy, and unusual susceptibility to osteomyelitis, which may be caused by organisms such as *Salmonella*, rarely encountered in other settings. The *hand-foot syndrome* is caused by painful infarcts of the digits and dactylitis. Stroke is especially common in children, a small subset of whom tend to suffer repeated episodes; stroke is less common in adults and is often hemorrhagic. A particularly painful complication in males is priapism, due to infarction of the penile venous outflow tracts; permanent impotence is a frequent consequence. Chronic lower leg ulcers probably arise from ischemia and superinfection in the distal circulation.

Acute chest syndrome is a distinctive manifestation characterized by chest pain, tachypnea, fever, cough, and arterial oxygen desaturation. It can mimic pneumonia, pulmonary emboli, bone marrow infarction and embolism, myocardial ischemia, or in situ lung infarction. Acute chest syndrome is thought to reflect in situ sickling within the lung, producing pain and temporary pulmonary dysfunction. Acute chest syndrome may be difficult or impossible to distinguish from other entities. Pulmonary infarction and pneumonia are the most frequent underlying or concomitant conditions in patients with this syndrome. Repeated episodes of acute chest pain correlate with reduced survival. Acutely, reduction in arterial oxygen saturation is especially ominous because it

promotes sickling on a massive scale. Repeated acute or subacute pulmonary crises lead to pulmonary hypertension and cor pulmonale, an increasingly common cause of death as patients survive further into adult life.

Sickle cell syndromes are remarkable for their clinical heterogeneity. Some patients remain virtually asymptomatic into or even through adult life, while others suffer repeated crises requiring hospitalization from early childhood. At least five haplotypes of sickle cell disease are recognized based upon their origin: Senegal, Cameroon, Benin, Central African Republic, and India. Among these, patients of the Central African Republic have the worst disease and those of Senegal the least severe. Patients with sickle thalassemia and sickle-HbE tend to have similar, slightly milder, symptoms, perhaps because of the ameliorating effects of production of other hemoglobins within the red cell. Hemoglobin SC disease, one of the more common variants of sickle cell anemia, is frequently marked by lesser degrees of hemolytic anemia and a greater propensity for the development of retinopathy and aseptic necrosis of bones. In most respects, however, the clinical manifestations resemble sickle cell anemia. Some rare hemoglobin variants actually aggravate the sickling phenomenon.

Sickle Cell Trait Sickle cell trait is usually asymptomatic. Anemia and painful crises are exceedingly rare. An uncommon, but highly distinctive, symptom is painless hematuria, often occurring in adolescent males, probably due to papillary necrosis. Sloughing of papillae with ureteral obstruction has been reported, as have isolated cases of massive sickling or sudden death due to exposure to high altitudes or extraordinary extremes of exercise and dehydration.

Diagnosis Sickle cell syndromes are readily suspected on the basis of characteristic hemolytic anemia, red cell morphology (Plate V-39), and intermittent episodes of ischemic pain. Diagnosis is confirmed by hemoglobin electrophoresis and sickling tests. Thorough characterization of the exact hemoglobin profile of the patient is important, because sickle thalassemia and hemoglobin SC disease are correlated with alterations in prognosis or clinical features. The diagnosis is usually established in childhood, but occasional patients, often with compound heterozygous states, do not develop symptoms until the onset of puberty, pregnancy, or early adult life. Genotyping of family members and potential parental partners is critical for genetic counseling. Details of the childhood history help to establish prognosis and eligibility for aggressive or experimental therapies. Factors associated with increased morbidity and mortality are more than three crises requiring hospitalization per year, chronic neutrophilia, a history of splenic sequestration or hand-foot syndrome, and second episodes of acute chest syndrome. Patients with a history of cerebrovascular accidents are at higher risk for repeated episodes and require especially close monitoring.

TREATMENT

Patients with sickle cell syndromes require ongoing continuity of care. Familiarity with the pattern of symptoms provides the best safeguard against excessive use of the emergency room, hospitalization, and habituation to addictive narcotics. Additional preventive measures include regular slit-lamp examinations to monitor development of retinopathy; antibiotic prophylaxis appropriate for splenectomized patients during dental or other invasive procedures; vaccination against pneumococci and *Haemophilus*

influenzae; and vigorous oral hydration before or during periods of extreme exercise, exposure to heat or cold, emotional stress, or infection.

The management of acute painful crisis includes vigorous hydration, thorough evaluation for underlying causes (such as infection), and aggressive narcotic analgesia administered by a standing order and/or PCA pump. Morphine (0.1 to 0.15 mg/kg every 3 to 4 h) or meperidine (0.75 to 1.5 mg/kg every 2 to 4 h) should control severe pain. Bone pain may respond as well to ketorolac (30 to 60 mg initial dose, then 15 to 30 mg every 6 to 8 h). Many crises can be managed at home with oral hydration and oral analgesia. Use of the emergency room should be reserved for especially severe symptoms or circumstances in which other processes (e.g., infection) are strongly suspected. Nasal oxygen should be employed as appropriate to protect arterial saturation. Most crises resolve in 1 to 7 days. Use of blood transfusion should be reserved for extreme cases; transfusion does not shorten the crisis.

No tests are definitive to diagnose acute painful crisis. Critical to good management is an approach that recognizes that most patients reporting crisis symptoms do indeed have crisis or another significant medical problem. Diligent diagnostic evaluation for underlying causes is imperative, even though these are found infrequently. In adults, the possibility of aseptic necrosis or sickle arthropathy must be considered, especially if pain and immobility become repeated or chronic at a single site. Nonsteroidal anti-inflammatory agents are often effective for sickle cell arthropathy.

Acute chest syndrome is a medical emergency that may require management in an intensive care unit. Hydration should be monitored carefully to avoid the development of pulmonary edema, and oxygen therapy should be especially vigorous for protection of arterial saturation. Diagnostic evaluation for pneumonia and pulmonary embolism should be thorough, since these may occur with atypical symptoms. Critical interventions are transfusion to maintain a hematocrit >30 and emergency exchange transfusion if arterial saturation drops below 90%.

As patients with sickle cell syndromes increasingly survive into their fifth and sixth decades (median age at death is 42 years for men, 48 years for women), end-stage renal failure and pulmonary hypertension are becoming increasingly prominent causes of end-stage morbidity; anecdotal evidence suggests that a sickle cell cardiomyopathy and/or premature coronary artery disease may compromise cardiac function in later years. Sickle cell patients have received kidney transplants, but they often experience an increase in the frequency and severity of crises, possibly due to increased infection as a consequence of immunosuppression.

The most significant advance in the therapy of sickle cell anemia has been the introduction of hydroxyurea as a mainstay of therapy for patients with severe symptoms. Hydroxyurea (10 to 30 mg/kg/per day) increases fetal hemoglobin and may also exert beneficial affects on red cell hydration, vascular wall adherence, and suppression of the granulocyte and reticulocyte counts; indeed, dosage is titrated to maintain a white cell count between 5,000 and 8,000. White cells and reticulocytes may play a major role in the pathogenesis of sickle cell crisis, and their suppression may be an important benefit of hydroxyurea therapy.

Hydroxyurea should be considered in patients experiencing repeated episodes of acute chest syndrome or more than three crises per year requiring hospitalization. The utility of this agent for reducing the incidence of other complications (e.g., priapism, retinopathy) is under evaluation, as are the long-term side effects. Therefore, when possible, treatment should be instituted as part of a clinical trial. Most patients respond within a few months with elevations of fetal hemoglobin.

Bone marrow transplantation can provide definitive cures but is known to be effective and safe only in children. Prognostic features justifying bone marrow transplant are the presence of repeated crises early in life, a high neutrophil count, or the development of hand-foot syndrome. Children at risk for stroke can be identified through the use of Doppler ultrasound techniques. Prophylactic exchange transfusion appears to reduce the risk of stroke substantially in this population. Children who do suffer a cerebrovascular accident should be maintained for at least 3 to 5 years on a program of vigorous exchange transfusion, since the risk of second strokes is extremely high in this population.

Gene therapy for sickle cell anemia is under investigation, but no safe therapy is currently available. Agents blocking red cell hydration or vascular adhesion, such as clotrimazole, may have value as an adjunct to hydroxyurea therapy; trials are ongoing.

UNSTABLE HEMOGLOBINS

Amino acid substitutions that reduce solubility or increase susceptibility to oxidation produce "unstable" hemoglobins that precipitate, forming inclusion bodies injurious to the red cell membrane. Representative mutations are those that interfere with contact points between the a and b subunits [e.g., Hb Philly ($b_{35Tyr®Phe}$)], alter the helical segments [e.g., Hb Genova ($b_{28Leu®Pro}$)], or disrupt interactions of the hydrophobic pockets of the globin subunits with heme [e.g., Hb Koln ($b_{98Val®Met}$)] (Table 106-3). The inclusions, called *Heinz bodies*, are clinically detectable by staining with supravital dyes such as crystal violet (Heinz body test). Removal of these inclusions by the spleen generates pitted, rigid cells that have shortened life spans, producing hemolytic anemia of variable severity, sometimes requiring chronic transfusion support. Splenectomy may be needed to correct the anemia. Leg ulcers and premature gallbladder disease due to bilirubin turnover are frequent stigmata.

Unstable hemoglobins occur sporadically, often by spontaneous new mutations. Heterozygotes are often symptomatic because a significant Heinz body burden can develop even when the unstable variant accounts for a portion of the total hemoglobin. Symptomatic unstable hemoglobins tend to be b-globin variants, because sporadic mutations affecting only one of the foura globins would generate only 20 to 30% abnormal hemoglobin.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

High-affinity hemoglobins [e.g., Hb Yakima ($b_{99Asp®His}$)] bind oxygen more readily but deliver less O_2 to tissues at normal capillary P_{O2}levels (Fig. 106-2). Mild tissue hypoxia ensues, stimulatingRBCproduction and erythrocytosis (Table 106-3). In extreme cases, the hematocrit can rise to 60 to 65%, increasing blood viscosity and producing typical

symptoms (headache, somnolence, or dizziness). Phlebotomy may be required. Typical mutations alter interactions within the heme pocket or disrupt the Bohr effect or salt-bond site. Mutations that impair the interaction of HbA with2,3-BPGcan increase O_2affinity, because 2,3-BPG binding lowers O_2affinity.

Low-affinity hemoglobins [e.g., Hb Kansas ($b_{102Asn®Thr}$)] bind sufficient oxygen in the lungs, despite their lower oxygen affinity, to achieve nearly full saturation. At capillary oxygen tensions, they lose sufficient amounts of oxygen to maintain homeostasis at a low hematocrit (Fig. 106-2) (pseudoanemia). Capillary hemoglobin desaturation can also be sufficient to produce clinically apparent cyanosis. Despite these findings, patients usually require no specific treatment.

METHEMOGLOBINEMIAS

Methemoglobin is generated by oxidation of the heme iron moieties to the ferric state, causing a characteristic bluish-brown, muddy color resembling cyanosis. Methemoglobin has such high oxygen affinity that virtually no oxygen is delivered to tissues. Levels >50 to 60% are often fatal.

Congenital methemoglobinemia arises from globin mutations that stabilize iron in the ferric state [e.g., HbM Iwata ($a_{87His®Tyr}$),Table 106-3] or from mutations that impair the enzymes that reduce methemoglobin to hemoglobin (e.g., methemoglobin reductase, NADP diaphorase). Acquired methemoglobinemia is caused by toxins that oxidize heme iron, notably nitrate and nitrite-containing compounds.

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE HEMOGLOBINS, HIGH-AFFINITY HEMOGLOBINS, AND METHEMOGLOBINEMIA

Unstable hemoglobin variants should be suspected in patients with nonimmune hemolytic anemia, jaundice, splenomegaly, or premature biliary tract disease. Severe hemolysis usually presents during infancy as neonatal jaundice or anemia. Milder cases may present in adult life with anemia or only as unexplained reticulocytosis, hepatosplenomegaly, premature biliary tract disease, or leg ulcers. Because spontaneous mutation is common, family history of anemia may be absent. The peripheral blood smear often shows anisocytosis, abundant cells with punctate inclusions, and irregular shapes (i.e., poikilocytosis).

The two best tests for diagnosing unstable hemoglobins are the Heinz body preparation and the isopropanol or heat stability test. Many unstable Hb variants are electrophoretically silent. A normal electrophoresis does not rule out the diagnosis.

Severely affected patients may require transfusion support for the first 3 years of life, because splenectomy before age 3 is associated with a significantly greater immune deficit. Splenectomy is usually effective thereafter, but occasional patients may require lifelong transfusion support. Even after splenectomy, patients can develop cholelithiasis and leg ulcers. Splenectomy can also be considered in patients exhibiting severe secondary complications of chronic hemolysis, even if anemia is absent. Precipitation of unstable hemoglobins is aggravated by oxidative stress, e.g., infection, antimalarial drugs.

High-O_2-affinity hemoglobin variants should be suspected in patients with erythrocytosis. The best test for confirmation is measurement of the P_{50}. A high-O_2-affinity Hb causes a significant left shift (i.e., lower numeric value of the P_{50}); confounding conditions, e.g., tobacco smoking or carbon monoxide exposure, can also lower the P_{50}.

Patients with high-affinity hemoglobin are often asymptomatic; rubor or plethora may be telltale signs. When the hematocrit reaches 55 to 60%, symptoms of high blood viscosity and sluggish flow (headache, lethargy, dizziness, etc.) may be present. These symptoms respond to judicious phlebotomy. Erythrocytosis represents an appropriate attempt to compensate for the impaired oxygen delivery by the abnormal variant. Overzealous phlebotomy may stimulate increased erythropoiesis or aggravate symptoms by thwarting this compensatory mechanism. The guiding principle of phlebotomy should be to improve oxygen delivery by reducing blood viscosity and increasing blood flow rather than restoration of a normal hematocrit. Modest iron deficiency may aid in control.

Low-affinity hemoglobins should be considered in patients with cyanosis or a low hematocrit with no other cause apparent after thorough evaluation. The P_{50} test confirms the diagnosis. Counseling and reassurance are the interventions of choice.

Methemoglobin should be suspected in patients with hypoxic symptoms who appear cyanotic but have a Pa_{O2}sufficiently high that hemoglobin should be fully saturated with oxygen. A history of nitrite or other oxidant ingestions may not always be available; some exposures may be unapparent to the patient, and others may result from suicide attempts. The characteristic muddy appearance of freshly drawn blood can be a critical clue. The diagnostic test of choice is measurement of the methemoglobin content, which is usually available on an emergency basis.

Methemoglobinemia often causes symptoms of cerebral ischemia at levels>15%; levels>60% are usually lethal. Intravenous injection of 1 mg/kg of methylene blue is effective emergency therapy. Milder cases and follow-up of severe cases can be treated orally with methylene blue (60 mg three to four times each day) or ascorbic acid (300 to 600 mg/d).

THALASSEMIA SYNDROMES

The thalassemia syndromes are inherited disorders of a- orb-globin biosynthesis. The reduced supply of globin diminishes production of hemoglobin tetramers, causing hypochromia and microcytosis. Unbalanced accumulation of a andb subunits occurs because the synthesis of the unaffected globins proceeds at normal rate. Unbalanced chain accumulation dominates the clinical phenotype. Clinical severity varies widely, depending on the degree to which the synthesis of the affected globin is impaired, altered synthesis of other globin chains, and coinheritance of other abnormal globin alleles.

b-THALASSEMIA SYNDROMES

Mutations causing thalassemia can affect any step in the pathway of globin gene

expression: transcription, processing of the mRNA precursor, translation, and posttranslational metabolism of the b-globin polypeptide chain. The most common forms arise from mutations that derange splicing of the mRNA precursor or prematurely terminate translation of the mRNA.

Hypochromia and microcytosis due to reduced amounts of hemoglobin tetramers characterize all forms ofb thalassemia. In heterozygotes (b-thalassemia trait), this is the only abnormality seen; anemia is minimal. In homozygous states, unbalanceda- and b-globin accumulation causes accumulation of highly insoluble unpaired achains, which form toxic inclusion bodies that kill developing erythroblasts in the marrow. Few of the proerythroblasts beginning erythroid maturation survive. The few surviving red cells bear a burden of inclusion bodies, detected in the spleen, shortening the red cell life span and producing severe hemolytic anemia. The resulting profound anemia stimulates erythropoietin release and compensatory erythroid hyperplasia, but the marrow response is sabotaged by ineffective erythropoiesis. Anemia persists. Erythroid hyperplasia can become exuberant and produce extramedullary erythropoietic tissue in the liver and spleen.

Massive bone marrow expansion deranges growth and development. Children develop characteristic "chipmunk" facies due to maxillary marrow hyperplasia and frontal bossing, thinning and pathologic fracture of long bones and vertebrae due to cortical invasion by erythroid elements, and profound growth retardation. Hemolytic anemia causes hepatosplenomegaly, leg ulcers, gallstones, and high-output congestive heart failure. The conscription of caloric resources to support erythropoiesis leads to inanition, susceptibility to infection, endocrine dysfunction, and, in the most severe cases, death during the first decade of life. Chronic transfusions with red cells improves oxygen delivery, suppresses the excessive ineffective erythropoiesis, and prolongs life, but the inevitable side effects, notably iron overload, usually prove fatal by age 30. Bone marrow transplantation in childhood is the only curative therapy.

Severity is highly variable. Known modulating factors are those that ameliorate the burden of unpaireda-globin inclusions. Alleles associated with milder synthetic defects and coinheritance of a-thalassemia trait reduce clinical severity by reducing accumulation of excessa globin. HbF persists to various degrees inb thalassemias. g-Globin gene chains can substitute for b chains, simultaneously generating more hemoglobin and reducing the burden ofa-globin inclusions. The terms*b-thalassemia major* and*b-thalassemia intermedia* are used to reflect the clinical heterogeneity. Patients withb-thalassemia major require intensive transfusion support to survive. Patients with b-thalassemia intermedia have a somewhat milder phenotype and can survive without transfusion. The terms *b-thalassemia minor* and*b-thalassemia trait* describe asymptomatic heterozygotes for bthalassemia.

a-THALASSEMIA SYNDROMES

The four classica thalassemias, most common in Asians, area-thalassemia-2 trait, in which one of the foura-globin loci is deleted;a-thalassemia-1 trait, with two deleted loci; HbH disease, with three loci deleted; and hydrops fetalis with Hb Bart's, with all four loci deleted (Table 106-4). Nondeletion forms ofa thalassemia also exist.

a-Thalassemia-2 trait is an asymptomatic, silent carrier state.*a-Thalassemia-1 trait* resemblesb-thalassemia minor. Offspring doubly heterozygous fora-thalassemia-2 anda-thalassemia-1 exhibit a more severe phenotype, called HbH disease. Heterozygosity for a deletion that removes both genes from the same chromosome (*cis* deletion) is common in Asians and Mediterranean individuals, as is homozygosity for a-thalassemia-2 (*trans* deletion). Both produce asymptomatic hypochromia and microcytosis.

In *HbH disease*, HbA production is only 25 to 30% of normal. Fetuses accumulate some unpaired b chains. In adults, unpairedb chains accumulate and are soluble enough to form$b_4$tetramers called *HbH*. HbH forms few inclusions in erythroblasts but does precipitate in circulating red cells. Patients with HbH disease have thalassemia intermedia characterized by moderately severe hemolytic anemia but milder ineffective erythropoiesis. Survival into midadult life without transfusions is common.

The homozygous state for thea-thalassemia-1 *cis* deletion (hydrops fetalis) causes total absence of a-globin synthesis. No physiologically useful hemoglobin is produced beyond the embryonic stage. Excessg globin forms tetramers called *Hb Bart's* (g_4), which has an extraordinarily high oxygen affinity. It delivers almost no O_2 to fetal tissues, causing tissue asphyxia, edema (hydrops fetalis), congestive heart failure, and death in utero. a-Thalassemia-2 trait is common (15 to 20%) among people of African descent. The *cis* a-thalassemia-1 deletion is almost never seen, however. Thus, a-thalassemia-2 and the *trans* form of a-thalassemia-1 are very common, but HbH disease and hydrops fetalis are almost never encountered.

DIAGNOSIS AND MANAGEMENT

The diagnosis ofb-thalassemia major is readily made during childhood on the basis of severe anemia accompanied by hepatosplenomegaly; profound microcytosis; a characteristic blood smear (Plate V-2); and elevated levels of HbF, HbA_2, or both. Many patients require chronic hypertransfusion therapy designed to maintain a hematocrit of at least 27 to 30% so that erythropoiesis is suppressed. Splenectomy is required if the annual transfusion requirement (volume ofRBCs per kilogram body weight per year) increases by>50%. Folic acid supplements may be useful. Vaccination with pneumococcal vaccine in anticipation of eventual splenectomy is advised, as is close monitoring for infection, leg ulcers, and biliary tract disease. Early endocrine evaluation is required for glucose intolerance, thyroid dysfunction, and delayed onset of puberty or secondary sexual characteristics. Many patients develop endocrine deficiencies as a result of iron overload.

Patients withb-thalassemia intermedia exhibit similar stigmata but can survive without chronic hypertransfusion. Management is particularly challenging because a number of factors can aggravate the anemia, including infection, onset of puberty, and development of splenomegaly and hypersplenism. Some patients may eventually benefit from splenectomy. The expanded erythron can cause excess absorption of dietary iron and hemosiderosis, even without transfusion.

b-Thalassemia minor (i.e., thalassemia trait) usually presents as profound microcytosis and hypochromia with target cells but only minimal or mild anemia. The mean

corpuscular volume is rarely >75 fL; the hematocrit is rarely<30 to 33%. Hemoglobin electrophoresis classically reveals an elevated HbA_2(3.5 to 7.5%), but some forms are associated with normal $HbA_2$and/or elevated HbF. Genetic counseling and patient education are essential. Patients with b-thalassemia trait should be warned that their blood picture resembles iron deficiency and can be misdiagnosed. They should eschew routine use of iron but know that iron deficiency requiring supplementation can develop, as in other persons, during pregnancy or from chronic bleeding.

Persons witha-thalassemia trait may exhibit mild hypochromia and microcytosis, usually without anemia. HbA_2 and HbF levels are normal. Affected individuals usually require only genetic counseling. HbH disease resembles b-thalassemia intermedia, with the added complication that the HbH molecule behaves like a moderately unstable hemoglobin. Patients with HbH disease should undergo splenectomy if excessive anemia or a transfusion requirement develops. Oxidative drugs should be avoided. Iron overload leading to death can occur in more severely affected patients.

PREVENTION

Antenatal diagnosis of thalassemia syndromes is now widely available. DNA diagnosis is based onPCRamplification of fetal DNA, obtained by amniocentesis or chorionic villus biopsy followed by hybridization to allele-specific oligonucleotides probes. The probes can be designed to detect simultaneously the subset of mutations that account for 95 to 99% of the a orb thalassemias that occur in a particular ethnic group.

THALASSEMIC STRUCTURAL VARIANTS

Thalassemic structural variants are characterized by both defective synthesis and abnormal structure.

HEMOGLOBIN LEPORE

Hb Lepore [$a_2(db)_2$] arises by an unequal crossover and recombination event that fuses the proximal end of the d gene with the distal end of the closely linked b gene. The resulting chromosome contains only the fused db gene. The Lepore (db) globin is synthesized poorly because the fused gene is under the control of the weak d-globin promoter. Hb Lepore alleles have a phenotype likeb-thalassemia, except for the added presence of 2 to 20% Hb Lepore. Compound heterozygotes for Hb Lepore and a classic b-thalassemia allele may also have severe thalassemia.

HEMOGLOBIN E

HbE (i.e.,$a_2b_{226Glu®Lys}$) is extremely common in Cambodia, Thailand, and Vietnam. The gene has become far more prevalent in the United States as a result of immigration of Asian persons, especially in California, where HbE is the most common variant detected. HbE is mildly unstable but not enough to affectRBC life span significantly. The high frequency of the HbE gene may be a result of the thalassemia phenotype associated with its inheritance. Heterozygotes resemble individuals with mild b-thalassemia trait. Homozygotes have somewhat more marked abnormalities but are asymptomatic. Compound heterozygotes for HbE and a b-thalassemia gene can have

b-thalassemia intermedia orb-thalassemia major, depending on the severity of the coinherited thalassemic gene.

Theb^{E}allele contains only a single base change, in codon 26, that causes the amino acid substitution. However, this mutation activates a cryptic RNA splice site generating a structurally abnormal globin mRNA that cannot be translated from about 50% of the initial pre-mRNA molecules. The remaining 40 to 50%, which are normally spliced, generate functional mRNA that is translated intob^{E}globin because the mature mRNA carries the base change that alters codon 26.

Genetic counseling of the persons at risk for HbE should focus on the interaction of HbE withb-thalassemia rather than HbE homozygosity, a condition associated with microcytosis and hypchromia that is usually asymptomatic, with hemoglobin levels rarely <10 gm/dL.

OTHER UNCOMMON HEMOGLOBINOPATHIES

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

HPFHis characterized by continued synthesis of high levels of HbF in adult life. No deleterious effects are apparent, even when all of the hemoglobin produced is HbF. These rare patients demonstrate convincingly that prevention or reversal of the fetal to adult hemoglobin switch would provide efficacious therapy for sickle cell anemia and bthalassemia.

ACQUIRED HEMOGLOBINOPATHIES

The two most important acquired hemoglobinopathies are carbon monoxide poisoning and methemoglobinemia (see above). Carbon monoxide has a higher affinity for hemoglobin than does oxygen; it can replace oxygen and diminish O_2delivery. Chronic elevation of carboxyhemoglobin levels to 10 or 15%, as occurs in smokers, can lead to secondary polycythemia. Carboxyhemoglobin is cherry red in color and masks the development of cyanosis usually associated with poor O_2delivery to tissues.

Abnormalities of hemoglobin biosynthesis have also been described in blood dyscrasias. In some patients with myelodysplastic, erythroleukemic, or myeloproliferative disorders, a mild form of HbH disease may also be seen. The abnormalities are not severe enough to alter the course of the underlying disease.

MANAGEMENT OF TRANSFUSIONAL HEMOSIDEROSIS

Chronic blood transfusion can lead to blood-borne infection, alloimmunization, febrile reactions, and lethal iron overload. A unit of packedRBCs contains 250 to 300 mg iron (1 mg/mL). The iron assimilated by a single transfusion of two units of packed RBCs is thus equal to a 1- to 2-year intake of iron. Iron accumulates in chronically transfused patients because no mechanisms exist for increasing iron excretion; an expanded erythron causes especially rapid development of iron overload because accelerated erythropoiesis promotes excessive absorption of dietary iron. Vitamin C should not be supplemented because it generates free radicals in iron excess states.

Patients who receive>100 units of packedRBCs usually develop hemosiderosis. The ferritin level rises, followed by early endocrine dysfunction (glucose intolerance and delayed puberty), cirrhosis, and cardiomyopathy. Liver biopsy shows both parenchymal and reticuloendothelial iron. Newer methods for assessing hepatic iron such as the superconducting quantum-interference device (SQUID) are accurate but not widely available. Cardiac toxicity is often insidious. Early development of pericarditis is followed by dysrhythmia and pump failure. The onset of heart failure is ominous, often presaging death within a year (Chap. 345).

The decision to start long-term transfusion support should be accompanied by therapy with iron-chelating agents. The only approved and available iron chelator, desferoxamine (Desferal), is expensive and poorly absorbed from the gastrointestinal tract. Its iron-binding kinetics require chronic slow infusion via a metering pump. The constant presence of the drug improves the efficiency of chelation and protects tissues from occasional releases of the most toxic fraction of iron -- low-molecular-weight iron -- which may not be sequestered by protective proteins. Oral iron-chelating agents such as deferiprone showed initial promise, but long-term trials have raised serious doubts about their efficacy and safety.

Desferoxamine is relatively nontoxic. Occasional cataracts, deafness, and local skin reactions, including urticaria, occur. Skin reactions can usually be managed with antihistamines. Negative iron balance can be achieved, even in the face of a high transfusion requirement, but this alone does not prevent long-term morbidity and mortality in chronically transfused patients. Irreversible end-organ deterioration develops at relatively modest levels of iron overload, even if symptoms do not appear for many years thereafter. To obtain a significant survival advantage, chelation must begin before 5 to 8 years of age.

EXPERIMENTAL THERAPIES

Bone marrow transplantation provides stem cells able to express normal hemoglobin; it has been used in a large number of patients with b thalassemia and a smaller number of patients with sickle cell anemia. Early in the course of disease, before end-organ damage occurs, transplantation is curative in 80 to 90% of patients. In highly experienced centers, the treatment-related mortality is<10%. Since survival into adult life is possible with conventional therapy, the decision to transplant is best made in consultation with specialized centers.

Gene therapy of thalassemia and sickle cell disease has proved to be an elusive goal. Uptake of gene vectors into the nondividing hematopoietic stem cells has been disappointingly inefficient.

Reestablishing high levels of fetal hemoglobin synthesis should ameliorate the symptoms ofb thalassemia. Cytotoxic agents such as hydroxyurea and cytarabine promote high levels of HbF synthesis, probably by stimulating proliferation of the primitive HbF-producing progenitor cell population (i.e., F cell progenitors). Unfortunately, no regimen has yet been identified that ameliorates the clinical manifestations of bthalassemia. Butyrates stimulate HbF production, but only

transiently. Pulsed or intermittent administration has been found to sustain HbF induction in the majority of patients with sickle cell disease. It is unclear whether butyrate will have similar activity in patients with bthalassemia.

APLASTIC AND HYPOPLASTIC CRISIS IN PATIENTS WITH HEMOGLOBINOPATHIES

Patients with hemolytic anemia sometimes exhibit an alarming decline in hematocrit during and immediately after acute illnesses. Bone marrow suppression occurs in almost everyone during acute inflammatory illnesses. In patients with shortened red cell life spans, suppression can cause anemia. These hypoplastic crises are usually transient and do not require transfusion.

Aplastic crisis refers to a profound cessation of erythroid activity in patients with chronic hemolytic anemia. It is associated with a rapidly falling hematocrit. Episodes are usually self-limited. Aplastic crises are caused by infection with a particular strain of parvovirus (B19A). Children infected with this virus usually develop permanent immunity. Aplastic crises do not often recur and are rarely seen in adults. Management requires close monitoring of the hematocrit and reticulocyte count. If anemia becomes symptomatic, transfusion support is indicated. Most crises resolve spontaneously within 1 to 2 weeks.

ACKNOWLEDGEMENT

Some material from Chap. 107 by Dr. Ernest Beutler in the last edition has been retained in this edition. In addition, portions of this chapter describe well-established aspects of this topic and are revised and updated from earlier chapters on this topic by the author.

107. MEGALOBLASTIC ANEMIAS - *Bernard M. Babior*, *H. Franklin Bunn*

The megaloblastic anemias are disorders caused by impaired DNA synthesis. Cells primarily affected are those having relatively rapid turnover, especially hematopoietic precursors and gastrointestinal epithelial cells. Cell division is sluggish, but cytoplasmic development progresses normally, so megaloblastic cells tend to be large, with an increased ratio of RNA to DNA. Megaloblastic erythroid progenitors tend to be destroyed in the marrow. Thus, marrow cellularity is often increased but production of red blood cells (RBC) is decreased, an abnormality termed *ineffective erythropoiesis* (Chap. 61).

Most megaloblastic anemias are due to a deficiency of cobalamin (vitamin B_{12}) and/or folic acid. The various clinical entities associated with megaloblastic anemia are listed in Table 107-1.

PHYSIOLOGIC AND BIOCHEMICAL CONSIDERATIONS

FOLIC ACID

Folic acid is the common name for pteroylmonoglutamic acid. It is synthesized by many different plants and bacteria. Fruits and vegetables constitute the primary dietary source of the vitamin. Some forms of dietary folic acid are labile and may be destroyed by cooking. The minimum daily requirement is normally about 50 ug, but this may be increased severalfold during periods of enhanced metabolic demand such as pregnancy.

The assimilation of adequate amounts of folic acid depends on the nature of the diet and its means of preparation. Folates in various foodstuffs are largely conjugated to a chain of glutamic acid residues. This highly polar side chain impairs the intestinal absorption of the vitamin. However, conjugases (g-glutamyl carboxypeptidases) in the lumen of the gut convert polyglutamates to mono- and diglutamates, which are readily absorbed in the proximal jejunum.

Plasma folate is primarily in the form of N_5-methyltetrahydrofolate, a monoglutamate, which is transported into cells by a carrier that is specific for the tetrahydro forms of the vitamin. Once in the cell, the N_5-methyl group is removed in a cobalamin-requiring reaction (see below), and the folate is then reconverted to the polyglutamate form. The polyglutamate form may be useful for retention of folate by the cell.

A folate-binding protein occurs in plasma, milk, and other body fluids. The function of this folate binder and its membrane-bound precursor is unknown. Neither the binder nor its precursor is related to the tetrahydrofolate carrier.

Normal individuals have about 5 to 20 mg folic acid in various body stores, half in the liver. In light of the minimum daily requirement, it is not surprising that a deficiency will occur within months if dietary intake or intestinal absorption is curtailed.

The prime function of folate compounds is to transfer 1-carbon moieties such as methyl and formyl groups to various organic compounds (Fig. 107-1). The sources of these

1-carbon moieties is usually serine, which reacts with tetrahydrofolate to produce glycine and $N_{5,10}$-methylenetetrahydrofolate. An alternative source is forminoglutamic acid, an intermediate in histidine catabolism, which gives up its formimino group to tetrahydrofolate to yield N_5-formiminotetrahydrofolate and glutamic acid. These derivatives provide entry into an interconvertible donor pool consisting of tetrahydrofolate derivatives carrying various 1-carbon moieties. The constituents of this pool can donate their 1-carbon moieties to appropriate acceptor compounds to form metabolic intermediates, which are ultimately converted to building blocks used in the synthesis of macromolecules. The most important building blocks are (1) purines, in which the C-2 and C-8 atoms are introduced in folate-dependent reactions; (2) deoxythymidylate monophosphate (dTMP), synthesized from $N_{5,10}$-methylenetetrahydrofolate and deoxyuridylate monophosphate (dUMP); and (3) methionine, formed by the transfer of a methyl group from N_5-methyltetrahydrofolate to homocysteine (two of these three reactions are shown inFig. 107-1).

In all but one of the 1-carbon transfer reactions, tetrahydrofolate is produced. It can immediately accept a 1-carbon moiety and reenter the donor pool. The single exception is the thymidylate synthase reaction (dUMP®dTMP), in which dihydrofolate is the product (Fig. 107-1). This must be reduced to tetrahydrofolate by the enzyme dihydrofolate reductase before it can reenter the donor pool. A number of drugs are able to inhibit dihydrofolate reductase (Table 107-1), thereby diverting folate from the donor pool and producing what amounts to a state of folate deficiency in the face of normal tissue folate concentrations.

COBALAMIN

This vitamin is a complex organometallic compound in which a cobalt atom is situated within a corrin ring, a structure similar to the porphyrin from which heme is formed. Unlike heme, however, cobalamin cannot be synthesized in the human body and must be supplied in the diet. The only dietary source of cobalamin is animal products: meat and dairy foods. The minimum daily requirement for cobalamin is about 2.5 ug.

During gastric digestion, cobalamin in food is released and forms a stable complex with gastric R binder, one of a closely related group of glycoproteins of unknown function that are found in secretions (e.g., saliva, milk, gastric juice, bile), phagocytes, and plasma. On entering the duodenum, the cobalamin-R binder complex is digested, releasing the cobalamin, which then binds to intrinsic factor (IF), a 50-kDa glycoprotein produced by the parietal cells of the stomach. The secretion of IF generally parallels that of hydrochloric acid. The cobalamin-IF complex is resistant to proteolytic digestion and travels to the distal ileum, where specific receptors on the mucosal brush border bind and absorb the cobalamin-IF complex. Thus IF, like transferrin for iron, serves as a cell-directed carrier protein. The receptor-bound cobalamin-IF complex is taken into the ileal mucosal cell, where the IF is destroyed and the cobalamin is transferred to another transport protein, transcobalamin (TC) II. The cobalamin-TC II complex is then secreted into the circulation, from which it is rapidly taken up by the liver, bone marrow, and other cells. The pathway of cobalamin absorption is shown inFig. 107-2. Normally, about 2 mg cobalamin is stored in the liver, and another 2 mg is stored elsewhere in the body. In view of the minimum daily requirement, about 3 to 6 years would be required for a normal individual to become deficient in cobalamin if absorption were to cease abruptly.

AlthoughTC II is the acceptor for newly absorbed cobalamin, most circulating cobalamin is bound to TC I, a glycoprotein closely related to gastric R binder. TC I appears to be derived in part from leukocytes. The paradox that most circulating cobalamin is bound to TC I rather than TC II, even though TC II initially carries all the cobalamin that is absorbed by the intestine, is explained by the fact that cobalamin bound to TC II is rapidly cleared from the blood ($t_{1/2}$about 1 h), while clearance of cobalamin bound to TC I requires many days. The function of TC I is unknown.

Cobalamin is an essential cofactor for two enzymes in human cells: methionine synthase and methylmalonyl-CoA synthase. Cobalamin exists in two metabolically active forms, identified by the alkyl group attached to the sixth coordination position of the cobalt atom: methylcobalamin and adenosylcobalamin. The vitamin preparation that is used therapeutically is cyanocobalamin (also called vitamin B_{12}). Cyanocobalamin has no known physiologic role and must be converted to a biologically active form before it can be used by tissues.

Methylcobalamin is the form required for methionine synthase, which catalyzes the conversion of homocysteine to methionine (Fig. 107-1). When this reaction is impaired, folate metabolism is deranged, and it is this derangement that underlies the defect in DNA synthesis and the megaloblastic maturation pattern in patients who are deficient in cobalamin. In cobalamin deficiency, the unconjugated N_5-methyltetrahydrofolate newly taken from the bloodstream cannot be converted to other forms of tetrahydrofolate by methyl transfer. This is the so-called folate trap hypothesis. Because N_5-methyltetrahydrofolate is a poor substrate for the conjugating enzyme, it largely remains in the unconjugated form and slowly leaks from the cell. Tissue folate deficiency therefore develops, and this results in megaloblastic hematopoiesis. This hypothesis explains why tissue folate stores in cobalamin deficiency are substantially reduced, with a disproportionate reduction in conjugated, as compared with unconjugated, folates, despite normal or supranormal serum folate levels. It also explains why large doses of folate can produce a partial hematologic remission in patients with cobalamin deficiency.

Megaloblastic changes in both cobalamin and folate deficiency as well as in methotrexate treatment are related to a deficiency in production ofdTMP. In addition, the excess deoxyuridylate that accumulates can be phosphorylated and mistakenly incorporated into DNA in place of thymidylate; base pairing can be affected by this U-for-T substitution.

Plasma homocysteine levels are elevated in both folate and cobalamin deficiency, and high levels of plasma homocysteine appear to be a risk factor for thrombosis in both veins and arteries. It is not yet known, however, if hyperhomocysteinemia due to folate or cobalamin deficiency predisposes to thrombosis or alters its response to treatment.

Impairment in the conversion of homocysteine to methionine may also be partly responsible for the neurologic complications of cobalamin deficiency (see below). The methionine formed in this reaction is needed for the production of choline and choline-containing phospholipids. Nervous system damage is postulated to result at least in part from interference with these processes due to decreased methionine

production in cobalamin deficiency.

Adenosylcobalamin is required for the conversion of methylmalonyl CoA to succinyl CoA. Lack of this cofactor leads to large increases in the tissue levels of methylmalonyl CoA and its precursor, propionyl CoA. As a consequence, nonphysiologic fatty acids containing an odd number of carbon atoms are synthesized and incorporated into neuronal lipids. This biochemical abnormality may also contribute to the neurologic complications of cobalamin deficiency (see below).

CLINICAL DISORDERS

CLASSIFICATION OF MEGALOBLASTIC ANEMIAS (Table 107-1)

The cause of megaloblastic anemia varies in different parts of the world. In temperate zones, folate deficiency in alcoholics and pernicious anemia are the common types of megaloblastic anemias. In certain areas close to the equator, tropical sprue is endemic and an important cause of megaloblastic anemia, while in Scandinavia, infestations by the fish tapeworm, *Diphyllobothrium latum*, may be a cause.

The dietary intake of cobalamin is more than adequate for the body's requirements, except in true vegetarians and their breast-fed infants. Thus deficiency of cobalamin is almost always due to malabsorption. Malabsorption can occur at several levels. In contrast, the dietary intake of folic acid is marginal in many parts of the world. Furthermore, because the body's stores of folate are relatively low, folic acid deficiency can arise rather suddenly during periods of decreased dietary intake or increased metabolic demand. Finally, folic acid deficiency may be due to malabsorption. Often two or more of these factors coexist in a given patient.

Combined deficiencies of cobalamin and folic acid are not uncommon. Patients with tropical sprue are often deficient in both vitamins. The biochemical lesion that results in megaloblastic maturation of bone marrow cells also causes structural and functional abnormalities of the rapidly proliferating epithelial cells of the intestinal mucosa. Thus severe deficiency of one vitamin can lead to malabsorption of the other. Furthermore, as discussed above, a deficiency of cobalamin causes a secondary reduction in cellular folic acid.

Finally, megaloblastic anemias may occasionally be induced by factors unrelated to a vitamin deficiency. Most such cases are caused by one or more of the many drugs that interfere with DNA synthesis. Less commonly, megaloblastic maturation is encountered in certain acquired defects of hematopoietic stem cells. Rarest of all are specific congenital enzyme deficiencies.

COBALAMIN DEFICIENCY

The clinical features of cobalamin deficiency involve the blood, the gastrointestinal tract, and the nervous system.

The hematologic manifestations are almost entirely the result of anemia, although very rarely purpura may appear, due to thrombocytopenia. Symptoms of anemia may include

weakness, light-headedness, vertigo, and tinnitus, as well as palpitations, angina, and the symptoms of congestive failure. On physical examination, the patient with florid cobalamin deficiency is pale, with slightly icteric skin and eyes. Elevated bilirubin levels are related to high erythroid cell turnover in the marrow. The pulse is rapid, and the heart may be enlarged; auscultation will usually reveal a systolic flow murmur.

The gastrointestinal manifestations reflect the effect of cobalamin deficiency on the rapidly proliferating gastrointestinal epithelium. The patient sometimes complains of a sore tongue, which on inspection will be smooth and beefy red. Anorexia with moderate weight loss may also be evident, possibly accompanied by diarrhea and other gastrointestinal symptoms. These latter manifestations may be caused in part by megaloblastosis of the small intestinal epithelium, which results in malabsorption.

The neurologic manifestations often fail to remit fully on treatment. They begin pathologically with demyelination, followed by axonal degeneration and eventual neuronal death; the final stage, of course, is irreversible. Sites of involvement include peripheral nerves; the spinal cord, where the posterior and lateral columns undergo demyelination; and the cerebrum itself. Signs and symptoms include numbness and paresthesia in the extremities (the earliest neurologic manifestations), weakness, and ataxia. There may be sphincter disturbances. Reflexes may be diminished or increased. The Romberg and Babinski signs may be positive, and position and vibration senses are usually diminished. Disturbances of mentation will vary from mild irritability and forgetfulness to severe dementia or frank psychosis. It should be emphasized that *neurologic disease may occur in a patient with a normal hematocrit* and normalRBCindexes. Although it has many benefits, folate supplementation of food may increase the likelihood of neurologic presentations of cobalamin deficiency.

In the classic patient, in whom hematologic problems predominate, the blood and bone marrow show characteristic megaloblastic changes (described under "Diagnosis," below). The anemia may be very severe -- hematocrits of 15 to 20 are not infrequent -- but is surprisingly well tolerated by the patient because it develops so slowly.

Defective Release of Cobalamin from Food Cobalamin in food is tightly bound to enzymes in meat and is split from these enzymes by hydrochloric acid and pepsin in the stomach. People older than 70 years are commonly unable to release cobalamin from food sources but retain the ability to absorb crystalline B_{12}, the form most commonly found in multivitamins. The exact incidence of the defect in cobalamin release from food has not been well defined; estimates vary from 10 to greater than 50% of those over age 70 years. Only a minority of these persons go on to develop frank cobalamin deficiency, but many have biochemical changes, including low levels of cobalamin bound toTC II and elevated homocysteine levels, that augur cobalamin deficiency (see below).

Similarly, patients on drugs that suppress gastric acid production, such as omeprazole, may also fail to release cobalamin from food.

Pernicious Anemia Pernicious anemia, considered the most common cause of cobalamin deficiency, is caused by the absence ofIF, from either atrophy of the gastric mucosa or autoimmune destruction of parietal cells. It is most frequently seen in

individuals of northern European descent and African Americans and is much less common in southern Europeans and Asians. Men and women are equally affected. It is a disease of the elderly, the average patient presenting near age 60; it is rare under age 30, although typical pernicious anemia can be seen in children under age 10 (juvenile pernicious anemia). Inherited conditions in which a histologically normal stomach secretes either an abnormal IF or none at all will induce cobalamin deficiency in infancy or early childhood.

The incidence of pernicious anemia is substantially increased in patients with other diseases thought to be of immunologic origin, including Graves' disease, myxedema, thyroiditis, idiopathic adrenocortical insufficiency, vitiligo, and hypoparathyroidism. Patients with pernicious anemia also have abnormal circulating antibodies related to their disease: 90% have antiparietal cell antibody, which is directed against the H^+,K^+-ATPase, while 60% have anti-IF antibody. Antiparietal cell antibody is also found in 50% of patients with gastric atrophy without pernicious anemia, as well as in 10 to 15% of an unselected patient population, but anti-IF antibody is usually absent from these patients. Relatives of patients with pernicious anemia have an increased incidence of the disease, and even clinically unaffected relatives may have anti-IF antibody in their serum. Finally, treatment with glucocorticoids may reverse the disease.

The destruction of parietal cells in pernicious anemia is thought to be mediated by cytotoxic T cells. Pernicious anemia is unusually common in patients with agammaglobulinemia, suggesting that the cellular immune system plays a role in its pathogenesis. In contrast, *Helicobacter pylori* does not cause parietal cell destruction in pernicious anemia.

The most characteristic finding in pernicious anemia is gastric atrophy affecting the acid- and pepsin-secreting portion of the stomach; the antrum is spared. Other pathologic changes are secondary to the deficiency of cobalamin; these include megaloblastic alterations in the gastric and intestinal epithelium and the neurologic changes described above. The abnormalities in the gastric epithelium appear as cellular atypia in gastric cytology specimens, a finding that must be carefully distinguished from the cytologic abnormalities seen in gastric malignancy.

The *clinical manifestations* are primarily those of cobalamin deficiency, as described above. The disease is of insidious onset and progresses slowly. Laboratory examination will reveal hypergastrinemia and pentagastrin-fast achlorhydria as well as the hematologic and other laboratory abnormalities discussed under "Diagnosis."

Through appropriate replacement therapy, patients with pernicious anemia should experience complete and lifelong correction of all abnormalities that are due to cobalamin deficiency, except to the extent that irreversible changes in the nervous system may have occurred before treatment. These patients, however, are unusually subject to gastric polyps and have about twice the normal incidence of cancer of the stomach. Thus, patients should be followed with frequent stool guaiac examinations and endoscopy when indicated.

Postgastrectomy Following total gastrectomy or extensive damage to gastric mucosa as, for example, by ingestion of corrosive agents, megaloblastic anemia will develop

because the source ofIF has been removed. In all such patients, the absorption of orally administered cobalamin is impaired. Megaloblastic anemia may also follow partial gastrectomy, but the incidence is lower than after total gastrectomy. The cause of cobalamin deficiency after partial gastrectomy is not clear; defective release of cobalamin from food and intestinal overgrowth of bacteria have been suggested, but response to antibiotics is not common.

Intestinal Organisms Megaloblastic anemia may occur with intestinal stasis due to anatomic lesions (strictures, diverticula, anastomoses, "blind loops") or pseudoobstruction (diabetes mellitus, scleroderma, amyloid). This anemia is caused by colonization of the small intestine by large masses of bacteria that consume intestinal cobalamin before absorption. Steatorrhea may also be seen under these circumstances because bile salt metabolism is disturbed when the intestine is heavily colonized with bacteria. Hematologic responses have been observed after administration of oral antibiotics such as tetracycline and ampicillin. Megaloblastic anemia is seen in persons harboring the fish tapeworm, *D. latum*, due to competition by the worm for cobalamin. Destruction of the worm eliminates the problem.

Ileal Abnormalities Cobalamin deficiency is common in tropical sprue, while it is an unusual complication of nontropical sprue (gluten-sensitive enteropathy;Chap. 286). Virtually any disorder that compromises the absorptive capacity of the distal ileum can result in cobalamin deficiency. Specific entities include regional enteritis, Whipple's disease, and tuberculosis. Segmental involvement of the distal ileum by disease can cause megaloblastic anemia without any other manifestations of intestinal malabsorption such as steatorrhea. Cobalamin malabsorption is also seen after ileal resection. The Zollinger-Ellison syndrome (intense gastric hyperacidity due to a gastrin-secreting tumor) may cause cobalamin malabsorption by acidifying the small intestine, retarding the transfer of the vitamin from R binder toIF and impairing the binding of the cobalamin-IF complex to the ileal receptors. Chronic pancreatitis may also cause cobalamin malabsorption by impairing the transfer of the vitamin from R binder to IF. This abnormality can be detected by tests of cobalamin absorption (see below, Schilling test), but it is invariably mild and never causes clinical cobalamin deficiency. Finally, there is a rare congenital disorder, Imerslund-Grasbeck disease, in which a selective defect in cobalamin absorption is accompanied by proteinuria. Affected individuals have a mutation in cubulin, a receptor that mediates intestinal absorption of the cobalamin-IF complex.

Nitrous Oxide Inhalation of nitrous oxide as an anesthetic destroys endogenous cobalamin. As ordinarily used, the magnitude of the effects are not sufficient to cause clinical cobalamin deficiency, but repeated or protracted exposure (>6 h), particularly in older patients with borderline cobalamin stores, can lead to severe megaloblastic anemia and/or acute neurologic deficits.

FOLIC ACID DEFICIENCY

Since January, 1998, folic acid has been added to all enriched grain products by order of the U.S. Food and Drug Administration; accordingly, the incidence of folic acid deficiency has fallen markedly. Patients with folic acid deficiency are more often malnourished than those with cobalamin deficiency. The gastrointestinal manifestations

are similar to but may be more widespread and more severe than those of pernicious anemia. Diarrhea is often present, and cheilosis and glossitis are also encountered. However, in contrast to cobalamin deficiency, neurologic abnormalities do not occur.

The hematologic manifestations of folic acid deficiency are the same as those of cobalamin deficiency. Folic acid deficiency can generally be attributed to one or more of the following factors: inadequate intake, increased demand, or malabsorption.

Inadequate Intake Alcoholics may become folate deficient because their main source of caloric intake is alcoholic beverages. Distilled spirits are virtually devoid of folic acid, while beer and wine do not contain enough of the vitamin to satisfy the daily requirement. In addition, alcohol may interfere with folate metabolism. Narcotic addicts are also prone to become folate deficient because of malnutrition. Many indigent and elderly individuals who subsist primarily on canned foods or "tea and toast" and occasional teenagers whose diet consists of "junk food" develop folate deficiency. Food folate supplementation has made folate deficiency very rare.

Increased Demand Tissues with a relatively high rate of cell division such as the bone marrow or gut mucosa have a large requirement for folate. Therefore, patients with chronic hemolytic anemias or other causes of very active erythropoiesis may become deficient. Pregnant women formerly were at risk to become deficient in folic acid because of the high demand of the developing fetus. Deficiency in the first weeks of pregnancy can cause neural tube defects in newborns. Often the pregnancy was not detected until the defect had developed; thus, provision of folate supplementation to women after they learned they were pregnant was ineffective. However, folate food supplementation has decreased neural tube defects by more than 50%. Folate deficiency may also occur during the growth spurts of infancy and adolescence. Patients on chronic hemodialysis may require supplementary folate to replace that lost in the dialysate.

Malabsorption Folic acid deficiency is a common accompaniment of tropical sprue. Both the gastrointestinal symptoms and malabsorption are improved by the administration of either folic acid or antibiotics by mouth. Patients with nontropical sprue (gluten-sensitive enteropathy) may also develop significant folic acid deficiency that parallels other parameters of malabsorption. Similarly, folate deficiency in alcoholics may be due in part to malabsorption. In addition, other primary small-bowel disorders are sometimes associated with folate deficiency (Chap. 286).

DRUGS

Next to deficiency of folate or cobalamin, the most common cause of megaloblastic anemia is drugs. Agents that cause megaloblastic anemia do so by interfering with DNA synthesis, either directly or by antagonizing the action of folate. They can be classified as follows:

1. *Direct inhibitors of DNA synthesis*. They include purine analogues (6-thioguanine, azathioprine, 6-mercaptopurine), pyrimidine analogues (5-fluorouracil, cytosine arabinoside), and other drugs that interfere with DNA synthesis by a variety of mechanisms (hydroxyurea, procarbazine). The antiviral agent zidovudine (AZT), used

for treating HIV, often causes severe megaloblastic anemia.

2. *Folate antagonists*. The most toxic of these is methotrexate, a powerful inhibitor of dihydrofolate reductase which is used in the treatment of certain malignancies. Much less toxic but still capable of inducing a megaloblastic anemia are several weak dihydrofolate reductase inhibitors used to treat a variety of nonmalignant conditions including pentamidine, trimethoprim, triamterene, and pyrimethamine.

3. *Others*. A number of drugs antagonize folate by mechanisms that are poorly understood but are thought to involve an effect on absorption of the vitamin by the intestine. In this category are the anticonvulsants phenytoin, primidone, and phenobarbital. Megaloblastic anemia induced by these agents is mild.

OTHER MECHANISMS

Hereditary Megaloblastic anemia may be seen in several hereditary disorders. Orotic aciduria is a deficiency of orotidylic decarboxylase and phosphorylase, leading to a defect in pyrimidine metabolism and characterized by retarded growth and development as well as by the excretion of large amounts of orotic acid. Megaloblastic anemia has been reported in a single case of the Lesch-Nyhan syndrome, a condition resulting from a deficiency of hypoxanthine-guanine phosphoribosyltransferase whose clinical manifestations include gout, mental retardation, and self-mutilation. It has also been described in methylmalonic aciduria due to a combined defect in the biosynthesis of methyl and adenosyl cobalamins, although it is not seen in methylmalonic aciduria due to methylmalonyl CoA mutase deficiency. Congenital folate malabsorption causes megaloblastic anemia, accompanied by ataxia and mental retardation. Megaloblastic anemia has been reported to accompany the congenital deficiency of two other folate-metabolizing enzymes: dihydrofolate reductase and N_5-methyltetrahydrofolate:homocysteine methyltransferase. These deficiencies are less well documented than is congenital folate malabsorption. A thiamine-responsive megaloblastic anemia accompanied by nerve deafness and diabetes mellitus has been reported in several children. Megaloblastic changes as well as multinuclearity of red blood cell precursors are seen in the marrow of certain patients with congenital dyserythropoietic anemia, a group of inherited disorders characterized by mild to moderate anemia and a benign course.

TCII deficiency, like the congenital abnormalities in cobalamin absorption described previously, causes pronounced deficiency in cobalamin in infancy or early childhood, with all the accompanying manifestations. Megaloblastic anemia is not seen in hereditary TC I deficiency.

Refractory Megaloblastic Anemia This is a form of myelodysplasia in which megaloblastic erythropoiesis may sometimes be seen. Megaloblastic changes are restricted to the RBCseries (see below). As with other forms of myelodysplasia, refractory megaloblastic anemia is associated with an increased incidence of acute leukemia.

Megaloblastic changes are seen in erythremic myelosis and acute erythroleukemia (di Guglielmo), whereRBCprecursors are prominently involved. Here, the marrow is

characterized by bizarre erythroid maturation, with multinuclearity and multipolar mitotic figures in the RBC precursors (Chap. 111).

MEGALOBLASTIC DISEASE WITHOUT ANEMIA

Megaloblastic disease is easily overlooked in nonanemic patients. It can present in one of two ways.

Acute Megaloblastic Anemia Occasionally, a full-blown megaloblastic state can develop over the course of just a few days. This is usually seen following nitrous oxide anesthesia but may occur in any patient with a serious illness requiring intensive care, especially a patient receiving multiple transfusions, dialysis, or total parenteral nutrition. An acute megaloblastic state can also be precipitated by the administration of a weak antifolate (e.g., trimethoprim) to a patient with marginal tissue folate stores.

The condition resembles an immune cytopenia, with a rapidly developing thrombocytopenia and/or leukopenia in the absence of anemia. The blood smear may be completely normal, but the marrow is floridly megaloblastic. Acute megaloblastic anemia responds rapidly to treatment with folate plus cobalamin in the usual therapeutic doses.

Cobalamin Deficiency without Anemia Cobalamin deficiency without hematologic abnormalities is surprisingly common, especially in the elderly. The risk of a nonhematologic presentation for cobalamin deficiency is increased by the folate food fortification because folate can mask the hematologic effects of cobalamin deficiency. Between 10 and 30% of persons over age 70 years have metabolic evidence of cobalamin deficiency, either elevated homocysteine levels, low cobalamin-TCII levels, or both. Only 10% of these patients have defective production ofIF, and the remainder often have atrophic gastritis and cannot release cobalamin from their food (see above). These patients may present with neuropsychiatric abnormalities, including peripheral neuropathies, gait disturbance, memory loss, and psychiatric symptoms, sometimes with abnormal evoked potentials. Serum cobalamin levels may be normal or low, but serum levels of methylmalonic acid are almost invariably increased due to a deficiency of cobalamin at the tissue level. The neuropsychiatric abnormalities tend to improve and serum methylmalonic acid levels generally return to normal after treatment with cobalamin. Neurologic defects do not always reverse with cobalamin supplementation.

DIAGNOSIS

The finding of significant macrocytosis [mean corpuscular volume (MCV)> 100 fL] suggests the presence of a megaloblastic anemia. Other causes of macrocytosis include hemolysis, liver disease, alcoholism, hypothyroidism, and aplastic anemia. If the macrocytosis is marked (MCV > 110 fL), the patient is much more likely to have a megaloblastic anemia. Macrocytosis is less marked with concurrent iron deficiency or thalassemia. The reticulocyte count is low, and the leukocyte and platelet count may also be decreased, particularly in severely anemic patients. The blood smear (see Plate V-24) demonstrates marked anisocytosis and poikilocytosis, together with macroovalocytes, which are large, oval, fully hemoglobinized erythrocytes typical of megaloblastic anemias. There is some basophilic stippling, and an occasional

nucleatedRBC may be seen. In the white blood cell series, the neutrophils show hypersegmentation of the nucleus (see Plate V-38). This is such a characteristic finding that a single cell with a nucleus of six lobes or more should raise the immediate suspicion of a megaloblastic anemia. A rare myelocyte may also be seen. Bizarre, misshapen platelets are also observed. The reticulocyte index is low. The bone marrow is hypercellular with a decreased myeloid/erythroid ratio and abundant stainable iron. RBC precursors are abnormally large and have nuclei that appear much less mature than would be expected from the development of the cytoplasm (nuclear-cytoplasmic asynchrony). The nuclear chromatin is more dispersed than expected, and it condenses in a peculiar fenestrated pattern that is very characteristic of megaloblastic erythropoiesis. Abnormal mitoses may be seen. Granulocyte precursors are also affected, many being larger than normal, including giant bands and metamyelocytes. Megakaryocytes are decreased and show abnormal morphology.

Megaloblastic anemias are characterized by ineffective erythropoiesis (Chap. 61). In a severely megaloblastic patient, as many as 90% of theRBCprecursors may be destroyed before they are released into the bloodstream, compared with 10 to 15% in normal individuals. Enhanced intramedullary destruction of erythroblasts results in an increase in unconjugated bilirubin and lactic acid dehydrogenase (isoenzyme 1) in plasma. Abnormalities in iron kinetics also attest to the presence of ineffective erythropoiesis, with increased iron turnover but low incorporation of labeled iron into circulating RBCs.

In evaluating a patient with megaloblastic anemia, it is important to determine whether there is a specific vitamin deficiency by measuring serum cobalamin and folate levels. The normal range of cobalamin in serum is 200 to 900 pg/mL; values<100 pg/mL indicate clinically significant deficiency. Measurements of cobalamin bound toTC II would be a more physiologic measure of cobalamin status, but such assays are not yet routinely available. The normal serum concentration of folic acid ranges from 6 to 20 ng/mL; values £4 ng/mL are generally considered to be diagnostic of folate deficiency. Unlike serum cobalamin, serum folate levels may reflect recent alterations in dietary intake. Measurement ofRBCfolate level provides useful information because it is not subject to short-term fluctuations in folate intake and is better than serum folate as an index of folate stores.

Once cobalamin deficiency has been established, its pathogenesis can be delineated by means of a Schilling test. A patient is given radioactive cobalamin by mouth, followed shortly thereafter by an intramuscular injection of unlabeled cobalamin. The proportion of the administered radioactivity excreted in the urine during the next 24 h provides an accurate measure of absorption of cobalamin, assuming that a complete urine sample has been collected. Because cobalamin deficiency is almost always due to malabsorption (Table 107-1), this first stage of the Schilling test should be abnormal (i.e., small amounts of radioactivity in the urine). The patient is then given labeled cobalamin bound toIF. Absorption of the vitamin will now approach normal if the patient has pernicious anemia or some other type of IF deficiency. If cobalamin absorption is still decreased, the patient may have bacterial overgrowth (blind loop syndrome) or ileal disease (including an ileal absorptive defect secondary to the cobalamin deficiency itself). Cobalamin malabsorption due to bacterial overgrowth can frequently be corrected by the administration of antibiotics. The Schilling test can provide equally reliable

information after the patient has had adequate therapy with parenteral cobalamin.

A normal Schilling test in a patient with documented cobalamin deficiency may indicate poor absorption of the vitamin when mixed with food. This can be established by repeating the Schilling test with radioactive cobalamin scrambled with an egg.

Serum methylmalonic acid and homocysteine levels are also useful in the diagnosis of megaloblastic anemias. Both are elevated in cobalamin deficiency, while elevated levels of homocysteine but not methylmalonic acid are seen in folate deficiency. These tests measure tissue vitamin stores and may demonstrate a deficiency even when the more traditional but less reliable folate and cobalamin levels are borderline or even normal. Patients (particularly older patients) without anemia and with normal serum cobalamin levels but elevated levels of serum methylmalonic acid may develop neuropsychiatric abnormalities. Treatment of patients with this "subtle" cobalamin deficiency will usually prevent further deterioration and may result in improvement.

TREATMENT

Cobalamin Deficiency Apart from specific therapy related to the underlying disorder (e.g., antibiotics for intestinal overgrowth with bacteria), the mainstay of treatment for cobalamin deficiency is replacement therapy. Because the defect is nearly always malabsorption, patients are generally given parenteral treatment, specifically in the form of intramuscular cyanocobalamin. Parenteral treatment begins with 1000 ug cobalamin per week for 8 weeks, followed by 1000 ug cyanocobalamin intramuscularly every month for the rest of the patient's life. However, cobalamin deficiency can also be managed very effectively by oral replacement therapy with 2 mg crystalline B_{12} per day.

The response to treatment is gratifying. Shortly after treatment is begun, and several days before a hematologic response is evident in the peripheral blood, the patient will experience an increase in strength and an improved sense of well-being. Marrow morphology begins to revert toward normal within a few hours after treatment is initiated. Reticulocytosis begins 4 to 5 days after therapy is started and peaks at about day 7 (Fig. 107-3), with subsequent remission of the anemia over the next several weeks. If a reticulocytosis does not occur, or if it is less brisk than expected from the level of the hematocrit, a search should be made for other factors contributing to the anemia (e.g., infection, coexisting iron and/or folate deficiency, or hypothyroidism). Hypokalemia and salt retention may occur early in the course of therapy. Thrombocytosis may also be seen.

In most cases, replacement therapy is all that is needed for the treatment of cobalamin deficiency. Occasionally, however, a patient with a severe anemia will have such a precarious cardiovascular status that emergency transfusion is necessary. This must be done with great care, because such patients may develop heart failure from fluid overload. Blood must be administered slowly in the form of packedRBCs, with very close observation. A small volume of packed RBCs will frequently be enough to ameliorate the acute cardiovascular problems. If necessary, blood may be administered by exchanging patient blood (mostly plasma) for packed cells.

With lifelong treatment, patients should experience no further manifestations of

cobalamin deficiency, although neurologic symptoms may not be fully corrected even by optimal therapy. The potential for late development of gastric carcinoma in pernicious anemia necessitates careful follow-up of the patient.

Folate, particularly in large doses, can correct the megaloblastic anemia of cobalamin deficiency without altering the neurologic abnormalities. The neurologic manifestations may even be aggravated by folate therapy. Cobalamin deficiency can thus be masked in patients who are taking large doses of folate. For this reason, a hematologic response to folate must never be used to rule out cobalamin deficiency in a given patient; cobalamin deficiency can be excluded only by appropriate laboratory evaluation.

In light of the high frequency of defective cobalamin absorption in older people and the possible increased risk that overt cobalamin deficiency will present with neurologic rather than hematologic symptoms (because of folate food fortification), some experts have recommended the use of 0.1 mg oral crystalline cobalamin prophylaxis daily in people over age 65 years.

Folate Deficiency As for cobalamin deficiency, folate deficiency is treated by replacement therapy. The usual dose of folate is 1 mg/d, by mouth, but higher doses (up to 5 mg/d) may be required for folate deficiency due to malabsorption. Parenteral folate is rarely necessary. The hematologic response is similar to that seen after replacement therapy for cobalamin deficiency, i.e., a brisk reticulocytosis after about 4 days, followed by correction of the anemia over the next 1 to 2 months. The duration of therapy depends on the basis of the deficiency state. Patients with a continuously increased requirement (such as patients with hemolytic anemia) or those with malabsorption or chronic malnutrition should continue to receive oral folic acid indefinitely. In addition, the patient should be encouraged to maintain an optimal diet containing adequate amounts of folate.

Other Causes of Megaloblastic Anemia Megaloblastic anemia due to drugs can be treated, if necessary, by reducing the dose of the drug or eliminating it altogether. The effects of folate antagonists that inhibit dihydrofolate reductase can be counteracted by folinic acid [5-formyl tetrahydrofolate (THF)] in a dose of 100 to 200 mg/d (Fig. 107-1), which circumvents the block in folate metabolism by providing a form of folate that can be converted to 5,10-methylene THF. For the megaloblastic forms of sideroblastic anemia, pyridoxine in pharmacologic doses (as high as 300 mg/d) should be tried. If this fails, pyridoxal phosphate may work, presumably in part by promoting the conversion of THF to 5,10-methylene THF. Simple supportive measures are all that appear to be in order for treatment of refractory megaloblastic anemia. Acute erythroleukemia (di Guglielmo's disease) is usually treated like other types of acute myeloid leukemia (Chap. 111).

108. HEMOLYTIC ANEMIAS AND ACUTE BLOOD LOSS - *H. Franklin Bunn*, *Wendell Rosse*

The loss of red cells either through hemorrhage or, less commonly, through premature destruction of the red cells (hemolysis) may cause anemia. Hemolysis or blood loss normally leads to an increase in red cell production, which is clinically manifested by an increase in reticulocytes.

HEMOLYTIC ANEMIAS

Red blood cells (RBC) normally survive 90 to 120 days in the circulation. The life span of RBC may be shortened in a number of disorders, often resulting in anemia if the bone marrow is not able to replenish adequately the prematurely destroyed RBC. The disorders associated with hemolytic anemias are generally identified by the abnormality that brings about the premature destruction of the RBC.

In all patients with hemolytic anemia, a careful history and physical examination provide important clues to the diagnosis. The patient may complain of fatigue and other symptoms of anemia (Chap. 61). Less commonly, jaundice and even red-brown urine (hemoglobinuria) are reported. A complete drug and toxin exposure history and the family history often provide crucial information. The physical examination may show jaundice of skin and mucosae. Splenomegaly is encountered in a variety of hemolytic anemias. A wide array of other historic and physical findings is associated with specific hemolytic anemias (see below).

Laboratory tests may be used initially to demonstrate the presence of hemolysis (Table 108-1) and define its cause. An elevated reticulocyte count in the patient with anemia is the most useful indicator of hemolysis, reflecting erythroid hyperplasia of the bone marrow; biopsy of the bone marrow is often unnecessary. Reticulocytes are also elevated in patients with active blood loss, those with myelophthisis, and those who are recovering from suppression of erythropoiesis (Chap. 61). The morphology of theRBC may provide evidence both of hemolysis and of its cause; the characteristic abnormalities and their associated causes and syndromes are listed inTable 108-2. While the findings on the peripheral blood smear alone are rarely pathognomonic, they may provide important clues to the presence of hemolysis and to diagnosis.

RBCmay be prematurely removed from the circulation by macrophages, particularly those of the spleen and liver (extravascular lysis), or, less commonly, by disruption of their membranes during their circulation (intravascular hemolysis). Both mechanisms result in increased heme catabolism and enhanced formation of unconjugated bilirubin, which is normally conjugated by the liver and excreted. The plasma level of unconjugated bilirubin may be high enough to produce readily apparent jaundice (detectable usually when serum bilirubin is>34 umol/L or 2 mg/dL). The unconjugated (indirect) bilirubin level can be further elevated by a commonly encountered defect in conjugation of bilirubin (Gilbert's syndrome) (Chap. 294). In patients with hemolysis, the level of unconjugated bilirubin never exceeds 70 to 85 umol/L (4 to 5 mg/dL), unless liver function is impaired.

In the absence of tissue damage in other organs, serum enzyme levels can be useful in

the diagnosis and monitoring of patients with hemolysis. Lactate dehydrogenase (LDH), particularly LDH-2, is elevated by acceleratedRBCdestruction. Serum AST (SGOT) may be somewhat elevated, whereas ALT (SGPT) is not.

Haptoglobin is ana globulin that is present in high concentration (~1.0 g/L) in the plasma (and serum). It binds specifically and tightly to the globin in hemoglobin. The hemoglobin-haptoglobin complex is cleared within minutes by the mononuclear phagocyte system. Thus patients with significant hemolysis, either intravascular or extravascular, have low or absent levels of serum haptoglobin. The fact that haptoglobin synthesis is decreased in patients with hepatocellular disease and increased in inflammatory states must be considered in the interpretation of serum haptoglobin.

Intravascular hemolysis (which is uncommon) results in the release of hemoglobin into the plasma. In these cases, plasma hemoglobin is increased in proportion to the degree of hemolysis. Plasma hemoglobin may be falsely elevated due to lysis ofRBC in vitro. If the haptoglobin-binding capacity of the plasma is exceeded, free hemoglobin passes through renal glomeruli. This filtered hemoglobin is reabsorbed by the proximal tubule, where it is catabolized in situ, and the heme iron is incorporated into storage proteins (ferritin and hemosiderin). The presence of hemosiderin in the urine, detected by staining the sediment with Prussian blue, indicates that a significant amount of circulating free hemoglobin has been filtered by the kidneys. Hemosiderin appears 3 to 4 days after the onset of hemoglobinuria and may persist for weeks after its cessation. When the absorptive capacity of the tubular cells is exceeded, hemoglobinuria ensues. Hemoglobinuria indicates severe intravascular hemolysis. Hemoglobinuria must be distinguished from hematuria (in which case RBC are seen on urine examination) and from myoglobin due to rhabdomyolysis; in all three cases, the urine is positive with the benzidine reaction, commonly used in analysis of urine. The distinction between hemoglobinuria and myoglobinuria can best be made by specific tests that exploit immunologic differences or differences in solubility. After centrifugation of an anticoagulated blood specimen, the plasma of patients with hemoglobinuria has a reddish-brown color, whereas that of patients with myoglobinuria is normal in color. Because of its higher molecular weight, hemoglobin has lower glomerular permeability than myoglobin and is less rapidly cleared by the kidneys.

CLASSIFICATION

The hemolytic anemias can be grouped in three different ways, shown inTable 108-3. The cause of acceleratedRBCdestruction can be regarded as (1) a molecular defect (hemoglobinopathy or enzymopathy) inside the red cell, (2) an abnormality in membrane structure and function, or (3) an environmental factor such as mechanical trauma or an autoantibody. In *intracorpuscular types* of hemolysis, the patient's RBC have an abnormally short life span in a normal recipient (with a compatible blood type), while compatible normal RBC survive normally in the patient. The opposite is true in *extracorpuscular types* of hemolysis. Finally, hemolytic disorders can be classified as either inherited or acquired.

INHERITED HEMOLYTIC ANEMIAS

The inherited hemolytic anemias are due to inborn defects in one of three main

components of red cells: the membrane, the enzymes, or hemoglobin. These defects are often known at the genomic level, but their identification still largely depends on their clinical and laboratory manifestations.

Red Cell Membrane Disorders These are usually readily detected by morphologic abnormalities of the RBC on the blood film. There are three types of inherited RBC membrane abnormalities: hereditary spherocytosis, hereditary elliptocytosis (including hereditary pyropoikilocytosis), and hereditary stomatocytosis.

Hereditary spherocytosis This condition is characterized by spherical RBC due to a molecular defect in one of the proteins in the cytoskeleton of the RBC membrane, leading to a loss of membrane and hence decreased ratio of surface area to volume and consequently spherocytosis. This disorder usually has an autosomal dominant inheritance pattern and an incidence of approximately 1:1000 to 1:4500. In ~20% of patients, the absence of hematologic abnormalities in family members suggests either autosomal recessive inheritance or a spontaneous mutation. The disorder is sometimes clinically apparent in early infancy but often escapes detection until adult life.

CLINICAL MANIFESTATIONS The major clinical features of hereditary spherocytosis are anemia, splenomegaly, and jaundice. The prominence of jaundice accounts for the disorder's prior designation as "congenital hemolytic jaundice" and is due to an increased concentration of unconjugated (indirect-reacting) bilirubin in plasma. Jaundice may be intermittent and tends to be less pronounced in early childhood. Because of the increased bile pigment production, pigmented gallstones are common, even in childhood. Compensatory erythroid hyperplasia of the bone marrow occurs, with the extension of red marrow into the midshafts of long bones and occasionally with extramedullary erythropoiesis, at times leading to the formation of paravertebral masses visible on chest x-ray. Because the bone marrow's capacity to increase erythropoiesis by six- to eightfold exceeds the usual rate of hemolysis, anemia is usually mild or moderate and may even be absent in an otherwise healthy individual. Compensation may be temporarily interrupted by episodes of relative erythroid hypoplasia precipitated by infections, particularly parvovirus, trauma, surgery, and pregnancy. Splenomegaly is very common. The hemolytic rate may increase transiently during systemic infections, which induce further splenic enlargement. Chronic leg ulcers, similar to those observed in sickle cell anemia, occur occasionally.

The characteristic erythrocyte abnormality is the spherocyte (Plate V-26). The mean corpuscular volume (MCV) is usually normal or slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is increased to 350 to 400 g/L. Spheroidicity may be quantitatively assessed by measurement of the osmotic fragility of theRBC on exposure to hypoosmotic solutions causing a net influx of water (Fig. 108-1). Because spherocytes have a decreased surface area per unit volume, they are able to take in less water and hence lyse at a higher concentration of saline than normal cells. On microscopic examination, spherocytes are usually detected as small cells without central pallor. They will ordinarily not influence the osmotic fragility test unless they constitute more than 1 or 2% of the total cell population. The autohemolysis test, which measures the amount of spontaneous hemolysis occurring after 48 h of sterile incubation, is also useful.

PATHOGENESIS The molecular abnormality in hereditary spherocytosis primarily involves the proteins responsible for tethering the lipid bilayer to the underlying cytoskeletal network. Nearly all patients have a significant deficiency of spectrin, which is sometimes secondary to an inherited molecular defect in that protein. About 50% of patients have a defect in ankyrin, the protein that forms a bridge between protein 3 and spectrin (Fig. 108-2). Homozygotes who have a recessive inheritance pattern for ankyrin deficiency have more severe anemia than heterozygotes with the more common dominant form. About 25% of patients have a mutation of protein 3, resulting in a deficiency of that protein and mild anemia with dominant inheritance. Most of the remaining 25% have mutations of spectrin, leading to impaired synthesis or self-association;b-spectrin deficiency is generally mild, with dominant inheritance, while a-spectrin deficiency is severe, with a recessive inheritance pattern. Because the lipid bilayer is not well anchored when these proteins are defective, part of it is lost by vesiculation, resulting in a more spherical and less deformable cell. Because of their shape and rigidity, spherocytes cannot traverse the interstices of the spleen where their increased metabolic rate cannot be sustained, causing a further loss of surface membrane. This "conditioning" produces a subpopulation of hyperspheroidalRBC in the peripheral blood.

DIAGNOSIS Hereditary spherocytosis must be distinguished primarily from the spherocytic hemolytic anemias associated withRBCantibodies. The family history of anemia and/or splenectomy is helpful, when present. The diagnosis of immune spherocytosis is usually readily established by a positive direct Coombs test (see below). Spherocytes are also seen in association with hemolysis induced by splenomegaly in patients with cirrhosis, in clostridial infections, and in certain snake envenomations (due to the action of phospholipases on the membrane). A few spherocytes are seen in the course of a wide variety of hemolytic disorders, particularly glucose-6-phosphate dehydrogenase (G6PD) deficiency.

TREATMENT

Splenectomy reliably corrects the anemia, although theRBCdefect and its consequent morphology persist. The operative risk is low. RBC survival after splenectomy is normal or nearly so; if it is not, an accessory spleen or another diagnosis should be sought. Because of the potential for gallstones and for episodes of bone marrow hypoplasia or hemolytic crises, splenectomy should be performed in symptomatic individuals; cholecystectomy should not be performed without splenectomy, as intrahepatic gallstones may result. Splenectomy in children should be postponed until age 4, if possible, to minimize the risk of severe infections with gram-positive encapsulated organisms. Polyvalent pneumococcal vaccine should be administered at least 2 weeks before splenectomy. In patients with severe hemolysis, folic acid (1 mg/d) should be administered prophylactically.

Hereditary elliptocytosis and hereditary pyropoikilocytosis Oval or ellipticRBC are normally found in birds, reptiles, camels, and llamas; however, they occur in appreciable numbers in humans only in *hereditary elliptocytosis*, a disorder that is transmitted as an autosomal dominant trait and affects 1 per 4000 to 5000 people, a frequency similar to that of hereditary spherocytosis (rarely, patients with myelodysplastic disorders of the bone marrow may have acquired elliptocytosis). The elliptic shape is acquired as the

cell deforms to traverse the microcirculation but does not spring back to its initial biconcave shape. In most affected individuals, a structural abnormality of erythrocyte spectrin that leads to impaired assembly of the cytoskeleton. In some families, affected individuals have a deficiency of erythrocyte membrane protein 4.1, which stabilizes the interaction of spectrin and actin in the cytoskeleton (Fig. 108-2); homozygotes with absence of this protein have more marked hemolysis. In Southeast Asia, there is a high incidence of hereditary ovalocytosis, in which a small internal deletion of protein 3 makes the membrane rigid and confers resistance against malaria.

The great majority of patients manifest only mild hemolysis, with hemoglobin levels>120 g/L, reticulocytes<4% (0.2 ´10_{12}/L), depressed haptoglobin levels, andRBCsurvival times just under the normal range. In 10 to 15% of patients with more severe abnormalities, the rate of hemolysis is substantially increased, with median survival times of RBC as short as 5 days and reticulocytes ranging up to 20%. Hemoglobin levels rarely fall below 90 to 100 g/L. RBC destruction occurs predominantly in the spleen, which is enlarged in patients with overt hemolysis. Hemolysis is corrected by splenectomy.

In both the anemic and nonanemic varieties of this disorder, at least 25% and, more commonly, >75% ofRBC are elliptic, with an axial ratio (width/length) of<0.78. Patients with hemolysis frequently have microovalocytes, bizarre-shaped RBC, and RBC fragments, all of which increase in number after splenectomy. The degree of hemolysis does not correlate with the percentage of elliptocytes. Osmotic fragility is usually normal but may be increased in patients with overt hemolysis.

Hereditary pyropoikilocytosis is a rare disorder related to hereditary elliptocytosis and is characterized by bizarre-shaped, microcyticRBC that undergo disruption at temperatures of 44 to 45°C (in contrast, normal RBC are stable up to 49°C). This condition results from a deficiency of spectrin and an abnormality of spectrin self-assembly. Hemolysis is usually severe, is recognized in childhood, and is partially responsive to splenectomy.

Hereditary Stomatocytosis Stomatocytes are cup-shapedRBC(concave on one face and convex on the other). This formation results in a slitlike central zone of pallor on dried smears. The syndrome of hereditary hemolytic anemia and stomatocytic RBC is inherited in an autosomal dominant pattern. RBC have an increased permeability to sodium and potassium, which is compensated for by an increased active transport of these cations. In some patients, the RBC are swollen with an excess of ions and water and a decreased mean corpuscular hemoglobin concentration (overhydrated stomatocytes, "hydrocytosis"); many of these patients lack the RBC membrane protein 7.2 (stomatin). In other patients, the RBC are shrunken, with a decreased ion and water content and an increased mean corpuscular hemoglobin concentration (dehydrated stomatocytes, "desiccytosis" or "xerocytosis"). Those patients in whom the RBC are overhydrated have true stomatocytes on dried smears. Dehydrated stomatocytes assume the morphology of target cells on dried smears. Osmotic fragility is increased in overhydrated stomatocytes and decreased in underhydrated stomatocytes. RBC lacking Rh proteins (Rh_{null}cells) are stomatocytic and have a shortened life span.

Most patients have splenomegaly and mild anemia. Splenectomy decreases but does

not totally correct the hemolytic process.

Red Cell Enzyme Defects During its maturation, theRBCloses its nucleus, ribosomes, and mitochondria and thus its capability for protein synthesis and oxidative phosphorylation. The mature circulating RBC has a relatively simple pattern of intermediary metabolism (Fig. 108-3) in keeping with its modest metabolic obligations. ATP must be generated from the Embden-Meyerhof pathway to drive the cation pump that maintains the ionic milieu in the RBC. Smaller amounts of energy are needed for the preservation of hemoglobin iron in the ferrous (Fe^{2+}) state and perhaps for the renewal of the lipids in the RBC membrane. About 10% of the glucose consumed by the RBC is metabolized via the hexose-monophosphate shunt (Fig. 108-3), which protects both hemoglobin and the membrane from exogenous oxidants, including certain drugs.

Deficiency states have been reported for most of the enzymes shown in Fig. 108-3. Many of these enzyme abnormalities appear to be restricted toRBC. Mutations can result in no protein product, a dysfunctional product, or an unstable product. Mutations resulting in decreased stability will be detected more readily in RBC compared with other cells having either a shorter life span or the synthetic capability to renew the enzyme.

Defects in the Embden-Meyerhof Pathway In general, these enzymopathies have similar pathophysiologic and clinical features. Patients present with a congenital nonspherocytic hemolytic anemia of variable severity. TheRBC are often relatively deficient in ATP, resulting in a leak of potassium ion out of these cells. Abnormalities in RBC morphology (see below) indicate that the membrane is affected by the enzyme defect. These RBC are rigid and thus more readily sequestered by the mononuclear phagocyte system.

Some of these glycolytic enzyme deficiencies such as pyruvate kinase (PK) deficiency and hexokinase deficiency are localized to theRBC, with no apparent metabolic abnormality in other cells; in the case of PK deficiency, this is due to specific isozymes confined to the RBC. In other disorders, the enzyme deficiency is more widespread. Glucose phosphate isomerase deficiency and phosphoglycerate kinase deficiency also involve leukocytes, although affected individuals have no apparent abnormalities of leukocyte function. Individuals with deficiency of triose phosphate isomerase have decreased levels of enzyme in leukocytes, muscle cells, and cerebrospinal fluid, and they have a progressive neurologic disorder. Some patients with phosphofructokinase deficiency have a myopathy.

About 95% of the clinically significant defects in the glycolytic pathway are due toPKdeficiency, and about 4% are due to glucose phosphate isomerase deficiency. The remainder, shown in Fig. 108-3, are extremely rare. Most have been encountered in isolated families; clinical manifestations are variable. A number of different mutations result in PK deficiency. Some missense mutations in decreased reaction with substrate (phosphoenolpyruvate), an enhancing molecule (fructose 1,6 diphosphate), or ADP. Thus, there is considerable variability in the clinical manifestations and laboratory findings among individuals reported as having PK deficiency. Most of these patients are compound heterozygotes who have inherited a different defective enzyme from each parent.

Most of the glycolytic enzyme defects are inherited in an autosomal recessive pattern. The parents of affected patients are heterozygotes and express half-normal levels of enzyme activity, which are more than adequate for normal metabolic function. Thus, the parents are entirely asymptomatic. Since the gene frequency for this group of enzymopathies is low, true homozygotes are often the offspring of a consanguineous mating. More often, affected individuals are compound heterozygotes. Phosphoglycerate kinase deficiency is inherited as a sex-linked disorder. Affected males have a severe hemolytic anemia, while female carriers may have a mild hemolytic process.

CLINICAL MANIFESTATIONS Patients with severe hemolysis usually present during early childhood with anemia, jaundice, and splenomegaly.

LABORATORY FINDINGS Patients have a normocytic (or slightly macrocytic), normochromic anemia with reticulocytosis. In those withPKdeficiency, bizarre erythrocytes, including spiculated cells, are noted on the peripheral smear, especially after splenectomy. Spherocytes are usually absent; hence the term *congenital nonspherocytic hemolytic anemia* has been applied to these disorders. Unlike hereditary spherocytosis, the osmotic fragility of freshly drawn blood is usually normal. Incubation brings out an osmotically fragile population ofRBC, an abnormality not corrected by the addition of glucose.

The diagnosis of this group of anemias depends on specific enzymatic assays; care must be taken to provide an appropriate concentration of substrate to detect those variants with a low affinity for substrate or enhancing molecule. An abnormality in enzyme kinetics, differences in electrophoretic mobility, pH optimum, or heat stability may be useful in documenting heterogeneity among enzyme variants.

TREATMENT

Most patients do not require therapy. Those with severe hemolysis should be given folic acid (1 mg/d). Blood transfusions may be necessary during a hypoplastic crisis. Women withPKdeficiency may become very anemic during pregnancy, sometimes leading to the diagnosis for the first time.

Because of their enzymatic defect, the younger cells (reticulocytes) depend on mitochondrial respiration rather than glycolysis for maintenance of ATP. However, in the hypoxic environment of the spleen, aerobic metabolism is curtailed and the ATP-depleted cells are destroyed in situ. Reticulocytes are normally retained in the spleen for 24 to 48 h. Patients withPKdeficiency may benefit from splenectomy, which usually leads to a marked increase in circulating reticulocytes. Patients with deficiency of glucose phosphate isomerase also may improve after splenectomy. Splenectomy has not been proven effective in individuals with other glycolytic enzymopathies.

Defects in the hexose-monophosphate shunt The normalRBC is well protected against oxidant stress. When the cell is exposed to a drug or toxin that generates oxygen radicals, glucose metabolism via the hexose-monophosphate shunt is normally increased severalfold. Reduced glutathione is regenerated, protecting the sulfhydryl

groups of hemoglobin and the RBC membrane from oxidation. Individuals with an inherited defect in the hexose-monophosphate shunt are unable to maintain an adequate level of reduced glutathione in their RBC, hemoglobin sulfhydryl groups become oxidized, and the hemoglobin precipitates within the RBC, forming Heinz bodies.

G6PD DEFICIENCY This is by far the most common congenital shunt defect, affecting more than 200 million people throughout the world; like hemoglobin S, it partially protects the patient from malaria by providing a defective home for the merozoite. Considerable genetic heterogeneity exists among affected individuals, and over 400 variants ofG6PDhave been described. In most cases, the alteration is a base substitution, leading to an amino acid replacement rather than a deletion or truncation of the protein. The mutations generate enzymes with differences in electrophoretic mobility, enzyme kinetics, pH optimum, and heat stability. These differences result in great variation of clinical severity, ranging from nonspherocytic hemolytic anemia without demonstrable oxidant stress (particularly shortly after birth), through hemolytic anemia only when stimulated by marked to mild oxidant stress, to no clinically detectable abnormality. The normal G6PD is designated as type B. About 20% of individuals of African descent have a G6PD (designated A+) that differs by a single amino acid and is electrophoretically distinguishable but functionally normal. Among the clinically significant G6PD variants, the most common, the so-called A- type, is due to two base substitutions and is encountered primarily in individuals of central African descent. The A- G6PD has the same electrophoretic mobility as the A+ type, but it is unstable and has abnormal kinetic properties. This variant is found in about 11% of African American males. A second relatively common G6PD variant is encountered among peoples of Mediterranean origin, particularly Sardinians and Sephardic Jews; this variant is more severe than the A- variant and may result in nonspherocytic hemolytic anemia in the absence of known oxidative stress. A third relatively common and slightly less severe variant occurs in southern Chinese populations.

TheG6PDgene is located on the X chromosome; thus the deficiency state is a sex-linked trait. Affected males (hemizygotes) inherit the abnormal gene from their mothers who are usually carriers (heterozygotes). Because of inactivation of one of the two X chromosomes (Lyon hypothesis:Chap. 65), the heterozygote has two populations ofRBC: normal and deficient in G6PD. Most female carriers are asymptomatic. Those who happen to have a high proportion of deficient cells resemble the male hemizygotes. G6PD activity normally declines ~50% during the 120-day life span of the RBC. This decay is moderately accelerated in A-RBC and markedly so in RBC containing the Mediterranean variant. Individuals with the A- variant normally have a slightly shortened RBC survival time, but they are not anemic. Clinical problems arise only when the affected individual is subjected to some type of environmental stress. Most often, hemolytic episodes are triggered by viral and bacterial infections. The mechanism is unknown. In addition, drugs or toxins that pose an oxidant threat to the RBC (most commonly sulfa drugs, antimalarials, and nitrofurantoin) cause hemolysis in individuals deficient in G6PD (Table 108-4). Although aspirin is frequently mentioned as a likely offender, it has no deleterious effect in A- individuals. Accidental ingestion of toxic compounds such as naphthalene (moth balls) may cause severe hemolysis. Metabolic acidosis can precipitate an episode of hemolysis in individuals deficient in G6PD.

CLINICAL AND LABORATORY FEATURES The patient may experience an acute hemolytic crisis within hours of exposure to the oxidant stress, leading to hemoglobinuria and peripheral vascular collapse in severe cases. Since only the older population ofRBC is rapidly destroyed, the hemolytic crisis is usually self-limited, even if the exposure to the oxidant continues. Among black males with the A- variant, the RBC mass decreases by a maximum of 25 to 30%. During acute hemolysis, a rapid drop in hematocrit is accompanied by a rise in plasma hemoglobin and unconjugated bilirubin and a decrease in plasma haptoglobin. The oxidation of hemoglobin leads to the formation of Heinz bodies, visualized by means of a supravital stain such as crystal violet. However, Heinz bodies are usually not seen after the first day or so, since these inclusions are readily removed by the spleen. Their removal leads to the formation of "bite cells" (RBC that have lost a peripheral portion of the cell). Multiple bites cause the formation of fragments. A few spherocytes also may be present. Individuals with the Mediterranean typeG6PDhave a more unstable enzyme and, therefore, a much lower overall enzyme activity than individuals with the A- variant. As a result, they have more severe clinical manifestations. A minority of patients are exquisitely sensitive to fava beans and develop a fulminant hemolytic crisis after exposure. The oxidants in *Vicia fava* are twob-glycosides whose aglycones, when autooxidized, produce oxygen free radicals. The incidence of favism is highly variable due to variations in concentration, in absorption, or in metabolism of the aglycones. Favism is not encountered in individuals with the A-variant.

The *diagnosis* ofG6PDdeficiency should be considered in any individual, particularly a male of African or Mediterranean descent, who experiences an acute hemolytic episode. The patient should be questioned about possible exposure to oxidant agents. The diagnosis can be established by a number of tests that assess either the enzyme activity or the effects of its deficiency. However, the test may yield a false-negative result during a hemolytic episode when the oldRBCcontaining the defective enzyme have already lysed.

TREATMENT

Since hemolysis in patients deficient in A-G6PD is usually self-limited, no specific treatment is necessary. Splenectomy does not benefit Mediterranean patients with chronic hemolysis. Blood transfusions are rarely indicated. Adequate urine flow should be maintained if hemoglobinuria develops during an acute hemolytic episode.

Prevention of hemolytic episodes is best. Infections ought to be treated promptly. Patients should be warned about risks posed by oxidant drugs and fava beans. Any patient of African or Mediterranean ancestry about to be given an oxidant drug should be screened forG6PDdeficiency.

OTHER DEFECTS OF THE HEXOSE-MONOPHOSPHATE SHUNT A few kindreds have been found to have congenital deficiency inRBCglutathione due to a defect in either of the two enzymes responsible for the synthesis of this tripeptide. Affected individuals have a hemolytic anemia with Heinz bodies that is aggravated by oxidant drugs. Deficiency of glutathione reductase has been reported, but its relationship to clinically significant hemolysis is not well established. Sometimes the deficiency state can be corrected by the administration of riboflavin (5 mg/d). Deficiencies of glutathione

peroxidase and 6-phosphogluconate dehydrogenase have been observed, but their association with hemolysis is uncertain.

Other enzyme defects Hemolytic anemia may sometimes be caused by abnormalities in enzymes of nucleotide metabolism. Individuals with pyrimidine 5¢-nucleotidase deficiency have marked coarse basophilic stippling in theirRBCbecause the mRNA of the cell is not properly metabolized. Hemolytic anemia also has been noted in individuals whose RBC have supranormal levels of adenosine deaminase and relatively low levels of ATP.

Hemoglobinopathies The sickling disorders constitute an important form of congenital hemolytic anemia. Less commonly, hemolysis may be due to the inheritance of an unstable hemoglobin variant.**For further discussion, see Chap. 106.*

ACQUIRED HEMOLYTIC ANEMIAS

In most patients with acquired hemolytic anemia,RBC are made normally but are prematurely destroyed because of damage acquired in the circulation. (The exceptions are rare disorders characterized by acquired dysplasia of the cells of the bone marrow and the production of structurally and functionally abnormal RBC.) The damage that occurs may be mediated by antibodies or toxins or may be due to abnormalities in the circulation, including an overactive mononuclear phagocyte system or traumatic lysis by natural or artificial impediments to circulation. The acquired hemolytic anemias can be classified into five categories (Table 108-5).

Hypersplenism The spleen is particularly efficient in trapping and destroyingRBC that have minimal defects. This unique ability of the spleen to filter mildly damaged RBC results from its unusual vascular anatomy (Chap. 63). Almost all the blood circulating through the spleen flows rapidly from arterioles in the white pulp to sinuses in the spleen's red pulp and then into the venous system. In contrast, a small portion of splenic blood flow (normally 1 to 2%) passes into the "marginal zone" of the lymphatic white pulp. Although the cells that occupy this zone are not phagocytic, they serve as a mechanical filter that hinders the progress of severely damaged blood cells. As RBC leave this zone and enter the red pulp, they flow into narrow cords, rich in macrophages, that end blindly but communicate with sinuses through small openings between the lining cells of the sinuses. These openings, averaging 3 um in diameter, test the ability of RBC (4.5 um in diameter) to undergo a deformation. RBC that cannot re-enter the vascular sinuses are engulfed by phagocytic cells and destroyed (seeFig. 63-1).

The normal spleen retains reticulocytes for 1 to 2 days but otherwise poses no threat to normalRBCuntil they become senescent. However, in the face of splenomegaly, increased destruction of the cells of the blood, including the RBC, may take place due to pooling of the blood in a relatively nutrient-poor environment full of phagocytic cells. When splenic sequestration causes cytopenia, hypersplenism is diagnosed. In infiltrative diseases of the spleen, substantial splenomegaly may exist with no apparent hemolysis; inflammatory and congestive splenomegaly is commonly associated with modest shortening of RBC survival time, along with more marked granulocytopenia and thrombocytopenia. Patients with cytopenia(s) sufficient to produce symptoms generally benefit from splenectomy.

Immunologic Causes of Hemolysis Immune hemolysis in the adult is usually induced by IgG or IgM antibodies with specificity for antigens associated with the patient'sRBC(often called "autoantibodies") (Table 108-6); rarely, transfused RBC may be hemolyzed by alloantibodies directed against foreign antigens on those cells (Chap. 114).

The Coombs antiglobulin test is the major tool for diagnosing autoimmune hemolysis. This test relies on the ability of antibodies specific for immunoglobulins (especially IgG) or complement components (especially C3) to agglutinateRBC when these proteins are present on the RBC. The *direct Coombs test* measures the ability of anti-IgG or anti-C3 antisera to agglutinate the patient's RBC. The presence or absence of IgG and/or C3 may help define the origin of the immune hemolytic anemia (Table 108-6). Rarely, neither IgG nor complement may be found on the RBC of the patient (Coombs-negative immune hemolytic anemia).

Antibodies to particularRBCantigens in the serum of the patient can be detected by reacting the serum with normal RBC bearing the antigen. IgM antibodies (usually cold-reacting) may be detected by agglutination of normal or fetal RBC. IgG antibodies may be detected by the *indirect Coombs test*, in which the serum of the patient is incubated with normal RBC and antibody is detected with anti-IgG, as in the direct Coombs test.

"Warm" antibodies Antibodies that react with protein antigens are nearly always IgG and react at body temperature; occasionally, they are IgA and rarely IgM. Hemolysis due to autologous antibodies is called *autoimmune hemolytic (or immunohemolytic) anemia, warm antibody type*.

CLINICAL MANIFESTATIONS Immunohemolytic anemia of the warm antibody type is induced by IgG antibody and occurs at all ages, but it is more common in adults, particularly women. In approximately one-fourth of patients this disorder occurs as a complication of an underlying disease affecting the immune system, especially lymphoid neoplasms (Chap. 112); collagen vascular diseases, especially systemic lupus erythematosus (SLE); and congenital immunodeficiency diseases (Table 108-7). In the initial evaluation of the patient, drugs that are known to cause immunohemolytic anemia must be ruled out (see below). The presentation and course of IgG immunohemolytic anemia are quite variable. In its mildest form, the only manifestation is a positive direct Coombs test. In this instance, insufficient antibody is present on theRBCsurface to permit the reticuloendothelial system to recognize the cell as abnormal.

Most symptomatic patients have a moderate to severe anemia [hemoglobin levels 60 to 100 g/L and reticulocyte counts 10 to 30% (200 to 600 ´10_3/uL)], spherocytosis (Plate V-8), and splenomegaly.

Severe immunohemolytic anemia presents with fulminant hemolysis associated with hemoglobinemia, hemoglobinuria, and shock; this syndrome may be rapidly fatal unless aggressively treated.

The direct Coombs test is positive in 98% of patients; usually IgG is detected with or

without C3. Rarely, the cells may be agglutinated by the antibody, causing difficulty in analysis by flow cytometry.

Immune thrombocytopenia also may be present (*Evans's syndrome*), a disorder in which separate antibodies are directed against platelets andRBC. Occasionally, venous thrombosis occurs.

PATHOGENESIS IgG antibodies lyse RBCby two mechanisms: (1) immune adherence of RBC to phagocytes mediated by the antibody and by complement components that become fixed to the membrane (by far the more important mechanism of destruction), and (2) complement activation. Upon binding to Fc receptors on macrophages, the antibody-coated red cell is engulfed and destroyed. If internalization is only partial, the RBC membrane is removed, resulting in the formation of spherocytes, which are destroyed in the spleen. Complement-mediated immune adherence involves the interaction of C3b and C4b with receptors on the macrophage; while much less likely to lead to RBC lysis, this mechanism markedly increases the immune adherence due to IgG. Immune adherence, particularly that due to the IgG antibody, is also enhanced by the transit of RBC into the cords and sinuses of the spleen, which brings cells into intimate contact with phagocytic cells.

TREATMENT

Patients having a mild degree of hemolysis usually do not require therapy. In those with clinically significant hemolysis, initial therapy consists of glucocorticoids (e.g., prednisone, 1.0 mg/kg per day). A rise in hemoglobin is frequently noted within 3 or 4 days and occurs in most patients within 1 to 2 weeks. Prednisone is continued until the hemoglobin level has risen to normal values, and thereafter it is tapered rapidly to about 20 mg/d, then slowly over the course of several months. An algorithm for this tapering process is given inFig. 108-4. For chronic therapy with prednisone, alternate-day administration is preferred. More than 75% of patients achieve an initial significant and sustained reduction in hemolysis; however, in half these patients the disease recurs, either during glucocorticoid tapering or after its cessation. Glucocorticoids have two modes of action: an immediate effect due to inhibition of the clearance of IgG-coatedRBC by the mononuclear phagocyte system and a later effect due to inhibition of antibody synthesis. Splenectomy is recommended for patients who cannot tolerate or fail to respond to glucocorticoid therapy.

Patients who have been refractory to glucocorticoid therapy and to splenectomy are treated with immunosuppressive drugs such as azathioprine and cyclophosphamide. A success rate of ~50% has been reported with each. Intravenous gamma globulin may cause rapid cessation of hemolysis; however, it is not nearly as effective in this disorder as in immune thrombocytopenia.

Patients with severe anemia may require blood transfusions. Because the antibody in this disease is usually a "panagglutinin," reacting with nearly all normal donor cells, cross-matching is impossible. The goal in selecting blood for transfusion is to avoid administeringRBC with antigens to which the patient may have alloantibodies. A common procedure is to adsorb the panagglutinin present in the patient's serum with the patient's own RBC from which antibody has been previously eluted. Serum cleared

of autoantibody can then be tested for the presence of alloantibody to donor blood groups. ABO-compatible RBC matched in this fashion are administered slowly, with watchfulness for signs of an immediate-type hemolytic transfusion reaction.

PROGNOSIS In most patients, hemolysis is controlled by glucocorticoid therapy alone, by splenectomy, or by a combination. Fatalities occur among three rare subsets of patients: (1) those with overwhelming hemolysis who die from anemia; (2) those whose host defenses are impaired by glucocorticoids, splenectomy, and/or immunosuppressive agents; and (3) those with major thrombotic events coincident with active hemolysis.

When immunohemolysis develops as a complication of an underlying disorder, the prognosis is often dominated by that of the primary disease.

Immunohemolytic anemia secondary to drugs Drugs cause immunohemolytic anemia by two mechanisms of action: (1) they induce a disorder identical in almost every respect to warm-antibody immunohemolytic anemia (e.g.,a-methyldopa (an antihypertensive;Chap. 246), and (2) they become associated as haptenes with theRBCsurface and induce the formation of an antibody directed against the RBC-drug complex (e.g., penicillin, quinidine).

A positive direct Coombs test is observed in up to 10% of patients receivinga-methyldopa therapy in doses of 2 g/d or higher. A small minority of these patients develop spherocytosis and hemolysis, which may be severe. a-Methyldopa alters and makes immunogenic the protein(s) of the Rh complex; the resulting antibodies cross-react with the normal Rh protein. Thus the antibody does not react with the drug, and the indirect Coombs test is positive in almost all patients even when the drug is not added to the test. TheRBC are coated with IgG but not C3. Hemolysis decreases over the course of several weeks after cessation of drug therapy, although the direct Coombs test may remain positive for more than 1 year.

In most other cases of drug-induced hemolysis, the antibody is directed against the combination of the drug and the membrane glycoprotein to which it is attached. The hemolytic reaction in vivo is dependent on the presence of the drug and usually ceases shortly after the drug has been discontinued. Penicillin and its congeners may cause this type of reaction if the drug is given in very high doses (10 million units per day or more). The drug adheres relatively firmly to the protein of theRBCmembrane. Complement is not usually fixed, and the hemolysis in vivo is usually not severe. Since the antibody is usually IgG, spherocytosis and splenic destruction may occur. Most other drugs (such as quinine, quinidine, sulfonamides, sulfonureas, phenacetin, stibophen, and dipyrone) do not adhere as tightly to their glycoproteins, and the drug-antibody complexes are removed during the washing steps of the direct and indirect Coombs reactions. These antibodies (particularly IgM) are usually able to fix complement, and these components remain on the RBC surface; thus the direct Coombs test is positive with anti-C3 but not anti-IgG. The antibody is detected in the *indirect* Coombs test only when the drug is added to the incubation mixture. Hemolysis may be quite severe, sometimes resulting in signs of intravascular hemolysis; resolution is usually prompt after the drug is discontinued.

Immune hemolysis due to cold-reactive antibodies Antibodies that react with

polysaccharide antigens are usually IgM and react better at temperatures lower than 37°C, hence the name *cold-reactive antibodies*. Uncommonly, the antibody is IgG (the Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria).

Cold agglutinins arise in two clinical settings: (1) monoclonal antibodies, the product of lymphocytic neoplasia or paraneoplasia, and (2) polyclonal antibodies in response to infection. In many elderly patients, the "neoplasm" is benign monoclonal gammopathy that does not progress, and the paraprotein remains its only manifestation. Occasionally, cold agglutinins are found in patients with nonlymphoid neoplasms.

Transient cold agglutinins occur commonly in two infections: *Mycoplasma pneumoniae* infection and infectious mononucleosis. In both, the titer of antibody is usually too low to cause clinical symptoms, but its presence is of diagnostic value; only occasionally is hemolysis present. Cold agglutinins are less frequently encountered in a number of other viral infections. Their manifestations are usually benign.

The specificity of the antibody may be of diagnostic value. Cold agglutinins reacting more strongly with adultRBC than fetal (cord) RBC are called *anti-I*; these antibodies are seen in benign lymphoproliferation (chronic cold agglutinin monoclonal gammopathy) and in *Mycoplasma* infections. Those reacting more strongly with cord RBC cells are called *anti-i*; these antibodies are seen in aggressive lymphomas and in infectious mononucleosis. Rarely, the antibody may react with other antigens that are equally expressed on adult and cord RBC. The clinical manifestations elicited by the antibody on exposure to cold are of two sorts: intravascular agglutination (acrocyanosis) and hemolysis. Acrocyanosis is the marked purpling of the extremities, ears, and nose when the blood becomes cold enough to agglutinate in the veins; it clears on warming and does not have the vasospastic characteristics of Raynaud's phenomenon (Chap. 248). Patients may also have symptoms when swallowing cold food or drinks.

The hemolysis is usually not severe and is manifested by a mild reticulocytosis, agglutination on the blood film, and agglutination during analysis of the blood by particle analysis (giving rise to a falsely high mean corpuscular volume). The degree of hemolysis depends on several variables.

1. *Antibody titer*. In general, the titer in symptomatic patients is above 1:2000 dilution of serum and may range to as high as 1:50,000. When collecting samples, great care must be taken that the serum is separated from the cells while the sample is maintained at 37°C so that the antibody will not adsorb onto the patient's own cells.

2. *Thermal amplitude of the antibody* (the highest temperature at which the antibody will react with theRBC). For most antibodies, this is 23 to 30°C. Those with a higher thermal amplitude (up to 37°C) are more hemolytic, since it is more likely that these temperatures will be encountered during RBC circulation.

3. *Environmental temperature*. Since the reaction can occur only at temperatures below body temperature, frequency and degree of exposure to cold are major determinants of the rate of hemolysis.

The hemolysis that occurs is due primarily to the hemolytic action of complement, since

there are no functional Fc receptors for the IgM antibody. Complement is readily fixed; a single molecule of IgM is enough to effect binding of C1 and initiate the cascade. However, the normal human RBC is remarkably resistant to the hemolytic action of complement because of several defense mechanisms. Therefore, severe hemolysis with hemoglobinuria occurs only with massive activation of the antibody, such as by sudden cooling. The activation of complement is always marked by the accumulation of a degradation product of C3, C3dg, on the surface; this product is what is detected with appropriate antisera in the direct Coombs test in all patients with significant cold agglutinin disease. The cutaneous manifestations and hemolysis are best treated by maintaining the patient in a warm environment.

Splenectomy is usually not of value in this disorder. Glucocorticoids are of limited value, although patients with the panthermal variety of cold agglutinin disease may respond. Chlorambucil and cyclophosphamide are commonly used to treat patients who have hemolysis associated with monoclonal gammopathy, but their efficacy is usually marginal. Successful treatment of the malignant neoplasm responsible for the cold agglutinin often reduces the titer of antibody and the severity of the hemolysis.

Chronic cold agglutinin disease tends to be unremitting. The overall prognosis is dominated by the underlying lymphoproliferative disease, if present. In those patients in whom cold agglutinin disease appears to arise spontaneously, malignant lymphoma may develop after several years.

Paroxysmal cold hemoglobinuria (PCH) Now a rare disorder, PCH was more frequent when tertiary syphilis was prevalent; now, most cases are either secondary to a viral infection or are autoimmune. PCH results from the formation of the Donath-Landsteiner antibody, an IgG antibody that is directed against the P antigen (Chap. 114) and that can induce complement-mediated lysis. Attacks are precipitated by exposure to cold and are associated with hemoglobinemia and hemoglobinuria; chills and fever; back, leg, and abdominal pain; headache; and malaise. Recovery from the acute episode is prompt, and between episodes patients are usually asymptomatic. When this syndrome accompanies acute viral infections (e.g., measles and mumps in children), it is self-limited but may be severe. Although the direct Coombs test may show complement to be present (seldom IgG), this test may be negative. The diagnosis is made by demonstrating cold-reacting IgG antibodies either by lytic tests (when the titer is very high) or by special antiglobulin tests. When PCH is secondary to syphilis, it responds to therapy for syphilis. Chronic autoimmune PCH may respond to prednisone or cytotoxic therapy (azathioprine or cyclophosphamide) but does not respond to splenectomy. The natural history of this disease often extends over many years.

Hemolysis due to Trauma in the Circulation RBC may be fragmented by mechanical trauma as they circulate; this circumstance leads to intravascular hemolysis and in most cases to RBC fragments called *schistocytes*. Schistocytes are identified by the sharp points that result from the faulty resealing of the fractured membrane (Plate V-28). Mechanical trauma leading to hemolysis occurs in three clinical settings: (1) when RBC flow through small vessels over the surface of bony prominences and are subject to external impact during various physical activities, (2) when RBC flow across a pressure gradient created by an abnormal heart valve or valve prosthesis (macrovascular), and (3) when the deposition of fibrin or small platelet thrombi in the microvasculature

exposes RBC to a physical impediment that fragments them (microvascular) (Table 108-8).

External impact Hemoglobinemia and hemoglobinuria have been observed in a small proportion of individuals who have undergone a prolonged march or a prolonged run, most typically on a hard surface and while wearing thin-soled shoes. The role of direct external trauma in this process has been demonstrated by the fact that hemolysis can be prevented by the insertion of a soft inner sole in the runner's shoes. Similar types of hemolysis have been described following karate and the playing of bongo drums. No abnormality ofRBC has been demonstrated, even during the acute episode. Susceptible individuals will develop hemoglobinemia and hemoglobinuria when exposed to the conditions described above. Muscle damage during some of these activities may produce myoglobinuria, but renal function is preserved. No specific therapy is required except to obtain better running shoes.

Macrovascular traumatic hemolysis Hemolysis associated with fragmentedRBC(Plate V-28) occurs in approximately 10% of patients with artificial aortic valve prostheses. This incidence is somewhat greater with valves having stellite rather than Silastic occluders, greater with small valves as compared with larger valves, and greater when valves are cloth-covered or when there is a paravalvular leak. Traumatic hemolysis is rare in recipients of porcine valves. Severe hemolysis may occur after repair of ostium primum or endocardial cushion defects with a prosthetic patch. Mitral valve prostheses may produce hemolysis, but since the pressure gradient across these valves is lower than across aortic prostheses, the incidence is lower. A moderately shortened RBC survival time with little or no anemia occurs in some patients with severe calcific aortic stenosis. Indeed, almost any intracardiac lesion that alters hemodynamics may lead to some shortening of RBC survival. Traumatic hemolysis has been observed in patients who have undergone aortofemoral bypass.

CLINICAL MANIFESTATIONS In severe cases, hemoglobin levels fall to 50 to 70 g/L with reticulocytosis, fragmentedRBC in the peripheral blood, depressed haptoglobin, elevated serumLDH, and hemoglobinemia and hemoglobinuria. Iron loss (as hemoglobin or hemosiderin) in the urine may lead to iron deficiency. The direct Coombs test may rarely become positive.

PATHOGENESIS A number of factors combine to cause the fragmentation ofRBC by prostheses: (1) the shear stress resulting from turbulent blood flow, particularly when blood is forced through a small aperture by high pressure (e.g., a paravalvular leak around an aortic valve); (2) direct mechanical trauma of RBC at the time of seating of the occluder of the prosthetic valve; and (3) the deposition of fibrin across disrupted attachment points.

TREATMENT

Iron deficiency should be corrected by the administration of oral iron. The elevated hemoglobin that results may permit a decrease in the cardiac output and a slowing of the hemolytic rate. Limitation in physical activity also lessens the hemolytic rate. When these measures fail, any paravalvular leak must be repaired or the prosthetic valve replaced.

Microvascular traumatic hemolysis If fibrin or platelet microthrombi are deposited in arteriolar sites,RBC may be trapped on the meshwork and fragmented by high shear forces.

ABNORMALITIES OF THE VESSEL WALL Disorders such as malignant hypertension, eclampsia, renal allograft rejection, disseminated cancer, hemangiomas, or disseminated intravascular coagulation (DIC) may cause traumatic hemolysis. The degree of hemolysis induced by this family of disorders is usually quite mild, but a large number of fragments may be seen in the peripheral blood. In some patients, thrombocytopenia may be severe. Therapy is best directed at the primary disease. Thus, reversal of renal graft rejection, treatment of malignant hypertension and eclampsia, control of cancer, and the like, lead to a cessation of hemolysis. The relative importance of the primary vascular abnormality versus fibrin deposition is unclear.

Thrombotic thrombocytopenia purpura (TTP) This disorder is characterized by arteriolar lesions in various organs that contain platelet thrombi and produce thrombocytopenia and hemolytic anemia due to fragmentation ofRBC. Tissue hypoxia resulting from vessel occlusion may cause organ dysfunction, most frequently manifest in the nervous system or the kidney. The disease affects individuals of all ages, but primarily young adults and more often women.

CLINICAL MANIFESTATIONS The classic pentad ofTTPincludes hemolytic anemia with fragmentation of erythrocytes and signs of intravascular hemolysis, thrombocytopenia, diffuse and nonfocal neurologic findings, decreased renal function, and fever. These signs and symptoms occur variably, depending on the number and sites of the arteriolar lesions. The anemia may be very mild to very severe, and the thrombocytopenia often parallels it. The neurologic and renal symptoms are usually seen only when the platelet count is markedly diminished (<20 to 30´10^3/uL). Fever is not reliably present. TTP may be acute in onset, but its course spans days to weeks in most patients and occasionally continues for months. Proteinuria and a moderate elevation of blood urea nitrogen may be found on initial presentation; the latter continues to rise while urine output falls if the patient develops renal failure. Neurologic symptoms develop in>90% of patients whose disease terminates in death. Initially, changes in mental status such as confusion, delirium, or altered states of consciousness may occur. Focal findings include seizures, hemiparesis, aphasia, and visual field defects. These neurologic symptoms may fluctuate and terminate in coma. Involvement of myocardial blood vessels may be a cause of sudden death. The severity of the disorder can be estimated from the degree of anemia and thrombocytopenia and the serumLDHlevel. Prothrombin time, partial thromboplastin time, fibrinogen concentration, and the level of fibrin split products are usually normal or only mildly abnormal. If the coagulation tests indicate a major consumption of clotting factors, the diagnosis of TTP is doubtful. A positive antinuclear antibody (ANA) determination is obtained in approximately 20% of patients.

PATHOGENESIS The manifestations ofTTP can be explained by *localized* platelet thrombi. The agglutination of platelets is mediated by unusually large multimers of von Willebrand factor. Patients with TTP have acquired an antibody that inhibits a protease that normally cleaves von Willebrand factor. Arterioles are filled with hyalin material, presumably fibrin and platelets, and similar material may be seen beneath the

endothelium of otherwise uninvolved vessels. Immunofluorescence studies have shown the presence of immunoglobulin and complement in arterioles. Microaneurysms of arterioles are often present. An association with pregnancy, AIDS, systemic lupus erythematosus (SLE), scleroderma, and Sjogren's syndrome suggests an immunologic origin.

DIAGNOSIS The combination of hemolytic anemia with fragmentedRBC, thrombocytopenia, normal coagulation tests, fever, neurologic disorders, and renal dysfunction is virtually pathognomonic ofTTP. Although they are not usually required for diagnosis, biopsies of skin and muscle, gingiva, lymph node, or bone marrow may show the typical arteriolar abnormalities. TTP must be distinguished from idiopathic thrombocytopenic purpura or Evans's syndrome (the former plus immunohemolytic anemia) by the finding of fragmented but not spherocytic RBC in the peripheral blood and a negative direct Coombs test.

TREATMENT

Plasma exhange permits >90% of patients to survive if therapy is promptly instituted. Many patients require daily or even twice daily plasmapheresis with plasma replacement. If a response is obtained (as indicated by increasing platelet count and decreasing plasmaLDH and fragmentedRBC), plasmapheresis may be done less frequently but sometimes must be continued for several weeks to months. Most patients also receive high doses of glucocorticoids and some receive platelet-active agents (dipyridamole, sulfinpyrazone, dextran, aspirin), but their efficacy is not proven. Vincristine, cyclophosphamide, or splenectomy has been used to treat patients who do not respond to plasma exchange. Even coma is not a contraindication to therapy, since full neurologic recovery is the rule in patients responding to therapy. Relapses have been noted in ~10% of patients but are usually responsive to retreatment. Platelet transfusions should not be given because they can precipitate thrombotic events.

Hemolytic-uremic syndrome This disorder is similar toTTP and is characterized by the same arteriolar lesions, which may be confined to the kidney, and by similar laboratory findings. It is usually encountered in young children. Often the patient has a prodrome of a gastroenteritic bloody diarrhea caused by *Escherichia coli* 0157:H7, and the lesions are thought to be due to the elaboration of Shiga-like verotoxins that damage renal vascular endothelial cells. This disorder has been associated with eating undercooked meat. Very rarely, the disorder appears to be familial. Patients present with acute hemolytic anemia, thrombocytopenic purpura, and acute oliguric renal failure. Most patients have either hemoglobinuria or anuria. Unlike TTP, neurologic manifestations are uncommon. The peripheral blood and coagulation tests are usually indistinguishable from those of TTP.

Patients are treated with plasmapheresis, dialysis, and transfusions. The efficacy of glucocorticoids, dextran, and heparin is uncertain. The mortality rate in children ranges from 5 to 20% but is considerably higher in adults. A disorder resembling the hemolytic-uremic syndrome has been described in adults treated with the antineoplastic drug mitomycin C, usually in combination with other drugs. It may also occur in patients receiving high-dose chemotherapy with autologous stem cell transplantation.

Disseminated intravascular coagulation Inappropriate activation of the clotting system with deposition of fibrin in small vessels may lead toRBCfragmentation in the microvasculature. RBC fragmentation occurs in about one-fourth of patients withDIC(Chap. 117). The degree of hemolysis is much less in DIC than in eitherTTP or the hemolytic-uremic syndrome, and anemia with reticulocytosis is rare.

Environmental Alteration of the Red Cell Membrane by "Toxic" Effects A variety of infections may be associated with severe hemolysis. The microbes that cause bartonellosis (Chap. 163), as well as malaria and babesiosis (Chap. 214) directly parasitizeRBC. *Clostridium welchii* (Chap. 145) produces a phospholipase that can cleave the phosphoryl bond of lecithin, thereby lysing human RBC. A mild, transient hemolysis frequently accompanies bacteremia with diverse organisms such as pneumococci, staphylococci, and *E. coli*.

Hemolysis may result from the direct action of snake and spider venoms on theRBC. Although cobra venom is directly lytic in vitro, the clinical disease induced by the bite of the cobra is one of moderate hemolysis associated with spherocytosis. Spider bites, particularly the bite of the brown recluse spider, induce acute intravascular hemolysis associated with spherocytosis and fragments of complement components on the RBC. The hemolysis continues for several days up to 1 week.

Copper has a direct hemolytic effect on RBC. Hemolysis has been observed after exposure of individuals to copper salts (such as during hemodialysis). Transient episodes of hemolysis occur in patients with Wilson's disease (Chap. 348).

TheRBCmembrane is unstable at temperatures above 49°C due to denaturation of the cytoskeletal protein spectrin. The RBC undergoes a process of budding, cleavage, and resealing above this temperature. Patients with extensive burns have prominent spherocytosis, hemoglobinemia, and sometimes hemoglobinuria.

Spur Cell Anemia Hemolytic anemia with bizarre-shapedRBCoccurs in about 5% of patients with severe hepatocellular disease, particularly advanced Laennec's cirrhosis.

Clinical manifestations Anemia is more severe than is observed in otherwise uncomplicated cirrhosis. Hematocrit levels range between 15 and 25%. Splenomegaly is always present and is greater than in patients who have cirrhosis without spur cell anemia. Jaundice may be severe because of the hemolysis and liver dysfunction, and hepatic encephalopathy is common. TheRBC are irregularly shaped with multiple spicules, and a small number of bizarre-shaped fragments are commonly seen on peripheral blood smears (Plate V-27). Reticulocytosis and other signs of hemolysis are present. The tests of liver function are typical of patients with severe cirrhosis.

RBChalf-life is decreased to as short as 6 days (normal being 26 to 32 days); RBC destruction is localized to the spleen. Normal transfused RBC acquire the defect and have a survival time similar to that of the patient's own RBC.

Pathogenesis The surface membrane of a spur cell contains 50 to 70% excess cholesterol, but its total phospholipid content is normal. By contrast, the target-shapedRBC is more common in liver disease and has an excess of both

cholesterol and phospholipid. The selective cholesterol excess in the spur cell is due to abnormal low-density lipoprotein with an increased mole ratio of free (unesterified) cholesterol to phospholipid. Cholesterol out of proportion to phospholipid decreases the fluidity of the spur cell membrane, and cell deformability is decreased. These rigid, cholesterol-laden RBC cannot pass through the filtering system of the spleen, further impeded by congestive splenomegaly in cirrhosis.

Diagnosis Patients with spur cell anemia have severe hemolysis and characteristicRBCmorphology. Increasing anemia in a patient with chronic cirrhosis most commonly results from blood loss, folic acid deficiency, or iron deficiency.

RBCof similar morphology are seen in patients with abetalipoproteinemia. However, hemolysis is minimal.

Spur cells or acanthocytes have irregular spikes (irregular in length of projections and their spacing) and must be distinguished from regularly spaced, crenatedRBC(echinocytes). Echinocytes are a frequent artifact on portions of some blood smears, and they are uniformly present in some patients with uremia ("burr cells") (Plate V-3). Small, dense crenated spheres (spheroechinocytes) are sometimes seen in congenital nonspherocytic hemolytic anemia due to enzyme deficiencies in the Embden-Meyerhof pathway (see above).

TREATMENT

Transfusion therapy is of limited benefit. Attempts to influenceRBCcholesterol with various lipid-lowering agents have been unsuccessful. Splenectomy has been reported to prevent both the conditioning of RBC in the spleen and their premature destruction. However, splenectomy carries a high risk in patients with severe liver disease complicated by portal hypertension and coagulation defects. It must be reserved for patients in whom hemolysis is a major problem and who are relatively good surgical risks.

Prognosis Spur cell anemia occurs during the late stages of cirrhosis, and>90% of patients succumb to their underlying liver disease within 1 year of the diagnosis of spur cell anemia.

Paroxysmal Nocturnal Hemoglobinuria (PNH) This hemolytic disorder is distinctive because it is an intracorpuscular defect acquired at the stem cell level.

Clinical manifestations The three common manifestations ofPNH are: hemolytic anemia, venous thrombosis, and deficient hematopoiesis. Anemia is highly variable with hematocrit values ranging from£20% to normal.RBC are normochromic and normocytic unless iron deficiency has occurred from chronic iron loss in the urine.

Granulocytopenia and thrombocytopenia are common and reflect deficient hematopoiesis. Clinical hemoglobinuria is intermittent in most patients and never occurs in some, but hemosiderinuria is usually present. The lack of two proteins, decay-accelerating factor (DAF, CD55) and a membrane inhibitor of reactive lysis (MIRL, CD59) (see below) make theRBC more sensitive to the lytic effect of

complement.

DAF normally disrupts the enzyme complexes from either the classical (antibody-driven) pathway or the alternative pathway that activate C3 and C5; CD59 inhibits the conversion of C9 by the membrane attack complex C5b-8 to a polymeric complex capable of penetrating the membrane.

The platelets also lack these proteins, but the life span of the platelet is normal. However, the activation of complement indirectly stimulates platelet aggregation and hypercoagulability; this probably accounts for the tendency to thrombosis seen inPNH.

Venous thrombosis is a common complication of patients of European origin, affecting ~40% at one time or another; it is less common in Asian patients. It occurs primarily in intraabdominal veins (hepatic, portal, mesenteric) and results in the Budd-Chiari syndrome, congestive splenomegaly, and abdominal pain. It may occur in cerebral venous sinuses and is a common cause of death in patients withPNH. The bone marrow may appear normocellular, but in vitro marrow progenitor assays are abnormal. In about 15 to 30% of long-term survivors of aplastic anemia, PNH cells appear in the circulation; in some patients, the manifestations of PNH become dominant. Patients with PNH may have aplastic periods lasting from weeks to years. PNH may be seen in association with other stem cell disorders, including myelofibrosis, and (rarely) other myelodysplastic or myeloproliferative disorders.

Pathogenesis PNH is an acquired clonal disease, arising from an inactivating somatic mutation in a single abnormal stem cell of a gene on the X-chromosome (*pig-A*) important for the biosynthesis of the glycosylphosphatidylinositol (GPI) anchor. This anchor is necessary for the attachment of a number of proteins to the external membrane surface, and its partial or complete absence results in the absence of those proteins; to date, about 20 proteins have been found to be missing on the blood cells of patients with PNH. The normal clone of stem cells does not completely disappear, and the proportion of cells that are abnormal varies among patients and over time in a single patient.

Diagnosis PNHshould be suspected in anyone with otherwise unexplained hemolytic anemia, especially with leukopenia and/or thrombocytopenia and with evidence of intravascular hemolysis (hemoglobinemia, hemoglobinuria, hemosiderinuria, elevatedLDH). Anyone recovering from aplastic anemia should be examined at intervals for the appearance of the diagnostic cells. The diagnosis is often delayed because (1) it is not considered, (2) hemoglobinuria is confused with hematuria, (3) elevation of the LDH is attributed to liver disease, and (4) the diagnostic tests (Ham's test and the sucrose lysis test) are not reliable.

For many years, the diagnosis ofPNHdepended on the demonstration of the lysis ofRBCafter complement activation either by acid (Ham or acidified serum lysis test) or by reduction in ionic strength (sucrose lysis test). These tests are inferior to the analysis of GPI-linked proteins (e.g., CD59, DAF) on RBC and granulocytes by flow cytometry.

TREATMENT

Transfusion therapy is useful inPNH not only for raising the hemoglobin level but also for suppressing the marrow production ofRBCduring episodes of sustained hemoglobinuria. Washed RBC are the preferred source to prevent exacerbation of hemolysis. Therapy with androgens sometimes results in a rise in hemoglobin level. Glucocorticoids reduce the rate of hemolysis in moderate doses (15 to 30 mg prednisone) on alternate days.

Iron deficiency is common. Iron replacement may exacerbate hemolysis because of the formation of many newRBC, which may be sensitive to complement. This occurrence may be minimized by giving prednisone (60 mg/d) or by suppressing the bone marrow with transfusions.

Acute thrombosis inPNH, particularly the Budd-Chiari syndrome and cerebral thrombosis, should be treated with thrombolytic agents. Heparin therapy should be instituted rapidly and maintained for several days before changing to coumadin therapy. Antithymoctye globulin (total dose of 150 mg/kg over 4 to 10 days) is often of use in treating marrow hypoplasia; prednisone counteracts the immune-complex disease that results from the administration of this foreign protein.

In patients with either hypoplasia or thrombosis who have an appropriate sibling donor, marrow transplantation should be considered early in the course of the disease. The usual conditioning programs are sufficient to eradicate the aberrant clone.

ANEMIA OF ACUTE BLOOD LOSS

The normal capacity to compensate for acute blood loss involves cardiovascular mechanisms, an adjustment in the oxygen affinity of hemoglobin, and an increase in erythropoiesis in the marrow. The signs and symptoms of blood loss relate to the volume of the blood loss and the time frame over which the hemorrhage occurs (Table 108-9). Losses of up to 20% of the blood volume are normally tolerated by redistribution of blood flow mediated by reflex venospasm, but the presence of fever or pain may interfere with this compensation. With larger losses, blood volume redistribution is not adequate to maintain normal blood pressure: initially, hypotension is only seen on standing, but with greater losses progressively greater problems are encountered in maintaining blood pressure in sitting or supine positions. If the blood loss is more gradual, plasma volume increases, but albumin production usually lags behind the fluid shifts. It may take 2 to 3 days for the liver to generate the albumin lost in a 1500-mL bleed.

The most rapid hematologic adjustment to acute blood loss is an increase in oxygen delivery to the tissues. This is first mediated by the Bohr effect, where the more acidic milieu of the hypoperfused hypoxic tissues shifts the hemoglobin oxygen dissociation curve to the right. Over several hours theRBCincrease their production of 2,3-bisphosphoglycerate, which also enhances the unloading of oxygen to tissues. These two mechanisms can substantially increase the capacity of RBC to deliver oxygen to the tissues.

The marrow response to hemorrhage is related to the generation of erythropoietin in the kidney in response to decreased oxygen tensions. A normal response depends on the production of erythropoietin, the presence of normal erythroid progenitors in the marrow,

and an adequate supply of iron. If these three elements are normal, reticulocytes begin to increase in number in the first 2 days based on early release of reticulocytes from the marrow. However, it takes 3 to 6 days for erythroid hyperplasia to appear and 7 to 10 days before the erythropoietic response is maximal, producing reticulocyte counts up to 20 to 30%, a reticulocyte index of³3, and a marked increase in the marrow erythoid/granulocytic ratio.

DIAGNOSIS

Usually it is clear that a patient is bleeding; however, in some cases, large volumes of blood loss can occur internally from the gastrointestinal tract (esophageal varicies, cancer in the stomach or colon), a ruptured spleen, fractures and other trauma, or other lesions that can cause massive hemorrhage into the peritoneal cavity, pleural cavity, or the retroperitoneal space. Patients who have bled sufficiently to develop hypotension generally develop anemia, which is apparent only after volume replacement. The granulocyte count may increase to³20,000 cells/uL and include immature cell types such as metamyelocytes and myelocytes. Epinephrine-induced demargination of peripheral granulocytes and release of cells from the marrow may account for this change. NucleatedRBC may appear in the circulation, and platelet counts may exceed 1´10⁶/uL. The basis for the increased platelet count is unclear. Hemorrhage in an internal cavity is accompanied by a rise in unconjugated bilirubin and a fall in serum haptoglobin.

TREATMENT

Treatment of the underlying cause of the hemorrhage is of paramount importance. If the patient is severely anemic or sufficiently hypovolemic, packedRBCshould be transfused. In less severe cases, if the patient has normal kidneys (and presumably a normal erythropoietin response to anemia), normal bone marrow function, and an adequate supply of iron, no specific therapy for the anemia is required.

109. APLASTIC ANEMIA, MYELODYSPLASIA, AND RELATED BONE MARROW FAILURE SYNDROMES - *Neal S. Young*

The hypoproliferative anemias associated with marrow damage include aplastic anemia, myelodysplasia (MDS), pure red cell aplasia (PRCA), and myelopthisis. Anemia in these disorders, which is normochromic, normocytic, or macrocytic and characterized by low reticulocyte count, is not a solitary or even the major finding in these diseases, which are better described as marrow failure states. In bone marrow failure, pancytopenia -- anemia, leukopenia, and thrombocytopenia (sometimes in various combinations) -- results from deficient hematopoiesis, as distinguished from blood count depression due to peripheral destruction of red cells (hemolytic anemias), platelets (idiopathic thrombocytopenic purpura or due to splenomegaly), and granulocytes (as in the immune leukopenias).

Hematopoietic failure syndromes are classified by dominant morphologic features of the bone marrow (Table 109-1). While practical distinction among these syndromes is clear in stereotypical cases, they can, of course, occur secondary to other diseases, and are so closely related that the differential diagnosis may be arbitrary, patients may seem to suffer from two or three related diseases simultaneously, or one diagnosis may appear to evolve into another. Finally, there is an important pathophysiologic relationship among these syndromes in their sharing of immune-mediated mechanisms of marrow destruction and some element of genomic instability resulting in a higher rate of malignant transformation.

APLASTIC ANEMIA

DEFINITION

Aplastic anemia is pancytopenia with bone marrow hypocellularity. Acquired aplastic anemia is distinguished from iatrogenic marrow aplasia, the common occurrence of marrow hypocellularity after intensive cytotoxic chemotherapy for cancer. Aplastic anemia can also be constitutional: the genetic disease Fanconi's anemia, while frequently associated with typical physical anomalies and the development of pancytopenia early in life, can also present as marrow failure in normal-appearing adults. Acquired aplastic anemia is often stereotypical in its manifestations, with the abrupt onset of low blood counts in a previously well young adult; seronegative hepatitis or a course of an incriminated medical drug may precede the onset. The diagnosis in these instances is uncomplicated. Sometimes blood count depression is moderate or incomplete, resulting in anemia, leukopenia, and thrombocytopenia in some combination. Aplastic anemia is related to both paroxysmal nocturnal hemoglobinuria (PNH;Chap. 108) and toMDS, and in some cases a clear distinction among these disorders may not be possible.

EPIDEMIOLOGY

The incidence of acquired aplastic anemia in Europe and Israel is 2 cases per million persons annually. In Thailand and China, rates of 5 to 7 per million have been established. In general, men and women are affected with equal frequency, but there is a biphasic age distribution, with the major peak among older children and young adults

and a second rise in the elderly.

ETIOLOGY

The origins of aplastic anemia have been inferred from several recurring clinical associations (Table 109-2); unfortunately, these relationships are neither a reliable guide in an individual patient nor necessarily etiologic. In addition, while most cases of aplastic anemia are idiopathic, little other than history separates these cases from those with a presumed etiology such as a drug exposure.

Radiation Marrow aplasia is a major acute sequela of radiation. Radiation damages DNA; tissues dependent on active mitosis are particularly susceptible. Nuclear accidents can involve not only power plant workers but also employees of hospitals, laboratories, and industry (food sterilization, metal radiography, etc.), as well as innocents exposed to stolen, misplaced, or misused sources. While the radiation dose can be approximated from the rate and degree of decline in blood counts, dosimetry by reconstruction of the exposure can help to estimate the patient's prognosis and also to protect medical personnel from contact with radioactive tissue and excreta.MDS and leukemia, but probably not aplastic anemia, are late effects of irradiation.

Chemicals Benzene is a notorious cause of bone marrow failure. Vast quantities of epidemiologic, clinical, and laboratory data link benzene to aplastic anemia, acute leukemia, and blood and marrow abnormalities. The occurrence of leukemia is roughly correlated with cumulative exposure, but susceptibility must also be important, as only a minority of even heavily exposed workers develop benzene myelotoxicity. The employment history is important, especially in industries where benzene is used for a secondary purpose, usually as a solvent. Benzene-related blood diseases have declined with regulation of industrial exposure. Although benzene is no longer generally available as a household solvent, exposure to its metabolites occurs in the normal diet and in the use of lead-free gasoline. The association between marrow failure and other chemicals that contain a benzene ring is much less well substantiated; these chemicals may have been contaminated with benzene in manufacture, or petroleum distillates may have been used to dissolve the product.

Drugs (SeeTable 109-3) Many chemotherapeutic drugs have marrow suppression as a major toxicity; effects are dose-dependent and will occur in all recipients. In contrast, idiosyncratic reactions to a large and diverse group of drugs may lead to aplastic anemia without a clear dose-response relationship. These associations rest largely on accumulated case reports, but a massive international study in Europe in the 1980s quantitated drug relationships, especially for nonsteroidal analgesics, sulfonamides, thyrostatic drugs, some psychotropics, penicillamine, allopurinol, and gold. Not all associations necessarily reflect causation: a drug may have been used to treat the first symptoms of bone marrow failure (antibiotics for fever or the preceding viral illness) or provoked the first symptom of a preexisting disease (petechiae by nonsteroidal anti-inflammatory agents administered to the thrombocytopenic patient). In the context of total drug use, idiosyncratic reactions, while individually devastating, are exceedingly rare events. Chloramphenicol, the most infamous culprit, reportedly produced aplasia in only about 1/60,000 therapy courses, and even this number is almost certainly an overestimate (risks are almost invariably exaggerated when based on collections of

cases; although the introduction of chloramphenicol was perceived to have created an epidemic of aplastic anemia, its diminished use was not followed by a changed frequency of marrow failure). Risk estimates are usually lower when determined in population-based studies; furthermore, the low absolute risk is also made more obvious: even a 10- or 20-fold increase in risk translates, in a rare disease, to but a handful of drug-induced aplastic anemia cases among hundreds of thousands of exposed patients.

Infections Hepatitis is the most common preceding infection, and posthepatitis marrow failure accounts for about 5% of etiologic associations in most series. Patients are usually young men who have recovered from a mild bout of liver inflammation 1 to 2 months earlier; the subsequent pancytopenia is very severe. The hepatitis is almost invariably seronegative (non-A, non-B, non-C, non-G) and presumably due to a novel, as yet undiscovered, virus. Fulminant liver failure in childhood can follow seronegative hepatitis, and marrow failure occurs at a high rate in these patients as well. Aplastic anemia can rarely follow infectious mononucleosis, and Epstein-Barr virus has been found in the marrow of a few aplastic anemia patients, some without a suggestive preceding history. Parvovirus B19, the cause of transient aplastic crisis in hemolytic anemias and of some pure red cell aplasia (see below), does not usually cause generalized bone marrow failure. Blood count depression is frequent in the course of many viral and bacterial infections but is comparatively moderate and resolves with the infection.

Immunologic Diseases Aplasia is a major consequence and the cause of death in *transfusion-associated graft-versus-host disease*, which can occur after infusion of unirradiated blood products to an immunodeficient recipient. Aplastic anemia is strongly associated with the rare collagen vascular syndrome called *eosinophilic fasciitis*, which is characterized by painful induration of subcutaneous tissues (Chap. 313). Pancytopenia with marrow hypoplasia can also occur in systemic lupus erythematosus.

Pregnancy Aplastic anemia very rarely may occur and recur during pregnancy and resolve with delivery or with spontaneous or induced abortion.

Paroxysmal Nocturnal Hemoglobinuria An acquired mutation in the *PIG-A* gene in a hematopoietic stem cell is required for the development ofPNH, but *PIG-A* mutations probably occur commonly in normal individuals. If the PIG-A mutant stem cell proliferates, the result is a clone of progeny deficient in glycosylphosphatidylinositol-linked cell surface membrane proteins (Chap. 108). Such PNH cells are now most accurately enumerated using fluorescence-activated flow cytometry of CD55 or CD59 expression on granulocytes rather than Ham or sucrose lysis tests on red cells. Deficient cells can be detected in about a quarter of patients with aplastic anemia at the time of presentation [and PNH cells are also seen in cases of hypocellularMDS (see below)]. In addition, functional studies of bone marrow from PNH patients, even those with mainly hemolytic manifestations, show evidence of defective hematopoiesis. Patients with an initial clinical diagnosis of PNH, especially younger individuals, may later develop frank marrow aplasia and pancytopenia; patients with an initial diagnosis of aplastic anemia may suffer from hemolytic PNH years after recovery of blood counts. One explanation for the aplastic anemia/PNH syndrome is selection of the deficient clones, perhaps because they are favored for proliferation in the peculiar environment of immune-mediated marrow destruction.

Congenital Disorders Fanconi's anemia, an autosomal recessive disorder, manifests as progressive pancytopenia, increased chromosome fragility, congenital developmental anomalies, and an increased risk of malignancy. Patients with Fanconi's anemia typically have short stature; cafe au lait spots; and anomalies involving the thumb, radius, and genitourinary tract. At least seven different genetic defects have been defined by complementation analysis. The most common, type A Fanconi's anemia, is due to a mutation in *FANCA*. The function of the four cloned genes so far identified in Fanconi's anemia remains unknown.

Patients with Shwachman-Diamond syndrome may develop pancreatic insufficiency, malabsorption, and neutropenia and are at risk of aplastic anemia. Dyskeratosis congenita is an X-linked disorder characterized by mucous membrane leukoplasia, dystrophic nails, reticular hyperpigmentation, and the later development of aplastic anemia in about half of patients. Mutation in the *DKC1 (dyskerin)* gene has been found in some cases.

PATHOPHYSIOLOGY

Bone marrow failure results from severe damage to the hematopoietic cell compartment. In aplastic anemia, replacement of the bone marrow by fat is apparent in the morphology of the biopsy specimen (Fig. 109-1;Plate V-13) and magnetic resonance imaging of the spine; cells bearing the CD34 antigen, a marker of early hematopoietic cells, are greatly diminished; and in functional studies, committed and primitive progenitor cells are virtually absent -- in vitro assays have suggested that the stem cell pool is reduced to 1% of normal in severe disease at the time of presentation. Qualitative abnormalities, such as limited number of operating stem cell clones or shortened telomere length, may follow from the quantitative deficiency, reflecting the shrunken and stressed state of hematopoiesis. An intrinsic stem cell defect exists for constitutional aplastic anemia, as cells from patients with Fanconi's anemia exhibit chromosome damage and death on exposure to certain chemical agents, but there is no convenient mechanism for the propagation of an *acquired* genetic abnormality that would produce a hypoproliferative (as opposed to neoplastic) disease. Aplastic anemia does not appear to result from defective stroma or growth factor production.

Drug Injury Extrinsic damage to the marrow follows massive physical or chemical insults such as high doses of radiation and toxic chemicals. For the more common idiosyncratic reaction to modest doses of medical drugs, altered drug metabolism has been invoked as a likely mechanism. The metabolic pathways of many drugs and chemicals, especially if they are polar and have limited water solubility, involve enzymatic degradation to highly reactive electrophilic compounds; these intermediates are toxic because of their propensity to bind to cellular macromolecules. For example, derivative hydroquinones and quinolones are responsible for benzene-induced tissue injury. Excessive generation of toxic intermediates or failure to detoxify the intermediates may be genetically determined and apparent only on specific drug challenge; the complexity and specificity of the pathways imply multiple susceptible loci and would provide an explanation for the rarity of idiosyncratic drug reactions.

Immune-Mediated Injury The recovery of marrow function in some patients prepared

for bone marrow transplantation with antilymphocyte globulin (ALG) first suggested that aplastic anemia might be immune-mediated. Consistent with this hypothesis was the frequent failure of simple bone marrow transplantation from a syngeneic twin, without conditioning cytotoxic chemotherapy, which also argued both *against* simple stem cell absence as the cause and *for* the presence of a host factor producing marrow failure. Laboratory data support an important role for the immune system in aplastic anemia. Blood and bone marrow cells of patients can suppress normal hematopoietic progenitor cell growth, and removal of T cells from aplastic anemia bone marrow improves colony formation in vitro. Increased numbers of activated cytotoxic T cells are observed in aplastic anemia patients and usually decline with successful immunosuppressive therapy; cytokine measurements suggest a predominant T_H1 immune response (interferon g, interleukin 2, and tumor necrosis factor). Interferon and tumor necrosis factor induce Fas expression on CD34 cells, leading to apoptotic cell death; localization of activated T cells to bone marrow and local production of their soluble factors are probably important in stem cell destruction.

Early immune system events in aplastic anemia are not well understood. Many different exogeneous antigens appear capable of initiating a pathologic immune response, but at least some of the active T cells recognize true self-antigens. The rarity of occurrence of aplastic anemia despite common exposures (medical drugs, hepatitis virus) suggests that genetically determined features of the immune response can convert a normal physiologic response into a sustained abnormal autoimmune process.

CLINICAL FEATURES

History Aplastic anemia can appear with seeming abruptness or have a more insidious onset. Bleeding is the most common early symptom; a complaint of days to weeks of easy bruising, oozing from the gums, nose bleeds, heavy menstrual flow, and sometimes petechiae will have been noticed. With thrombocytopenia, massive hemorrhage is unusual, but small amounts of bleeding in the central nervous system can result in catastrophic intracranial or retinal hemorrhage. Symptoms of anemia are also frequent, including lassitude, weakness, shortness of breath, and a pounding sensation in the ears. Infection is an unusual first symptom in aplastic anemia (unlike in agranulocytosis, where pharyngitis, anorectal infection, or frank sepsis occur early). A striking feature of aplastic anemia is the restriction of symptoms to the hematologic system, and patients often feel and look remarkably well despite drastically reduced blood counts. Systemic complaints and weight loss should point to other etiologies of pancytopenia. History of drug use, chemical exposure, and preceding viral illnesses must often be elicited with repeated questioning.

Physical Examination Petechiae and ecchymoses are often present, and retinal hemorrhages may be present. Pelvic and rectal examinations should be performed with great gentleness to avoid trauma; these will often show bleeding from the cervical os and blood in the stool. Pallor of the skin and mucous membranes is common except in the most acute cases or those already transfused. Infection on presentation is unusual but may be present if the patient has been symptomatic for a few weeks. Lymphadenopathy and splenomegaly are highly atypical of aplastic anemia. Cafe au lait spots and short stature suggest Fanconi's anemia; peculiar nails, dyskeratosis congenita.

LABORATORY STUDIES

Blood The smear shows large erythrocytes and a paucity of platelets and granulocytes. Mean corpuscular volume (MCV) is commonly increased. Reticulocytes are absent or few, and lymphocyte numbers may be normal or reduced. The presence of immature myeloid forms suggests leukemia orMDS; nucleated red blood cells suggest marrow fibrosis or tumor invasion; abnormal platelets suggest either peripheral destruction or MDS.

Bone Marrow The bone marrow is usually readily aspirated but appears dilute on smear, and the fatty biopsy specimen may be grossly pale on withdrawal; a "dry tap" suggests fibrosis or myelophthisis. In severe aplasia the smear of the aspirated specimen shows only red cells, residual lymphocytes, and stromal cells; the biopsy, which should be>1 cm in length, is superior for determination of cellularity and shows mainly fat under the microscope, with hematopoietic cells occupying, by definition, <25% of the marrow space. In the most serious cases the biopsy is virtually 100% fat. The correlation between marrow cellularity and disease severity is imperfect. Some patients with moderate disease by blood counts will have empty iliac crest biopsies, while "hot spots" of hematopoiesis may be seen in severe cases. If an iliac crest specimen is inadequate, cells should also be obtained by aspiration from the sternum. Residual hematopoietic cells should have normal morphology, except for mildly megaloblastic erythropoiesis; megakaryocytes are invariably greatly reduced and usually absent. Areas adjacent to the spicule should be searched for myeloblasts. Granulomas (in cellular specimens) may indicate an infectious etiology of the marrow failure.

Ancillary Studies Chromosome breakage studies of peripheral blood using diepoxybutane (DEB) or mitomycin C should be performed on children and younger adults to exclude Fanconi's anemia. Chromosome studies of bone marrow cells are often revealing inMDS and should be negative in typical aplastic anemia. Flow cytometric assays have replaced the Ham test for the diagnosis ofPNH. Serologic studies may show evidence of viral infection, especially Epstein-Barr virus and HIV. Posthepatitis aplastic anemia is typically seronegative. The spleen size should be determined by scanning if the physical examination of the abdomen is unsatisfactory. Magnetic resonance imaging may be helpful to assess the fat content on a few vertebrae in order to distinguish aplasia from MDS.

DIAGNOSIS

The diagnosis of aplastic anemia is usually straightforward, based on the combination of pancytopenia with a fatty, empty bone marrow. Aplastic anemia is a disease of the young and should be a leading diagnosis in the pancytopenic adolescent or young adult. When pancytopenia is secondary, the primary diagnosis is usually obvious from either history or physical examination: the massive spleen of alcoholic cirrhosis, the history or metastatic cancer or systemic lupus erythematosus, or obvious miliary tuberculosis on chest radiograph (Table 109-1).

Diagnostic problems can occur with atypical presentations and among related

hematologic diseases. While pancytopenia is most common, some patients with bone marrow hypocellularity have depression of only one or two of three blood lines, sometimes showing later progression to more recognizable aplastic anemia. The bone marrow in constitutional or Fanconi's anemia is indistinguishable morphologically from the aspirate in acquired disease. The diagnosis can be suggested by family history, abnormal blood counts since childhood, or the presence of associated anomalies of the skeletal and urogenital systems. Patients with Fanconi's anemia may have no peculiar physical findings and can present with aplastic anemia as adults, in the third and fourth decades and, rarely, even later. Aplastic anemia may be difficult to distinguish from the hypocellular variety ofMDS: MDS is favored by finding morphologic abnormalities, particularly of megakaryocytes and myeloid precursor cells, and typical cytogenetic abnormalities (see below).

PROGNOSIS

The natural history of severe aplastic anemia is rapid deterioration and death. Provision first of red blood cell and later platelet transfusions and effective antibiotics were of some benefit, but few patients showed spontaneous recovery. The major prognostic determinant is the blood count; severe disease is defined by the presence of two of three parameters: absolute neutrophil count<500/uL, platelet count<20,000/uL, and corrected reticulocyte count<1% (or absolute reticulocyte count<50,000/uL). Survival of patients who fulfill these criteria is about 20% at 1 year after diagnosis; patients with very severe disease, defined by an absolute neutrophil count<200/uL, fare even more poorly. Treatment has markedly improved survival in this disease.

TREATMENT

Treatment includes therapies that reverse the underlying marrow failure and supportive care of the pancytopenic patient. Severe acquired aplastic anemia can be cured by replacement of the absent hematopoietic cells (and the immune system) by stem cell transplant, or ameliorated by suppression of the immune system to allow recovery of the patient's residual bone marrow function. Hematopoietic growth factors have limited usefulness and glucocorticoids are of no value. Suspect exposures to drugs or chemicals should be discontinued; however, spontaneous recovery of severe blood count depression is rare, and a waiting period before beginning treatment may not be advisable unless the blood counts are only modestly depressed.

Bone Marrow Transplantation This is the best therapy for the young patient with a fully histocompatible sibling donor (Chap. 115). HLA typing should be ordered as soon as the diagnosis of aplastic anemia is established in a child or younger adult. In transplant candidates, transfusion of blood from family members should be avoided so as to prevent sensitization to histocompatability antigens; while transfusions in general should be minimized, limited numbers of blood products probably do not seriously affect outcome.

For allogeneic transplant from fully matched siblings, long-term survival rates for children are about 80%. Transplant morbidity and mortality are increased among adults, due mainly to the increased risk of chronic graft-versus-host disease and serious infections. Graft rejection was historically a major determinant of outcome in bone

marrow transplant for aplastic anemia; high rates of primary or secondary graft failure may be related to the pathophysiology of marrow failure as well as to alloimmunization from transfusions.

Most patients do not have a suitable sibling donor. Occasionally, a full phenotypic match can be found within the family and serve as well. Far more available are other alternative donors, either unrelated but histocompatible volunteers, or closely but not perfectly matched family members. Survival using alternative donors is about half that of conventional sibling transplants. These patients will be at risk for late complications, especially a higher rate of cancer, if radiation is used as a component of conditioning. The majority of adults who undergo alternative donor transplants succumb to transplant-related complications.

Immunosuppression Used alone,ALG or antithymocyte globulin (ATG) induces hematologic recovery (independence from transfusion and a leukocyte count adequate to prevent infection) in about 50% of patients. The addition of cyclosporine to either ALG or ATG has further increased response rates to about 70 to 80% and especially improved outcomes for children and for severely neutropenic patients. Combined treatment is now standard for patients with severe disease. Hematologic response strongly correlates with survival. Improvement in granulocyte number is generally apparent within 2 months of treatment. Most recovered patients continue to have some degree of blood count depression, theMCVremains elevated, and the bone marrow cellularity returns towards normal only very slowly, if at all. Relapse (recurrent pancytopenia) is frequent, often occurring as cyclosporine is discontinued; most, but not all, patients respond to reinstitution of immunosuppression, and some responders become dependent on continued cyclosporine administration. Development ofMDS, with typical marrow morphologic or cytogenetic abnormalities, occurs in about 15% of treated patients, usually but not invariably associated with a return of pancytopenia, and some patients develop leukemia. Although the laboratory diagnosis ofPNH can generally be made at the time of presentation of aplastic anemia by flow cytometry, recovered patients showing frank hemolysis or, less commonly, thrombosis should be retested for PNH. Bone marrow examinations should be performed annually or if there is an unfavorable change in blood counts.

HorseATG(ATGAM; Upjohn) is given at 40 mg/kg per day for 4 days; rabbit ALG (Thymoglobulin; SangStat), is administered at 3.5 mg/kg per day for 5 days. For ATG, anaphylaxis is a rare but occasionally fatal complication; allergy should be tested by a prick skin test with an undiluted solution and immediate observation; desensitization is feasible. ATG binds to peripheral blood cells, and therefore, platelet and granulocyte numbers may fall further during active treatment. Serum sickness, a flulike illness with a characteristic cutaneous eruption and arthralgia, often develops about 10 days after initiating treatment. Most patients are given methylprednisolone, 1 mg/kg per day for 2 weeks, to ameliorate the immune consequences of heterologous protein infusion. Excessive or extended glucocorticoid therapy is associated with avascular joint necrosis. Cyclosporine is administered orally at an initial dose of 12 mg/kg per day in adults (15 mg/kg per day in children), with subsequent adjustment according to blood levels obtained every 2 weeks. Trough levels should be between 150 and 200 ng/mL. The most important side effects of chronic cyclosporine treatment are nephrotoxicity, hypertension, seizures, and opportunistic infections, especially *Pneumocystis carinii*

(prophylactic treatment with monthly inhaled pentamidine is recommended).

Most patients with aplastic anemia lack a suitable marrow donor and immunosuppression is the treatment of choice. Long-term survival is equivalent with transplantation and immunosuppression. However, successful transplant cures marrow failure, while patients who recover adequate blood counts after immunosuppression remain at risk of relapse and malignant evolution. Because of the excellent results in children, allogeneic transplant should always be performed in the pediatric population if a suitable sibling donor is available. Increasing age and the severity of neutropenia are the most important factors weighing in the decision between transplant and immunosuppression in adults who have a matched family donor: older patients do better withATG and cyclosporine, while transplant is preferred if granulocytopenia is profound. Some reluctant patients may be treated by immunosuppression followed by transplant for failure to recover blood counts or occurrence of late complications.

Outcomes following both transplant and immunosuppression have improved with time. High doses of cyclophosphamide, without stem cell rescue, have been reported to produce durable hematologic recovery, without relapse or evolution toMDS, but this treatment can produce sustained severe neutropenia and response is often delayed. Novel immunosuppressive drugs such as mycophenolate mofetil may further improve outcome.

Other Therapies The effectiveness of androgen therapy has not been verified in controlled trials, but occasional patients will respond or even demonstrate blood count dependence on continued therapy. For patients with moderate disease or those with severe pancytopenia who have failed immunosuppression, a 3- to 4-month trial is appropriate. Hematopoietic growth factors, granulocyte colony stimulating factor (G-CSF), granulocyte-macrophage CSF (GM-CSF), and interleukin 3, are not recommended as initial therapy for severe aplastic anemia, and even their role as adjuncts to immunosuppression is not well defined. Some patients may respond to chronic administration of growth factors in combination after failing immunosuppression. Splenectomy may occasionally increase blood counts in relapsed or refractory cases.

Supportive Care Meticulous medical attention is required so that the patient may survive to benefit from definitive therapy or, having failed treatment, to maintain a reasonable existence in the face of pancytopenia. First and most important, infection in the presence of severe neutropenia must be aggressively treated by prompt institution of parenteral, broad-spectrum antibiotics, usually ceftazadime or a combination of an aminoglycoside, cephalosporin, and semisynthetic penicillin. Therapy is empirical and must not await results of culture, although specific foci of infection such as oropharyngeal or anorectal abscesses, pneumonia, sinusitis, and typhlitis (necrotizing colitis) should be sought on physical examination and with radiographic studies. When indwelling plastic catheters become contaminated, vancomycin should be added. Persistent or recrudescent fever implies fungal disease: *Candida* or *Aspergillus* are common, especially after several courses of antibacterial antibiotics, and a progressive course may be averted by timely initiation of amphotericin. Granulocyte transfusions using G-CSF-mobilized peripheral blood have been effective in the treatment of overwhelming infections in a few patients. Hand washing, the single most effective method of preventing the spread of infection, remains a neglected practice.

Nonabsorbed antibiotics for gut decontamination are poorly tolerated and not of proven value. Total reverse isolation is not clearly beneficial in reducing mortality from infections.

Both platelet and erythrocyte numbers can be maintained by transfusion. Alloimmunization limits the usefulness of platelet transfusions and can be avoided or minimized by several strategies, including use of single donors to reduce exposure and physical or chemical methods to diminish leukocytes in the product; HLA-matched platelets are often effective in patients refractory to random donor products. Inhibitors of fibrinolysis such as aminocaproic acid have not been shown to relieve mucosal oozing; the use of low-dose glucocorticoids to induce "vascular stability" is unproven. Whether platelet transfusions are better used prophylactically or only as needed remains unclear. Any rational regimen of prophylaxis requires transfusions once or twice weekly in order to maintain the platelet count>10,000/uL (oozing from the gut, and presumably also from other vascular beds, increases precipitously at counts<5000/uL). Menstruation should be suppressed either by oral estrogens or nasal follicle-stimulating hormone/luteinizing hormone (FSH/LH) antagonists. Aspirin and other nonsteroidal anti-inflammatory agents inhibit platelet function and must be avoided.

Red blood cells should be transfused to maintain a normal level of activity, usually at a hemoglobin value of 70 g/L (90 g/L if there is underlying cardiac or pulmonary disease); a regimen of 2 units every 2 weeks will replace normal losses in a patient without a functioning bone marrow. In chronic anemia, the iron chelator deferoxamine should be added at the time of the fiftieth transfusion in order to avoid secondary hemochromatosis.

PURE RED CELL APLASIA

More restricted forms of marrow failure occur, in which only a single circulating cell type is affected and the aregenerative marrow shows corresponding absence or decreased numbers of specific precursor cells: aregenerative anemia as inPRCA(see below), thrombocytopenia with amegakaryocytosis (Chap. 116), and neutropenia without marrow myeloid cells in agranulocytosis (Chap. 64). In general, and in contrast to aplastic anemia andMDS, the unaffected lineages appear quantitatively and qualitatively normal. Agranulocytosis, the most frequent of these syndromes, is usually a complication of medical drug use (with agents similar to those related to aplastic anemia), either by a mechanism of direct chemical toxicity or by immunologic mediation. Agranulocytosis has an incidence similar to aplastic anemia but is especially frequent among the elderly and in women. The syndrome should resolve with discontinuation of exposure, but significant mortality is attached to neutropenia in the older and often previously unwell patient. Both pure white cell aplasia (agranulocytosis without incriminating drug exposure) and amegakaryocytic thrombocytopenia are exceedingly rare and, like PRCA, appear to be due to destructive antibodies or lymphocytes and can respond to immunosuppressive therapies. In all the single lineage failure syndromes, progression to pancytopenia or leukemia is unusual.

DEFINITION AND DIFFERENTIAL DIAGNOSIS

PRCAis characterized by anemia, reticulocytopenia, and absent or rare erythroid

precursor cells in the bone marrow. The classification of PRCA is shown inTable 109-4. In adults, PRCA is acquired. An identical syndrome can occur constitutionally: Diamond-Blackfan anemia, or congenital PRCA, is diagnosed at birth or in early childhood and often responds to glucocorticoid treatment. Temporary red cell failure occurs in transient aplastic crisis of hemolytic anemias, due to acute parvovirus infection (Chap. 187), and in transient erythroblastopenia of childhood, which affects normal children.

CLINICAL ASSOCIATIONS AND ETIOLOGY

PRCAhas important associations with immune system diseases. A small minority of cases occur with a thymoma. More frequently, red cell aplasia can be the major manifestation of large granular lymphocytosis or may occur in chronic lymphocytic leukemia. Some patients may be hypogammaglobulinemic. As with agranulocytosis, PRCA can be due to an idiosyncratic reaction to a drug.

Like aplastic anemia,PRCAresults from diverse mechanisms. Antibodies to red blood cell precursors are frequently present in the blood, but T cell inhibition is probably the more common immune mechanism. Cytotoxic lymphocyte activity restricted by histocompatibility locus or specific for human T cell leukemia/lymphoma virus I-infected cells, as well as natural killer cell activity inhibitory of erythropoiesis, have been demonstrated in particularly well-studied individual cases.

Persistent Parvovirus B19 Infection Chronic parvovirus infection is an important, treatable cause ofPRCA. This common virus causes a benign exanthem of childhood (fifth disease) and a polyarthralgia syndrome in adults. In patients with underlying hemolysis (or any condition that increases demand for red blood cell production), parvovirus infection can cause a transient aplastic crisis and an abrupt but temporary worsening of the anemia due to failed erythropoiesis. In normal individuals, acute infection is resolved by production of neutralizing antibodies to the virus, but in the setting of congenital, acquired, or iatrogenic immunodeficiency, persistent viral infection may occur. The bone marrow shows red cell aplasia and the presence of giant pronormoblasts (Fig. 109-2), the cytopathic sign of B19 parvovirus infection and highly suggestive of the diagnosis. Viral tropism for human erythroid progenitor cells is due to its use of erythrocyte P antigen as a cellular receptor for entry. Direct cytotoxicity of virus causes anemia if demands on erythrocyte production are high; in normal individuals, the temporary cessation of red cell production is not clinically apparent, and skin and joint symptoms are mediated by immune complex deposition.

TREATMENT

History, physical examination, and routine laboratory studies may disclose an underlying disease or a suspect drug exposure. Thymoma should be sought by radiographic procedures. Tumor excision is indicated, but anemia does not necessarily improve with surgery. The diagnosis of parvovirus infection requires detection of viral DNA sequences in the blood (IgG and IgM antibodies are commonly absent). The presence of erythroid colonies has been considered predictive of response to immunosuppressive therapy in idiopathicPRCA.

Red cell aplasia is compatible with long survival with supportive care alone, a combination of erythrocyte transfusions and iron chelation. For persistent B19 parvovirus infection, almost all patients respond to intravenous immunoglobulin therapy (for example, 0.4 g/kg daily for 5 days), although relapse and retreatment may be expected, especially in patients with AIDS. The majority of patients with idiopathicPRCArespond favorably to immunosuppression. Most first receive a course of glucocorticoids, followed in the absence of a response by cyclosporine,ATG, azathioprine, or cyclophosphamide.

MYELODYSPLASIA

DEFINITION

The myelodysplastic syndromes are a heterogeneous group of hematologic disorders broadly characterized by cytopenias associated with a dysmorphic (or abnormal appearing) and usually cellular bone marrow, and consequent ineffective blood cell production (Table 109-5). The current nomenclature was developed by the French-American-British (FAB) Cooperative Group and, while increasing recognition of the syndromes, is not entirely satisfactory: chronic myelomonocytic leukemia, while associated with dysplastic morphology, behaves as a myeloproliferative disease; sideroblastic anemias likely have a distinctive etiology; and the borderline between refractory anemia with excess blasts in transformation and acute myeloid leukemia is so arbitrary as to have been abandoned in the most recent World Health Organization classification. The FAB scheme has been recently supplemented by the International Prognostic Scoring System (IPSS; Table 109-6).

EPIDEMIOLOGY

IdiopathicMDS is a disease of the elderly; the mean age at onset is 68 years. There is a slight male preponderance. MDS is a relatively common form of bone marrow failure, with incidence rates reported of 35 to >100 per million persons in the general population and 120 to >500 per million in the aged. MDS is rare in children, but monocytic leukemia can be seen. Therapy-related MDS is not age-related and may occur in as many as 15% of patients within a decade following intensive combined modality treatment for cancer. Rates of MDS have increased over time, due to the recognition of the syndrome by physicians and the aging of the population.

ETIOLOGY AND PATHOPHYSIOLOGY

The myelodysplastic syndromes have been convincingly linked to environmental exposures such as radiation and benzene; other risk factors have been reported inconsistently. SecondaryMDSoccurs as a stereotypical late toxicity of cancer treatment, usually with a combination of radiation and the radiomimetic alkylating agents such as busulfan, nitrosourea, or procarbazine (with a latent period of 5 to 7 years) or the DNA topoisomerase inhibitors (2 years). Both acquired aplastic anemia following immunosuppressive treatment and Fanconi's anemia can evolve into MDS.

MDSis a clonal hematopoietic stem cell disorder leading to impaired cell proliferation and differentiation. Cytogenetic abnormalities are found in about half of patients, and

some of the same specific lesions are also seen in frank leukemia; deletions are more frequent than translocations. Both presenting and evolving hematologic manifestations result from the accumulation of multiple genetic lesions, loss of tumor suppressor genes, activating oncogene mutations, or other harmful alterations. Cytogenetic abnormalities are not random (loss of all or part of 5, 7, and 20, trisomy of 8) and may be related to etiology (11q23 following topoisomerase II inhibitors); chronic myelomonocytic leukemia is often associated with t(5;12) that creates a chimeric *tel-PDGFb* gene. The type and number of cytogenetic abnormalities strongly correlate with the probability of leukemic transformation and survival. Mutations of N-*ras* (an oncogene), *p53* and *IRF-1* (tumor suppressor genes), *Bcl-2* (an antiapoptotic gene), and others have been reported in some patients but may occur relatively late in the sequence leading to leukemic transformation. Apoptosis of marrow cells is increased in MDS, presumably due to these acquired genetic alterations or possibly to an overlaid immune response. Sideroblastic anemia may be related to mutations in mitochondrial genes. Ineffective erythropoiesis and disordered iron metabolism are the functional consequences of the genetic alterations.

CLINICAL FEATURES

Anemia dominates the early course. Most symptomatic patients complain of the gradual onset of fatigue and weakness, dyspnea, and pallor, but at least half the patients are asymptomatic andMDS is discovered only incidentally on routine blood counts. Previous chemotherapy or radiation exposure is an important historic fact. Fever and weight loss should point to a myeloproliferative rather than myelodysplastic process. Children with Down's syndrome are susceptible to MDS, and a family history may indicate a hereditary form of sideroblastic anemia or Fanconi's anemia.

The physical examination is remarkable for signs of anemia; about 20% of patients have splenomegaly. Some unusual skin lesions, including Sweet's syndrome (febrile neutrophilic dermatosis), have been associated withMDS.

LABORATORY STUDIES

Blood Anemia is present in the majority of cases, either alone or as part of bi- or pancytopenia; isolated neutropenia or thrombocytopenia is more unusual. Macrocytosis is common, and the smear may be dimorphic with a distinctive population of large red blood cells. Platelets are also large and lack granules. In functional studies, they may show marked abnormalities, and patients may have bleeding symptoms despite seemingly adequate numbers. Neutrophils are hypogranulated; have hyposegmented, ringed, or abnormally segmented nuclei; and contain Dohle bodies and may be functionally deficient. Circulating myeloblasts usually correlate with marrow blast numbers, and their quantitation is important for classification and prognosis. The total white blood cell count is usually normal or low, except in chronic myelomonocytic leukemia. As in aplastic anemia,MDS also can be associated with a clonal population ofPNHcells.

Bone Marrow The bone marrow is usually normal or hypercellular but in 20% of cases is sufficiently hypocellular to be confused with aplasia. No single characteristic feature of marrow morphology distinguishesMDS, but the following are commonly observed:

dyserythropoietic changes (especially nuclear abnormalities) and ringed sideroblasts in the erythroid lineage; hypogranulation and hyposegmentation in granulocytic precursors, with an increase in myeloblasts; and megakaryocytes showing reduced numbers of disorganized nuclei. Prognosis strongly correlates with the proportion of marrow blasts. Cytogenetic analysis also is important. A much more sensitive method to detect infrequent chromosome aberrations is fluorescent in situ hybridization, and gene amplification by polymerase chain reaction can detect known chromosomal translocations.

DIFFERENTIAL DIAGNOSIS

Deficiencies of vitamin B_{12} or folate should be suggested by history and excluded by appropriate blood tests; vitamin B_6deficiency can be assessed by a therapeutic trial of pyridoxine if the bone marrow shows ringed sideroblasts. Marrow dysplasia can be observed in acute viral infections, drug reactions, or chemical toxicity but should be transient. More difficult (arbitrary) are the distinctions between hypocellularMDS and aplasia or between refractory anemia with excess blasts in transformation and early acute leukemia.

PROGNOSIS

The median survival varies greatly withFAB type and, according toIPSScalculations, ranges from years for patients with 5q- or sideroblastic anemia to a few months in refractory anemia with excess blasts or severe pancytopenia associated with monosomy 7. Most patients die as a result of complications of pancytopenia and not due to leukemic transformation; perhaps one-third will succumb to other diseases unrelated to theirMDS. Precipitous worsening of pancytopenia, acquisition of new chromosomal abnormalities on serial cytogenetic determination, and increase in the number of blasts are all poor prognostic indicators. The outlook in therapy-related MDS, regardless of FAB type, is very poor, and most patients will progress within a few months to refractory acute myeloid leukemia.

TREATMENT

The therapy ofMDS is generally unsatisfactory. Only stem cell transplantation offers cure: survival rates of 40% have been reported, but older patients are particularly prone to develop treatment-related mortality and morbidity. Those with better prognostic features (and a more favorable natural history) have much better outcomes than patients with more malignant subtypes. Surprisingly, results of transplant using matched unrelated donor are comparable, although most series contain younger and more highly selected cases.

MDShas been regarded as particularly refractory to cytotoxic chemotherapy regimens but is probably no more resistant to effective treatment than acute myeloid leukemia in the elderly, in whom drug toxicity is often fatal and remissions, if achieved, are brief. Low doses of cytotoxic drugs have been administered for their "differentiating" potential: responses to cytosine arabinoside did not translate into a survival advantage; etoposide and 5-azacytidine are under active study. Amifostine, an organic thiophosphonate that blocks apoptosis, can improve blood counts but has significant toxicities.

Immunosuppressive therapies, includingATG and cyclosporine, that are effective in aplastic anemia may induce sustained remissions in a high proportion of patients with refractory anemia, especially in those with hypocellular marrows or without cytogenetic abnormalities.

Hematopoietic growth factors can improve blood counts but, as in most other marrow failure states, have been most beneficial in patients with the least severe pancytopenia. G-CSF treatment alone failed to improve survival in a controlled trial. The combination of G-CSF and erythropoietin increased blood counts in one-third to one-half of patients, but survival advantage is not yet proven.

The same principles of supportive care described for aplastic anemia apply toMDS. Because many patients will be anemic for years, erythrocyte transfusion support should be accompanied by iron chelation in order to prevent secondary hemochromatosis.

MYELOPHTHISIC ANEMIAS

Fibrosis of the bone marrow (seePlate V-19), usually accompanied by a characteristic blood smear picture called *leukoerythroblastosis*, can occur as a primary hematologic disease, called *myelofibrosis* or *myeloid metaplasia* (Chap. 110), and as a secondary process, called *myelophthisis*. Myelophthisis, or secondary myelofibrosis, is reactive. Fibrosis can be a response to invading tumor cells, usually of an epithelial cancer of breast, lung, and prostate or neuroblastoma. Marrow fibrosis may occur with infection of mycobacteria (both *Mycobacterium tuberculosis* and *M. avium*) fungi, or HIV, and in sarcoidosis. Intracellular lipid deposition in Gaucher's disease and obliteration of the marrow space related to absence of osteoclast remodeling in congenital osteopetrosis also can produce fibrosis. Secondary myelofibrosis is a late consequence of radiation therapy or treatment with radiomimetic drugs. Usually, the infectious or malignant underlying processes are obvious. Marrow fibrosis can also be a feature of a variety of hematologic syndromes, especially chronic myeloid leukemia, multiple myeloma, lymphomas, myeloma, and hairy cell leukemia.

The pathophysiology has three distinct features: proliferation of fibroblasts in the marrow space (myelofibrosis); the extension of hematopoiesis into the long bones and most particularly into extramedullary sites, usually the spleen, liver, and lymph nodes (myeloid metaplasia); and ineffective erythropoiesis. The etiology of fibrosis is unknown but most likely involves dysregulated production of growth factors: platelet-derived growth factor and transforming growth factorb have been implicated. Abnormal regulation of other hematopoietins would lead to localization of blood-producing cells in nonhematopoietic tissues and uncoupling of the usually balanced processes of stem cell proliferation and differentiation. Myelofibrosis is remarkable for pancytopenia despite extraordinarily large numbers of circulating hematopoietic progenitor cells.

Anemia is dominant in secondary myelofibrosis, usually normocytic and normochromic. The diagnosis is suggested by the characteristic leukoerythroblastic smear (seePlate V-9). Erythrocyte morphology is very abnormal, with circulating nucleated red blood cells, teardrops, and shape distortions. White blood cell numbers are often elevated, sometimes mimicking a leukemoid reaction, with circulating myelocytes, promyelocytes, and myeloblasts. Platelets may be abundant and are often giant size. Inability to

aspirate the bone marrow, the characteristic "dry tap," can allow a presumptive diagnosis before the biopsy is decalcified.

The course of secondary myelofibrosis is determined by its cause, usually a metastatic tumor or an advanced hematologic malignancy. Treatable causes must be excluded, especially tuberculosis and fungus. Transfusion support can relieve symptoms.

110. POLYCYTHEMIA VERA AND OTHER MYELOPROLIFERATIVE DISEASES - *Jerry L. Spivak*

Polycythemia vera, idiopathic myelofibrosis, essential thrombocytosis, and chronic myeloid leukemia (CML) are commonly classified together under the rubric *the chronic myeloproliferative disorders*, because their pathophysiology involves the clonal expansion of a multipotent hematopoietic progenitor cell with the overproduction of one or more of the formed elements of the blood. These entities may transform into acute leukemia naturally or as a consequence of mutagenic treatment. However, while polycythemia vera, idiopathic myelofibrosis, essential thrombocytosis, and CML share similar phenotypic characteristics, CML is genotypically distinct from the other three disorders because it alone is associated with translocation of genetic material between the long arms of chromosomes 9 and 22, resulting in the production of the unique fusion protein, bcr-abl. Furthermore, based on its natural history, CML is more appropriately considered as a form of leukemia.**CML is discussed with the acute myeloid leukemias in Chap. 111.*

POLYCYTHEMIA VERA

Polycythemia vera is a clonal disorder involving a multipotent hematopoietic progenitor cell in which there is accumulation of phenotypically normal red cells, granulocytes, and platelets in the absence of a recognizable physiologic stimulus. Polycythemia vera, the most common of the chronic myeloproliferative disorders, occurs in about 2 per 100,000 people. It spares no adult age group. Vertical transmission has been documented, establishing a genetic basis for the disorder. A slight overall male predominance has been observed, but females predominate within the reproductive age range.

ETIOLOGY

The etiology of polycythemia vera is unknown. Although nonrandom chromosome abnormalities such as 20q-, trisomy 8 or 9 have been documented in a small percentage of untreated polycythemia vera patients, no consistent cytogenetic abnormality has been associated with the disorder and no specific genetic defect has yet been identified. Impaired posttranslational processing of the thrombopoietin receptor, Mpl, has been noted in polycythemia vera patients; the extent of the defect correlated with disease duration and splenomegaly. While this defect is specific for polycythemia vera and is not found in secondary polycythemias, its role in the pathophysiology of the disorder is still undefined. In contrast to normal erythroid progenitor cells, polycythemia vera erythroid progenitor cells can grow in vitro in the absence of erythropoietin due to hypersensitivity to insulin-like growth factor I. However, this phenotypic abnormality is not specific for polycythemia vera and has been documented in essential thrombocytosis and secondary polycythemias. Polycythemia vera erythroid progenitor cells are more resistant to apoptosis induced by erythropoietin deprivation, due to upregulation of bcl-X_L, an antiapoptotic protein. The polycythemia vera erythroid progenitors do not divide more rapidly than their normal counterparts, but they accumulate because they do not die normally. Additionally, the transformed hematopoietic progenitor cells in polycythemia vera, as in other neoplastic disorders, exhibit clonal dominance and suppress the proliferation of normal hematopoietic progenitor cells by an unknown mechanism. Consequently, the circulating formed

elements of the blood represent only progeny of the transformed clone.

CLINICAL FEATURES

Although massive splenomegaly may be the initial presenting sign in polycythemia vera, most often the disorder is first recognized by the discovery of a high hemoglobin or hematocrit, and with the exception of aquagenic pruritus, no symptoms distinguish polycythemia vera from other causes of erythrocytosis.

Uncontrolled erythrocytosis can lead to neurologic symptoms such as vertigo, tinnitus, headache, and visual disturbances. Systolic hypertension also accompanies an elevated red cell mass. In some patients, venous or arterial thrombosis may be the presenting manifestation of polycythemia vera. Intraabdominal venous thrombosis is particularly common and may be catastrophic when there is sudden compromise of the hepatic vein. Polycythemia vera should be suspected in any patient who develops the Budd-Chiari syndrome. Digital ischemia may also occur. Easy bruising, epistaxis, or gastrointestinal hemorrhage may be observed, and polycythemia vera patients are frequently hypermetabolic. Hypercuricemia with secondary gout and uric acid stones and acid-peptic disease also complicate the disorder. Because isolated erythrocytosis is a common initial presentation for polycythemia vera but no clonal marker is available for the disease, the first task of the physician is to distinguish this autonomous clonal form of erythrocytosis from the many other types of erythrocytosis, most of which are correctable (Table 110-1).

Erythropoiesis is normally regulated by the glycoprotein hormone erythropoietin. Erythropoietin, which in adults is produced primarily in the kidneys and to a small extent in the liver, promotes the proliferation of erythroid progenitor cells, maintains their survival, and facilitates their differentiation. Because erythropoietin acts as a survival factor, it is constitutively produced and, like the red cell mass, its level is constant as long as tissue oxygenation is adequate. The plasma erythropoietin level, like the red cell mass, differs among individuals but in adults is not affected by either age or gender. Erythropoietin production is regulated at the level of gene transcription. Hypoxia is the only physiologic stimulus that increases the number of cells producing erythropoietin, and thus the production and metabolism of erythropoietin are independent of its plasma level. In the absence of renal or hepatic disease, plasma erythropoietin levels reflect erythropoietin production, and therefore the assay for plasma erythropoietin is a surrogate assay for tissue hypoxia. Erythropoietin is active at the picomolar level, and its production is tightly regulated. Thus, the plasma erythropoietin level does not rise outside the normal range until the hemoglobin level falls below 105 g/L. This is not meant to imply that an increase in erythropoietin production does not occur as the hemoglobin level falls below normal, but because the normal range for plasma erythropoietin is wide (4 to 26 mU/mL), unless the patient's baseline level is known, any increase will not be recognized until the hemoglobin falls below 105 g/L. Thereafter, there is a log-linear inverse correlation between the levels of plasma erythropoietin and hemoglobin. With erythrocytosis, erythropoietin production is suppressed; this suppression reflects not only the increase in tissue oxygen transport associated with the increase in red cell number but also additional negative-feedback mechanism unrelated to oxygen transport but related to the increase in blood viscosity and an increase in red cell precursors capable of taking up erythropoietin. The summation of these

mechanisms accounts for the paradoxical observation that many patients with hypoxic erythrocytosis due to cyanotic congenital heart disease or obstructive lung disease have a "normal" plasma erythropoietin level. The plasma erythropoietin level is a useful diagnostic test in patients with isolated erythrocytosis, because an elevated level essentially excludes polycythemia vera as the cause for the erythrocytosis.

DIAGNOSIS

When confronted with an elevated hemoglobin or hematocrit level, it is important to obtain previous values to determine the duration of this laboratory abnormality. Because the hemoglobin or hematocrit level is affected by the plasma volume, and hematocrit and red cell mass are not linearly related, a red cell mass determination must also be performed to distinguish absolute erythrocytosis from relative erythrocytosis due to a reduction in plasma volume alone (also known as *stress* or *spurious erythrocytosis* or *Geisbock's syndrome*). Red cell mass determination is important because in polycythemia vera, in contrast to erythropoietin-driven erythrocytosis, the plasma volume is frequently elevated, not only masking the true extent of red cell mass expansion but often its presence. Indeed, a significant proportion of patients with polycythemia vera have a hematocrit within the normal range, particularly in patients with a substantial splenomegaly. Failure to recognize this phenomenon is undoubtedly the basis for many of the reported instances of hepatic or portal vein thrombosis in patients with a so-called undefined myeloproliferative disorder.

Red cell mass is reliably determined by isotope dilution using the patient's ^{51}Cr-tagged red cells; extrapolations made by determining directly only the plasma volume are unacceptable. Furthermore, to allow ample time for equilibration of the labeled red cells, measurements should be made over a period of ^{3}90 min.

Once the presence of absolute erythrocytosis has been established, its cause must be determined. An elevated plasma erythropoietin level suggests either an hypoxic cause for erythrocytosis or autonomous erythropoietin production, in which case assessment of pulmonary function and an abdominal computed tomography scan to evaluate renal and hepatic anatomy are appropriate. A normal erythropoietin level does not exclude an hypoxic cause for erythrocytosis. In polycythemia vera, in contrast to hypoxic erythrocytosis, the arterial oxygen saturation is normal. However, a normal oxygen saturation does not exclude a high-affinity hemoglobin as a cause for erythrocytosis, and it is here that documentation of previous hemoglobin levels and a family study become important. Because there is no clonal marker for polycythemia vera, clinical guidelines have been proposed to define the disease. A modified version is provided inTable 110-2. However, these guidelines do not establish clonality, and in some patients only with time will the underlying disorder become apparent. Diagnostic ambiguity does not preclude the initiation of therapy.

Other laboratory studies that may aid in diagnosis include the red cell count, mean corpuscular volume, and red cell distribution width (RDW). Only three situations cause microcytic erythrocytosis:b-thalassemia trait, hypoxic erythrocytosis, and polycythemia vera. However, with b-thalassemia trait the RDW is normal, whereas with hypoxic erythrocytosis and polycythemia vera, the RDW is usually elevated. A properly made blood smear from a patient with erythrocytosis will be virtually unreadable due to the

marked elevation in red cell count, but no specific morphologic abnormalities are seen in the leukocytes or platelets in polycythemia vera. However, when these are also elevated the diagnosis is assured. In many patients, the leukocyte alkaline phosphatase level is also increased, as is the uric acid level. Elevated serum vitamin B_{12} or B_{12}-binding capacity may be present. In patients with associated acid-peptic disease, occult gastrointestinal bleeding may lead to presentation with hypochromic, microcytic anemia.

A bone marrow aspirate and biopsy will provide no specific diagnostic information, and unless there is a need to establish the presence of myelofibrosis or exclude some other disorder, these procedures need not be done. Although the presence of a cytogenetic abnormality such as trisomy 8 or 9 or 20q- in the setting of an expansion of the red cell mass supports the clonal etiology, no specific cytogenetic abnormality is associated with polycythemia vera, and the absence of a cytogenetic marker does not exclude the diagnosis.

COMPLICATIONS

The major clinical complications of polycythemia vera relate directly to the increase in blood viscosity associated with elevation of the red cell mass and indirectly to the increased turnover of red cells, leukocytes, and platelets and the attendant increase in uric acid and histamine production. The latter appears to be responsible for the increase in peptic ulcer disease and for the pruritus associated with this disorder, although little formal proof for this has been obtained. A sudden massive increase in spleen size is another problem and can be associated with splenic infarction or progressive cachexia. Myelofibrosis and myeloid metaplasia can also develop with transfusion-dependent anemia, but the frequency is low in those not receiving chemotherapy or irradiation. Although acute nonlymphocytic leukemia is reported to be increased in polycythemia vera, the incidence of acute leukemia in patients not exposed to chemotherapy or radiation is low and the development of leukemia is not related to disease duration, suggesting that the treatment exposure may be a more important risk factor than the disease itself.

Erythromelalgia is a curious syndrome of unknown etiology involving primarily the lower extremities and manifested usually by erythema, warmth, and pain of the affected appendage and occasionally digital infarction. It occurs with a variable frequency in patients with a myeloproliferative disorder and is usually responsive to salicylates. Some of the central nervous system symptoms observed in patients with polycythemia vera may represent a variant of erythromelalgia.

If left uncontrolled, erythrocytosis can lead to intravascular thrombosis involving vital organs such as the liver, heart, brain, or lungs. Patients with massive splenomegaly are particularly prone to thrombotic events because the associated increase in plasma volume masks the true extent of the red cell mass elevation as measured by the hematocrit or hemoglobin level. A "normal" hematocrit or hemoglobin level in a polycythemia vera patient with massive splenomegaly should be considered as indicative of an elevated red cell mass until proven otherwise.

TREATMENT

Polycythemia vera is generally an indolent disorder whose clinical course can run many decades, and its medical management should reflect the tempo of the disorder. Maintenance of the hemoglobin level at £140 g/L in men and £120 g/L in women is mandatory to avoid the thrombotic complications. Thrombosis due to erythrocytosis is the most significant complication of this disorder. Phlebotomy serves initially to reduce hyperviscosity by bringing the red cell mass into the normal range. Periodic phlebotomies thereafter serve to maintain the red cell mass within the range of normal and to induce a state of iron deficiency, which prevents an accelerated reexpansion of the red cell mass. In most polycythemia vera patients, once an iron-deficient state is achieved, phlebotomy is usually required only at 3-month intervals. Although both phlebotomy and iron deficiency, in addition to the disease itself, tend to increase the platelet count, thrombocytosis is not correlated with thrombosis in polycythemia vera, in contrast to the strong correlation between erythrocytosis and thrombosis in this disease. The use of salicylates as a tonic against thrombosis in polycythemia vera patients is potentially harmful, and salicylates should be employed only to treat erythromelalgia. Oral anticoagulants are not routinely indicated and are difficult to assess owing to the artifactual imbalance between the test tube anticoagulant and plasma that occurs when blood from these patients is assayed for prothrombin or partial thromboplastin activity. Asymptomatic hyperuricemia requires no therapy, but allopurinol should be administered to avoid further elevation of the uric acid when chemotherapy is employed to reduce splenomegaly or leukocytosis-associated pruritus. Generalized pruritus intractable to antihistamines can be a major problem in polycythemia vera, and hydroxyurea, interferon (IFN)-a, and psoralens with ultraviolet light in the A range (PUVA) therapy may have some palliative effects. Asymptomatic thrombocytosis requires no therapy. Symptomatic thrombocytosis or splenomegaly can be treated with hydroxyurea or IFN-a, although each can be associated with significant side effects. Anagrelide, a quinazolin derivative and platelet antiaggregant that also lowers the platelet count, can control thrombocytosis. A reduction in platelet number may be necessary in the treatment of erythromelalgia if salicylates are not effective or if the thrombocytosis is associated with migraine-like symptoms. However, the highest priority for treatment is reduction of the red cell mass to normal. Alkylating agents and ^{32}P are leukemogenic in polycythemia vera, and their use should be avoided. If a cytotoxic agent must be used, hydroxyurea is preferred, but it also may be leukemogenic with chronic use. Chemotherapy should be used for as short a time as possible. In some patients, massive splenomegaly unresponsive to reduction by hydroxyurea or IFN-a therapy and associated with intractable weight loss will require splenectomy. Allogeneic bone marrow transplantation may be effective in young patients.

Patients with polycythemia vera can be expected to live long and useful lives when their red cell mass is effectively managed with phlebotomy. Chemotherapy is never indicated to control the red cell mass unless venous access is impossible.

IDIOPATHIC MYELOFIBROSIS

Idiopathic myelofibrosis (other designations include *agnogenic myeloid metaplasia* or *myelofibrosis with myeloid metaplasia*) is a clonal disorder of a multipotent hematopoietic progenitor cell of unknown etiology characterized by marrow fibrosis, myeloid metaplasia with extramedullary hematopoiesis, and splenomegaly. Idiopathic myelofibrosis is uncommon; in the absence of a specific clonal marker, establishing this

diagnosis is difficult because myelofibrosis and myeloid metaplasia with splenomegaly are also features of both polycythemia vera andCML. Furthermore, myelofibrosis and splenomegaly occur in a variety of benign and malignant disorders (Table 110-3), many of which are amenable to specific therapies not effective in idiopathic myelofibrosis. In contrast to the other chronic myeloproliferative disorders and so-called acute or malignant myelofibrosis, which can occur at any age, idiopathic myelofibrosis primarily afflicts individuals in their sixth decade or later.

ETIOLOGY

The etiology of idiopathic myelofibrosis is unknown. Although nonrandom chromosome abnormalities such as 20q-, 13q-, and trisomy 1q are not uncommon, no specific cytogenetic abnormality has been identified. The degree of myelofibrosis and the extent of extramedullary hematopoiesis are not related. This disorder is associated with overproduction of type III collagen, a finding that has been attributed to platelet-derived growth factor or transforming growth factorb, but no proof has been forthcoming. Importantly, fibroblasts in idiopathic myelofibrosis are not part of the neoplastic clone.

CLINICAL FEATURES

No specific signs or symptoms are associated with idiopathic myelofibrosis. Most patients are asymptomatic at presentation and are usually detected by the discovery of splenic enlargement and/or abnormal blood counts during a routine examination. A blood smear reveals the characteristic features of extramedullary hematopoiesis: teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes; myeloblasts may also be present but have no prognostic significance. Anemia, usually mild initially, is the rule, while the leukocyte and platelet counts are either normal or increased but either can be depressed. Mild hepatomegaly may accompany the splenomegaly, and both the lactate dehydrogenase and serum alkaline phosphatase levels can be elevated. The level of leukocyte alkaline phosphatase can be low, normal, or elevated. Marrow may be unaspirable due to the myelofibrosis, and bone x-rays may reveal osteosclerosis. Exuberant extramedullary hematopoiesis can cause ascites, pulmonary hypertension, intestinal or ureteral obstruction, intracranial hypertension, pericardial tamponade, spinal cord compression, or skin nodules. Splenic enlargement can be sufficiently rapid to cause splenic infarctions with fever and pleuritic chest pain. Hyperuricemia and secondary gout may ensue.

DIAGNOSIS

While the clinical picture described above is characteristic of idiopathic myelofibrosis, all of the clinical features described can be observed in polycythemia vera orCML. Massive splenomegaly commonly masks erythrocytosis in polycythemia vera, and reports of intraabdominal thromboses in idiopathic myelofibrosis likely represent instances of unrecognized polycythemia vera. Furthermore, many other disorders have features that overlap with idiopathic myelofibrosis but respond to distinctly different therapies. Therefore, the diagnosis of idiopathic myelofibrosis is one of exclusion, which requires that the disorders listed inTable 110-3 be ruled out.

The presence of teardrop-shaped red cells, nucleated red cells, myelocytes, and

promyelocytes establishes the presence of extramedullary hematopoiesis; the presence of leukocytosis, thrombocytosis with large and bizarre platelets, as well as circulating myeloblasts suggests the presence of a myeloproliferative disorder as opposed to a secondary form of myelofibrosis (Table 110-3). Marrow is usually not aspirable due to increased marrow reticulin, but marrow biopsy will reveal a hypercellular marrow with trilineage hyperplasia and, in particular, increased megakaryocytes, but there are no characteristic morphologic abnormalities that distinguish idiopathic myelofibrosis from the other chronic myeloproliferative disorders. Splenomegaly due to extramedullary hematopoiesis may be sufficiently massive to cause portal hypertension and variceal formation. In some patients, exuberant extramedullary hematopoiesis can dominate the clinical picture. An intriguing feature of idiopathic myelofibrosis is the occurrence of autoimmune abnormalities such as immune complexes, antinuclear antibodies, rheumatoid factor, or a positive Coombs' test. Whether these represent a host reaction to the disorder or are involved in its pathogenesis is unknown. Cytogenetic analysis of blood or marrow is useful both to exclude CML and for prognostic purposes, because complex karyotype abnormalities portend a poor prognosis in idiopathic myelofibrosis.

COMPLICATIONS

Idiopathic myelofibrosis is a chronic disorder but with a median survival of only 5 years (range 1 to 15 years), a duration much shorter than for polycythemia vera or essential thrombocytosis. The natural history of idiopathic myelofibrosis is one of inexorable marrow failure with transfusion-dependent anemia and increasing organomegaly. Patients are prone to deep-seated tissue infections, particularly of the lungs. As with CML, idiopathic myelofibrosis can evolve from a chronic phase to an accelerated phase with constitutional symptoms and increasing marrow failure. About 10% of patients develop an aggressive form of acute leukemia for which therapy is usually ineffective. Important prognostic factors for disease acceleration include anemia; thrombocytopenia; age; the presence of complex cytogenetic abnormalities; and constitutional symptoms such as unexplained fever, night sweats, or weight loss. Any nonrandom cytogenetic abnormality is associated with a shortened life span, and the presence or development of multiple cytogenetic abnormalities is highly indicative of disease acceleration.

TREATMENT

There is no specific therapy for idiopathic myelofibrosis. Anemia may be exacerbated by deficiency of folic acid or iron, and in rare instances, pyridoxine therapy has been effective. However, anemia is more often due to ineffective erythropoiesis not compensated for by the extramedullary hematopoiesis in the spleen and liver; neither androgens nor erythropoietin has been consistently effective therapy. Erythropoietin may worsen splenomegaly. A red cell splenic sequestration study can establish the presence of hypersplenism, for which splenectomy is indicated. Splenectomy may also be necessary if splenomegaly impairs alimentation and should be performed before cachexia sets in. In this situation, splenectomy should not be avoided because of concern over rebound thrombocytosis, loss of hematopoietic capacity, or compensatory hepatomegaly. However, for unexplained reasons, splenectomy increases the risk of blastic transformation. Allopurinol can control significant hyperuricemia and hydroxyurea has proved useful for controlling organomegaly. The role of interferon-a is undefined,

and its side effects are more pronounced in the older individuals who are affected with this disorder, but reversal of myelofibrosis has been observed. Glucocorticoids are used to control autoimmune complications. Allogeneic bone marrow transplantation should be considered in younger patients.

ESSENTIAL THROMBOCYTOSIS

Essential thrombocytosis (other designations include *essential thrombocythemia*, *idiopathic thrombocytosis*, *primary thrombocytosis*, *hemorrhagic thrombocythemia*) is a clonal disorder of unknown etiology involving a multipotent hematopoietic progenitor cell and is manifested clinically by the overproduction of platelets without a definable cause. Essential thrombocytosis is an uncommon disorder, but its exact frequency is unknown. No clonal marker distinguishes it from the more common nonclonal, reactive forms of thrombocytosis (Table 110-4). Clinical recognition of thrombocytosis is unlikely in the largely asymptomatic persons affected by this disorder. As a consequence, essential thrombocytosis was formerly considered to be a disease of the elderly and to be responsible for significant morbidity due to hemorrhage or thrombosis. However, with the widespread application of platelet counting, it is now clear that essential thrombocytosis can occur at any age in adults and often occurs without symptoms or disturbances of hemostasis. There is an unexplained female predominance, in contrast to the reactive forms of thrombocytosis where no sex bias exists. Because no clonal marker is available for the disorder, clinical criteria have been proposed to distinguish it from the other chronic myeloproliferative disorders, which may also present with thrombocytosis but have distinct prognosis and treatment (Table 110-5). These criteria do not establish clonality; therefore, they are truly useful only in identifying disorders such asCML, polycythemia vera, or myelodysplasia, which can masquerade as essential thrombocytosis, as opposed to establishing the presence of essential thrombocytosis. Furthermore, as with "primary" erythrocytosis, nonclonal, benign forms of thrombocytosis exist (such as hereditary overproduction of thrombopoietin) that are not widely recognized because we currently lack the diagnostic tools to do so.

ETIOLOGY

Megakaryocytopoiesis and platelet production depend upon thrombopoietin and its receptor, Mpl. As in the case of early erythroid and myeloid progenitor cells, early megakaryocytic progenitors require the presence of interleukin (IL) 3 and stem cell factor for optimal proliferation, and their subsequent development is enhanced by IL-6 and -11. However, megakaryocyte maturation and differentiation require thrombopoietin.

Megakaryocytes are unique amongst hematopoietic progenitor cells because they undergo endomitotic as opposed to mitotic reduplication of their genome. In the absence of thrombopoietin, endomitotic megakaryocytic reduplication and, by extension, the cytoplasmic development necessary for platelet production are impaired. Like erythropoietin, thrombopoietin is produced in both the liver and the kidneys, and an inverse correlation between the platelet count and plasma thrombopoietic activity exists. Like erythropoietin, plasma levels of thrombopoietin are controlled in part by the size of its progenitor cell pool. In contrast to erythropoietin, but like its myeloid counterparts granulocyte and granulocyte-macrophage colony stimulating factors, thrombopoietin not only enhances the proliferation of its target cells but also enhances the reactivity of their

end-stage product, the platelet. In addition to its role in thrombopoiesis, thrombopoietin enhances the survival of multipotent hematopoietic stem cells.

The clonality of essential thrombocytosis has been established by the use of the isoenzymes of glucose-6-phosphate dehydrogenase in patients who are hemizygous for this gene, by the use of X-linked DNA polymorphisms, and by the identification of nonrandom, although variable cytogenetic abnormalities. The multipotent hematopoietic progenitor cell involved in this disorder can vary; in some patients lymphocytes contained the same clonal marker as the megakaryocytes, erythrocytes, and myeloid cells, whereas in others the lymphocytes were not involved. Similar observations have been made in polycythemia vera. Furthermore, a number of families have been described in which essential thrombocytosis was inherited, in one instance as an autosomal dominant trait. In one kindred, in addition to essential thrombocytosis, idiopathic myelofibrosis and polycythemia vera were also individually documented.

CLINICAL FEATURES

Clinically, essential thrombocytosis is most often identified incidentally when a platelet count is obtained during the course of a routine evaluation. Occasionally, review of previous platelet counts will reveal that an elevation was present but overlooked. No symptoms or signs are specific for essential thrombocytosis, but patients do have hemorrhagic and thrombotic tendencies expressed as easy bruising for the former or microvascular occlusions for the latter, which may be manifested by erythromelalgia, migraine, or transient ischemic attacks. Physical examination is generally unremarkable except for the presence of mild splenomegaly. Massive splenomegaly is more characteristic of the other myeloproliferative disorders, particularly polycythemia vera or idiopathic myelofibrosis.

Anemia is unusual, but a mild neutrophilic leukocytosis is not. The blood smear, however, is most remarkable for the number of platelets present, some of which may be very large. The leukocyte alkaline phosphatase score is either normal or elevated. The large mass of circulating platelets may prevent the accurate measurement of serum potassium due to the release of platelet potassium upon blood clotting. This hyperkalemia is a laboratory artifact and is not associated with any electrocardiographic abnormalities. Similarly, arterial oxygen measurements can be inaccurate unless the blood is collected on ice. The prothrombin and partial thromboplastin times are normal, while abnormalities of platelet function such as a prolonged bleeding time and impaired platelet aggregation can be present. However, in spite of much study, characteristic platelet function abnormalities associated are not defined, and no platelet function test predicts the presence of clinically significant bleeding or thrombosis.

The elevated platelet count may hinder the collection of a marrow aspirate, but marrow biopsy usually reveals both megakaryocyte hyperplasia and hypertrophy, as well as an overall increase in marrow cellularity. An increase in marrow reticulin may be present, but if extensive, another diagnosis should be considered. The absence of stainable iron demands an explanation, because iron deficiency alone can cause thrombocytosis and absent marrow iron is a feature of polycythemia vera.

While nonrandom cytogenetic abnormalities have been identified in essential

thrombocytosis, no consistently identifiable abnormality is noted, even involving chromosomes 3 and 1 where the genes for thrombopoietin and its receptor Mpl, respectively, are located.

DIAGNOSIS

Thrombocytosis is encountered in a variety of clinical disorders (Table 110-4) in which production of cytokines is increased. Thus, the first obligation when confronted with a high platelet count is to determine if it is a consequence of another disorder. Cytogenetic evaluation is mandatory to determine if the thrombocytosis is due toCML or a myelodysplastic disorder such as the 5q-syndrome. Because the bcr-abl translocation can be present in the absence of the Ph chromosome, polymerase chain reaction analysis for bcr-abl expression should be performed in all patients with thrombocytosis in whom a cytogenetic study is normal. Anemia and ringed sideroblasts are not features of essential thrombocytosis, but they are features of idiopathic refractory sideroblastic anemia, in which thrombocytosis can also occur. The presence of massive splenomegaly should suggest the possibility of another myeloproliferative disorder, and in this setting a red cell mass determination is mandatory because substantial splenomegaly can mask the presence of erythrocytosis. What appears to be essential thrombocytosis can evolve into polycythemia vera, revealing the true nature of the underlying myeloproliferative disorder.

COMPLICATIONS

Perhaps no other condition in clinical medicine has caused otherwise astute physicians to intervene inappropriately more often than thrombocytosis, particularly if the platelet count is greater than 1 ´10^6/uL. It is commonly believed that a high platelet count must cause intravascular stasis and thrombosis; however, no controlled clinical study has ever established either association.

To the contrary, very high platelet counts are associated primarily with hemorrhage, while platelet counts of <1´10^6/uL are more often associated with thrombosis. This is not meant to imply that an elevated platelet count cannot cause symptoms in a patient with essential thrombocytosis, but rather that the focus should be on the patient, not the platelet count. For example, some of the most dramatic neurologic problems in essential thrombocytosis are migraine-related but may respond only to lowering of the platelet count; other symptoms may be a manifestation of erythromelalgia and respond simply to platelet cyclooxygenase inhibitors such as aspirin, without a reduction in platelet number. Still others may represent an interaction between an atherosclerotic vascular system and a high platelet count, and others may have no relationship to the platelet count whatsoever. Progress in distinguishing essential thrombocytosis from polycythemia vera and in defining new causes of hypercoagulability (like factor V Leiden) make the older literature on thrombocytosis less reliable.

TREATMENT

An elevated platelet count in an asymptomatic patient requires no therapy, and before any therapy is initiated in a patient with thrombocytosis, the cause of symptoms must be clearly identified to be a consequence of the elevated platelet count. Plasmapheresis

and cytotoxic therapy have never been proven efficacious and cannot be recommended. Furthermore, patients with essential thrombocytosis treated with ^{32}P, hydroxyurea, or alkylating agents are placed at risk of developed acute leukemia without any proof of benefit from such therapy. If platelet reduction is deemed necessary on the basis of neurologic symptoms refractory to salicylates, IFN-aor anagrelide, a quinazolin derivative, can reduce the platelet count, but neither is uniformly effective nor without significant side effects. Bleeding associated with thrombocytosis usually responds toe-aminocaproic acid, which can be given prophylactically before and after elective surgery. As more clinical experience is acquired, it appears that essential thrombocytosis is more benign than previously thought, and that evolution to acute leukemia is more likely to be a consequence of prior therapy than of the disease itself. In managing patients with thrombocytosis, the physician's first obligation is to do no harm.

111. ACUTE AND CHRONIC MYELOID LEUKEMIA - *Meir Wetzler*, *John C. Byrd*, *Clara D. Bloomfield*

The myeloid leukemias are a heterogeneous group of diseases characterized by infiltration of the blood, bone marrow, and other tissues by neoplastic cells of the hematopoietic system. In 2000, the estimated number of new myeloid leukemia cases in the United States was 10,100. These leukemias comprise a spectrum of malignancies that, untreated, range from rapidly fatal to slowly growing. Based on their untreated course, the myeloid leukemias have traditionally been designated *acute* or *chronic*.

ACUTE MYELOID LEUKEMIA

INCIDENCE

The incidence of acute myeloid leukemia (AML) is approximately 2.3 per 100,000 people per year, and the age-adjusted incidence is higher in men than in women (2.9 versus 1.9). AML incidence increases with age; it is 1.3 in individuals younger than 65 years and 12.2 in those older than 65. No significant change in AML incidence has occurred over the past 20 years.

ETIOLOGY

Heredity, radiation, chemical and other occupational exposures, and drugs have been implicated in the development ofAML. No direct evidence suggests a viral etiology.

Heredity Certain syndromes with somatic cell chromosome aneuploidy, e.g., Down (chromosome 21 trisomy), Klinefelter (XXY and variants), and Patau (chromosome 13 trisomy), are associated with an increased incidence ofAML. Inherited diseases with excessive chromatin fragility, e.g., Fanconi anemia, Bloom syndrome, ataxia telangiectasia, and Kostmann syndrome, are also associated with AML.

Radiation Survivors of the atomic bomb explosions in Japan had an increased incidence of myeloid leukemias that peaked 5 to 7 years after exposure. Therapeutic radiation alone seems to add little risk of AML but can increase the risk in people exposed to alkylating agents (see below).

Chemical and Other Exposures Exposure to benzene, which is used as a solvent in the chemical, plastic, rubber, and pharmaceutical industries, is associated with an increased incidence of AML. Smoking and exposure to petroleum products, paint, embalming fluids, ethylene oxide, herbicides, and pesticides, have also been associated with an increased risk of AML.

Drugs Anticancer drugs are the leading cause of treatment-associatedAML. Alkylating agent-associated leukemias occur on average 4 to 6 years after exposure, and affected individuals have aberrations in chromosomes 5 and 7. Topoisomerase II inhibitor-associated leukemias occur 1 to 3 years after exposure, and affected individuals usually have aberrations involving chromosome 11q23. Chloramphenicol, phenylbutazone, and, less commonly, chloroquine and methoxypsoralen can result in bone marrow failure that may evolve into AML.

CLASSIFICATION

The categorization of acute leukemia into biologically distinct groups is based on morphology, cytochemistry, and immunophenotype as well as cytogenetic and molecular techniques.

Morphologic and Cytochemical Classification The diagnosis ofAML is established by the presence of >20% myeloblasts in blood and/or bone marrow. Myeloblasts have nuclear chromatin that is uniformly fine or lacelike in appearance and large nucleoli (two to five per cell). If specific cytoplasmic granules, Auer rods, or the nuclear folding and clefting characteristic of monocytoid cells are not present, the morphologic features observed under light microscopy may not be sufficient to clarify the diagnosis. A positive myeloperoxidase reaction in >3% of the blasts may be the only feature distinguishing AML from acute lymphoblastic leukemia (ALL).

AMLis classified based on morphology and cytochemistry according to the French, American, and British (FAB) schema, which includes eight major subtypes, M0 to M7 (Table 111-1). The World Health Organization classification incorporates molecular (including cytogenetic), morphologic, and clinical features (such as prior hematologic disorder) in defining disease entities (Table 111-1).

Immunophenotypic Classification The phenotype of human myeloid leukemia cells can be studied by multiparameter flow cytometry after the cells are labeled with monoclonal antibodies to cell-surface antigens. For example, M0, which is characterized by immature morphology and no lineage-specific cytochemical reactions, is diagnosed by flow cytometric demonstration of the myeloid-specific antigens cluster designation (CD) 13 or 33. Similarly, M7 can often be diagnosed only by expression of the platelet-specific antigen CD41 or by electron-microscopic demonstration of myeloperoxidase.

Chromosomal Classification Chromosomal analysis of the leukemic cell provides the most important pretreatment prognostic information inAML. Only two cytogenetic abnormalities have been invariably associated with a specificFABgroup: t(15;17)(q22;q12) with M3 and inv(16)(p13q22) with M4Eo. However, many chromosomal abnormalities have been associated primarily with one FAB group, including t(8;21)(q22;q22) with M2, and t(9;11)(p22;q23), and other translocations involving 11q23, with M5. Many of the recurring chromosomal abnormalities in AML have been associated with specific clinical characteristics. More commonly associated with younger age are t(8;21) and t(15;17), and with older age, del(5q) and del(7q). Granulocytic sarcomas are associated with t(8;21); disseminated intravascular coagulation (DIC) with t(15;17); and diabetes insipidus, fever, and infection all with monosomy 7. The reasons for most associations of chromosomal abnormalities with specific clinical features are unknown.

Molecular Classification The many recurring cytogenetic abnormalities led to molecular studies, which have revealed genes that may be involved in leukemogenesis. The 15;17 translocation, characteristic of M3, encodes a chimeric protein, Pml/Rara, which is formed by the fusion of the retinoic acid receptor-a(*RAR*a) gene from

chromosome 17 and the promyelocytic leukemia (*PML*) gene from chromosome 15. The *RAR*a gene encodes a member of the nuclear hormone receptor family of transcription factors. After binding retinoic acid, *RAR*a can promote expression of a variety of genes. The 15;17 translocation juxtaposes *PML* with *RAR*a in a head-to-tail configuration that is under the transcriptional control of *PML*. Three different breakpoints in the *PML* gene lead to various fusion proteins. The Pml-Rara fusion protein tends to suppress gene transcription and blocks differentiation of the cells. Pharmacologic doses of the Rara ligand, all-trans-retinoic acid (tretinoin or ATRA), relieve the block and promote differentiation (see below).

The inv(16), characteristic of M4Eo orAML with abnormal bone marrow eosinophils, and the t(8;21) characteristic of M2 both involve subunits of the transcription factor complex core-binding factor (Cbf), also known as polyomavirus enhancer binding protein 2. This transcription factor contains two subunits, an a subunit, the Am11 protein, and a b subunit, the Pebp2 protein, and is involved in the expression of a number of differentiation-dependent genes in myeloid cells. The inv(16) results in a fusion of the core-binding factorb (*CBFB*) gene on the q arm (encodes Pebp2 protein) and the myosin heavy chain (*MYH11*) gene on the p arm. The 8;21 translocation involves the core-binding factor a(*CBFA*) gene on chromosome 21, called the *AML1* gene, joining the *ETO* gene on chromosome 8. Similar to the t(15;17) gene product, the Aml1/Eto protein acts to block transcription of *CBFA*-*CBFB*-controlled genes.

Most translocations that involve 11q23 rearrange the *MLL* (myeloid-lymphoid or mixed-lineage leukemia) gene. The *MLL* gene has two regions that encompass multiple zinc fingers and has at least two additional potential DNA-binding motifs. Abnormalities in the *MLL* gene are relatively common in patients with AMLwho do not have 11q23 rearrangements cytogenetically.

These molecular aberrations are increasingly being used for diagnosis and detection of residual disease after treatment.

CLINICAL PRESENTATION

Symptoms Patients withAML most often present with nonspecific symptoms that begin gradually or abruptly and are the consequence of anemia, leukocytosis, leukopenia or leukocyte dysfunction, or thrombocytopenia. Nearly half have had symptoms for 3 months or more before the leukemia is diagnosed.

Half mention fatigue as the first symptom, but most complain of fatigue or weakness at the time of diagnosis. Anorexia and weight loss are common. Fever with or without an identifiable infection is the initial symptom in ~10% of patients. Signs of abnormal hemostasis (bleeding, easy bruising) are noted first in 5% of patients. On occasion, bone pain, lymphadenopathy, nonspecific cough, headache, or diaphoresis is the presenting symptom.

Rarely patients may present with symptoms from a mass lesion located in the soft tissues, breast, uterus, ovary, cranial or spinal dura, gastrointestinal tract, lung, mediastinum, prostate, bone, or other organs. The mass lesion represents a tumor of leukemic cells and is called a *granulocytic sarcoma*, or *chloroma*. TypicalAML may

occur simultaneously, later, or not at all in these patients. This rare presentation is more common in patients with 8;21 translocations.

Physical Findings Fever, splenomegaly, hepatomegaly, lymphadenopathy, sternal tenderness, and evidence of infection and hemorrhage are often found at diagnosis. Significant gastrointestinal bleeding, intrapulmonary hemorrhage, or intracranial hemorrhage occur most often in M3AML. Bleeding associated with coagulopathies may also occur in M5 AML and with extreme degrees of leukocytosis or thrombocytopenia in otherFABsubtypes. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingivae, skin, soft tissues, or the meninges with leukemic blasts at diagnosis is characteristic of the monocytic subtypes (M4 and M5).

Hematologic Findings Anemia is usually present at diagnosis and can be severe. The degree varies considerably irrespective of other hematologic findings, splenomegaly, or the duration of symptoms. The anemia is usually normochromic normocytic. Decreased erythropoiesis often results in a reduced reticulocyte count, and erythrocyte survival is decreased by accelerated destruction. Active blood loss also contributes to the anemia.

The median presenting leukocyte count is about 15,000/uL. Twenty-five to 40% of patients have counts <5000/uL, and 20% have counts>100,000/uL. Fewer than 5% have no detectable leukemic cells in the blood. Poor neutrophil function may be noted functionally by impaired phagocytosis and migration and morphologically by abnormal lobulation and deficient granulation.

Platelet counts<100,000/uL are found at diagnosis in ~75% of patients, and about 25% have counts <25,000/uL. Both morphologic and functional platelet abnormalities can be observed, including large and bizarre shapes with abnormal granulation and inability of platelets to aggregate or adhere normally to one another.

Pretreatment Evaluation Once the diagnosis ofAML is suspected, a rapid evaluation and initiation of appropriate therapy should follow (Table 111-2). In addition to clarifying the subtype of leukemia, initial studies should evaluate the overall functional integrity of the major organ systems, including the cardiovascular, pulmonary, hepatic, and renal systems. Factors that have prognostic significance, either for achieving complete remission (CR) or for predicting the duration of CR, should also be assessed before initiating treatment. Leukemic cells should be obtained from all patients and cryopreserved for future use as new tests become available. All patients should be evaluated for infection.

Most patients are anemic and thrombocytopenic at presentation. Replacement of the appropriate blood components, if necessary, should begin promptly. Because qualitative platelet dysfunction or the presence of an infection may increase the likelihood of bleeding, evidence of hemorrhage justifies the immediate use of platelet transfusion, even if the platelet count is only moderately decreased.

About 50% of patients have a mild to moderate elevation of serum uric acid at presentation. Only 10% have marked elevations, but renal precipitation of uric acid and the nephropathy that may result is a serious but uncommon complication. The initiation of chemotherapy may aggravate hyperuricemia, and patients are usually immediately

started on allopurinol and hydration at diagnosis. Finally, the presence in high concentrations of lysozyme, a marker for monocytic differentiation, may be etiologic in renal tubular dysfunction, which could worsen other renal problems that arise during the initial phases of therapy.

PROGNOSTIC FACTORS

The single most important prognostic factor is attainment ofCR. CR is defined after examination of both blood and bone marrow and should last³4 weeks. The blood neutrophil count must be³1500/uL and the platelet count³100,000/uL. Hemoglobin concentration or hematocrit are not considered in determining CR. Circulating blasts should be absent. While rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. Bone marrow cellularity should be >20% with trilineage maturation. The bone marrow should contain <5% blasts, and Auer rods should be absent. Extramedullary leukemia should not be present. For patients in CR, reverse transcriptase polymerase chain reaction (RT-PCR) to detectAML-associated molecular abnormalities, and fluorescence in situ hybridization (FISH) to detect AML-associated cytogenetic aberrations are currently used to detect residual disease. Such detection of minimal residual disease may become a reliable discriminator between patients in CR who do or do not require additional and/or alternative therapies.

Many factors influence the likelihood of enteringCR, the length of CR, and the curability ofAML. Prognostic factors are influenced by the treatment used. Age at diagnosis remains among the most important pretreatment risk factors, with>60 years being associated with a poorer prognosis primarily because of its influence on the patient's ability to survive induction therapy and thus achieve CR. Chronic and intercurrent diseases impair tolerance to rigorous therapy; acute medical problems at diagnosis reduce the likelihood of survival. Performance status, independent of age, also influences ability to survive induction therapy and thus respond to treatment. Age may also influence outcome because AML in older patients differs biologically. The leukemic cells in elderly patients more commonly express CD34 and the mdr1 efflux pump that conveys resistance to natural product-derived agents such as the anthracyclines (see below). With each successive decade of age, a greater proportion of patients have more resistant disease.

Chromosome findings at diagnosis are an independent prognostic factor. Patients with t(8;21), inv(16), or t(15;17) have extremely good prognoses, while those with no cytogenetic abnormality have a moderately favorable outcome when treated with high-dose cytarabine. Patients with del(5q), -7, and abnormalities involving 12p have a very poor prognosis. Patients with certain abnormalities, such as inv(3), rarely achieveCR with standard induction chemotherapy.

A prolonged symptomatic interval with cytopenias preceding diagnosis or a history of an antecedent hematologic disorder are other pretreatment clinical features that are associated with a lowerCR rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >1 month before the diagnosis of AML when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder(s)

increases. SecondaryAMLdeveloping after treatment with cytotoxic agents and/or irradiation for other malignancies is extremely difficult to treat successfully.

A high presenting leukocyte count is an independent prognostic factor; duration ofCR is inversely related to the presenting leukocyte count or absolute circulating myeloblast count. Among patients with hyperleukocytosis (>100,000/uL), early central nervous system bleeding and pulmonary leukostasis and late relapse contribute to poor outcome.

TheFABclassification diagnosis has been found to be an independent prognostic factor in some series. Other characteristics of the leukemic cell have been reported to have prognostic significance, including Auer rods, ultrastructural features, in vitro and in vivo growth characteristics and chemotherapeutic sensitivity, and immunophenotype. Expression of the *MDR1* gene adversely influences outcome. This gene encodes a protein that actively pumps out a variety of lipophilic compounds (e.g., anthracyclines) from the cell.

In addition to pretreatment variables, several treatment factors have been reported to correlate with prognosis inAML, in particular withCRduration. One is the rapidity with which the blast cells disappear from the blood after the institution of therapy. In addition, patients who achieve CR after one induction cycle have longer CR than those requiring multiple cycles.

TREATMENT

Treatment of the newly diagnosed patient withAML is usually divided into two phases, induction and postremission management (Fig. 111-1). The initial goal is to quickly induceCR. Once CR is obtained, further therapy must be used to prolong survival.

Induction Chemotherapy The most commonly usedCRinduction regimens (for patients with allFABsubtypes except M3) consist of combination chemotherapy with cytarabine (cytosine arabinoside) and an anthracycline. Cytarabine is a cell cycle S-phase-specific antimetabolite that becomes phosphorylated to an active triphosphate form that interferes with DNA synthesis. Anthracyclines are DNA intercalaters. Their primary mode of action is thought to be inhibition of topoisomerase II, leading to DNA breaks. Cytarabine is usually administered as a continuous intravenous infusion at 100 to 200 mg/m^{2}per day for 7 days. Anthracycline therapy generally consists of daunorubicin, 45 mg/m^{2}intravenously on days 1, 2, and 3 (*the 7 and 3 regimen*). Treatment with idarubicin at 12 or 13 mg/m^{2}per day for 3 days in conjunction with cytarabine by 7-day continuous infusion is at least as effective and may be superior to daunorubicin in younger patients. The addition of etoposide or other agents does not increase the CR rate but may improve the CR duration.

After induction chemotherapy, the bone marrow is examined to determine if the leukemia has been eliminated. If >5% blasts exist with^{3}20% cellularity, the patient has traditionally been retreated with cytarabine and an anthracycline in doses similar to those given initially, but for 5 and 2 days, respectively. Our recommendation, however, is to consider changing therapy in this setting. Patients who fail to attainCR after two induction courses should immediately proceed to an allogeneic stem cell transplant

(SCT) if an appropriate donor exists.

With the 7 and 3 cytarabine/daunorubicin regimen outlined above, 65 to 75% of adults with de novoAMLachieveCR. Two-thirds achieve CR after a single course of therapy, and one-third require two courses. About 50% of patients who do not achieve CR have a drug-resistant leukemia, and 50% do not achieve CR because of fatal complications of bone marrow aplasia or impaired recovery of normal stem cells.

High-dose cytarabine-based regimens have very highCR rates after a single cycle of therapy. When given in high doses, more cytarabine may enter the cells, saturate the cytarabine-inactivating enzymes, and increase the intracellular levels of 1-b-D-arabinofuranylcytosine-triphosphate, the active metabolite incorporated into DNA. Thus, higher doses of cytarabine may increase the inhibition of DNA synthesis and thereby overcome resistance to standard-dose cytarabine. In two randomized studies, one by the Southwest Oncology Group (SWOG) and one by the Australian Leukemia Study Group (ALSG), high-dose cytarabine with an anthracycline produced CR rates similar to those achieved with standard 7 and 3 regimens. However, the ALSG demonstrated that the CR duration was much longer after high-dose cytarabine than after standard-dose cytarabine.

The hematologic toxicity of high-dose cytarabine-based induction regimens has typically been greater than that associated with 7 and 3 regimens. Toxicity with high-dose cytarabine includes myelosuppression, pulmonary toxicity, and significant and occasionally irreversible cerebellar toxicity. All patients treated with high-dose cytarabine must be closely monitored for cerebellar toxicity. Full cerebellar testing should be performed before each dose, and further high-dose cytarabine should be withheld if evidence of cerebellar toxicity develops.

Supportive Care Measures geared to supporting patients through several weeks of granulocytopenia and thrombocytopenia are critical to the success ofAMLtherapy. Patients with AML should be treated in centers expert in providing supportive measures for their management.

Recombinant hematopoietic growth factors have been incorporated into clinical trials inAML. These trials have been designed to lower the infection rate after chemotherapy or to sensitize (prime) the leukemic blasts to chemotherapy, or both. Both granulocyte colony stimulating factor (G-CSF) and granulocyte-macrophage colony stimulating factor (GM-CSF) have reduced the median time to neutrophil recovery by an average of 5 to 7 days. This accelerated rate of neutrophil recovery, however, has not always translated into significant reductions in infection rates. In most randomized studies, both G-CSF and GM-CSF have failed to improve the CR rate, disease-free survival, or overall survival. Although receptors for both G-CSF and GM-CSF are present on AML blasts, therapeutic efficacy is neither enhanced nor inhibited by these agents. The use of growth factors as supportive care for AML patients is controversial. We favor their use in elderly patients, those receiving intensive regimens, patients with uncontrolled infections, or those participating in clinical trials.

Multilumen right atrial catheters should be inserted through a subcutaneous tunnel as soon as patients with newly diagnosedAML have been stabilized. They should be used

thereafter for administration of intravenous medications and transfusions, as well as for blood drawing. The separation between the vascular access site and the exit site and the presence of a Dacron cuff in the subcutaneous channel reduce the risk of infection. With meticulous attention to sterile technique in catheter placement and maintenance, catheters may often be left in place for months.

Adequate and prompt blood bank support is critical to therapy ofAML. Platelet transfusions should be given as needed to maintain a platelet count>10,000 to 20,000/uL. We believe that the platelet count should be kept at higher levels in febrile patients and during episodes of active bleeding orDIC. Patients with poor posttransfusion platelet count increments may benefit from administration of platelets from human leukocyte antigen (HLA)-matched donors. Red blood cell transfusions should be administered to keep the hemoglobin level>80 g/L (8 g/dL) in the absence of active bleeding or DIC. Blood products leukodepleted by filtration should be used to avert or delay alloimmunization as well as febrile reactions. Blood products should also be irradiated to prevent graft-versus-host disease (GVHD). Cytomegalovirus (CMV)-negative blood products should be used for CMV-seronegative patients who are potential candidates for allogeneicSCT. Leukodepleted products are also effective for these patients if CMV-negative products are not available.

Infectious complications remain the major cause of morbidity and death during induction and postremission chemotherapy forAML. Prophylactic administration of antibiotics in the absence of fever is controversial. Oral nystatin or clotrimazole are recommended to prevent localized candidiasis. For patients who are herpes simplex virus antibody titer-positive, acyclovir prophylaxis is effective in preventing reactivation of latent oral herpes infections.

Fever develops in most patients withAML, but infections are documented in only half of febrile patients. Early initiation of empiric broad-spectrum antibacterial and antifungal antibiotics has significantly reduced the number of patients dying of infectious complications (Chap. 85). An antibiotic regimen adequate to treat gram-negative and gram-positive organisms should be instituted at the onset of fever in a granulocytopenic patient after clinical evaluation, including a detailed physical examination with inspection of the indwelling catheter exit site and a perirectal examination, as well as procurement of cultures and radiographs aimed at documenting the source of fever. Specific antibiotic regimens should be based on antibiotic sensitivity data obtained from the institution at which the patient is being treated. Acceptable regimens include imipenem-cilastin, an antipseudomonal semisynthetic penicillin (e.g., piperacillin) combined with an aminoglycoside, a third-generation cephalosporin with antipseudomonal activity (i.e., ceftazidine or cefapime) or doubleb-lactam combinations (ceftazidine and piperacillin). Empiric vancomycin is not given initially in the absence of suspected gram-positive infection or mucositis. Aminoglycosides should be avoided if possible in patients with renal insufficiency. For patients with known immediate-type hypersensitivity reactions to penicillin, aztreonam may be substituted for b-lactams. Aztreonam should be combined with an aminoglycoside or a quinolone antibiotic rather than used alone. Empiric vancomycin should be initiated in neutropenic patients who remain febrile for 3 days, and amphotericin B is added at 7 days if fever persists. Liposomal amphotericin is at least equivalent to regular amphotericin for empiric antifungal treatment and has less renal toxicity. Antibacterial and antifungal antibiotics

should be continued until patients are no longer neutropenic, regardless of whether a specific source has been found for the fever.

Treatment of Promyelocytic Leukemia ATRA is an oral drug that induces the differentiation of leukemic cells bearing the t(15;17); it is not effective in other forms ofAML. Acute promyelocytic leukemia is responsive to cytarabine and daunarubicin, but about 10% of patients treated with these drugs die fromDICinduced by the release of granule components by dying tumor cells. ATRA does not produce DIC but produces another complication called the retinoic acid syndrome. Occurring within the first 3 weeks of treatment, it is characterized by fever, dyspnea, chest pain, pulmonary infiltrates, pleural and pericardial effusions, and hypoxia. The syndrome is related to the adhesion of differentiated neoplastic cells in the pulmonary vasculature. Glucocorticoids, chemotherapy, and/or supportive measures can be effective. About 10% of patients die from this syndrome.

ATRA (45 mg/$m_2$per day orally until remission is documented) plus concurrent chemotherapy (7 and 3) appears to be the safest and most effective treatment for acute promyelocytic leukemia. Unlike patients with other types ofAML, patients with this subtype may benefit from maintenance therapy with either ATRA or chemotherapy. The optimal regimen is being sought in clinical studies.

Arsenic trioxide produces meaningful responses in patients refractory to ATRA.

The detection of minimal residual disease byRT-PCRamplification of the t(15;17) chimeric gene product appears to predict relapse. Disappearance of the signal is associated with long-term disease-free survival; its persistence predicts relapse. With increases in the sensitivity of the assay, some patients with persistent abnormal gene product have been found who do not suffer a relapse. It is not known whether there is a critical threshold level of transcripts that predicts for leukemia relapse.

Postremission Therapy Induction of a durable firstCR is critical to long-term disease-free survival inAML. Without further therapy virtually all patients experience relapse. Once relapse has occurred, AML is generally curable only bySCT.

Postremission therapy is designed to eradicate any residual leukemic cells. Therefore, it should prevent relapse and prolong survival. Approaches to postremission therapy in AMLinclude intensive chemotherapy and allogeneic or autologousSCT. In patients older than 65 years, such therapy is of uncertain benefit. High-dose cytarabine is more effective than standard-dose cytarabine. The Cancer and Leukemia Group B, for example, compared the duration ofCR in patients randomly assigned postremission to four cycles of high (3 g/$m_2$every 12 h on days 1, 3, and 5), intermediate (400 mg/$m_2$for 5 days by continuous infusion), or standard (100 mg/$m_2$per day for 5 days by continuous infusion) doses of cytarabine. A dose-response effect for cytarabine in patients with AML who were age 60 years or younger was demonstrated. High-dose cytarabine significantly prolonged CR and increased the fraction cured in patients with favorable [t(8;21) and inv(16)] and normal cytogenetics, but it had no significant effect on patients with other abnormal karyotypes.

Allogeneic and autologousSCT in first CRhas been studied extensively in younger

patients with no major organ dysfunction. Allogeneic SCT is used in patients <55 years with an HLA-compatible donor. Relapse with this therapy occurs in only a small fraction of patients, but toxicity is relatively high from treatment; complications include veno-occlusive disease,GVHD, and infections. Autologous transplantation can be used in young and older patients and uses the same type of high-dose therapy. Patients subsequently receive their own stem cells collected while in remission. The toxicity is lower with autologous SCT (5% mortality rate), but the relapse rate is higher than with allogeneic SCT. The increased relapse rate is due to the absence of the graft-vs-leukemia effect seen with allogeneic SCT and possible contamination of the autologous stem cells with tumor cells. Purging the autologous stem cells does not lower the relapse rate with autologous SCT.

Randomized trials comparing intensive therapy and autologous and allogeneicSCT have shown improved duration of remission with allogeneic SCT compared to autologous SCT or chemotherapy alone. However, overall survival is generally not different; the improved disease control with allogeneic SCT is erased by the increase in fatal toxicity. Prognostic factors may help select patients in firstCR for whom transplant is most effective.

Our approach includes strong consideration for allogeneicSCT in first CRfor patients with high risk karyotypes. Patients with normal karyotypes who have other poor risk factors (antecedent hematologic disorder, failure to attain remission with a single induction course, hyperleukocytosis,*MLL*gene abnormalities) are also potential candidates. If a suitable HLA donor does not exist, autologous SCT or novel therapeutic approaches are considered. Patients with t(8;21) and inv(16) are treated with repetitive doses of high-dose cytarabine, which offers a high frequency of cure without the morbidity of transplant.

Relapse Once relapse occurs after the standard induction and postremission chemotherapy approach described above and outlined in Fig. 111-1, patients are rarely cured with further standard-dose chemotherapy. Patients eligible for allogeneicSCTshould receive transplants expeditiously at the first sign of relapse. Long-term disease-free survival is approximately the same (30 to 50%) with allogeneic SCT in first relapse or in second remission. Autologous SCT rescues about 20% of relapsed patients with AML who have chemosensitive disease. The most important factors predicting response at relapse are the length of the previousCR, whether initial CR was achieved with one or two courses of chemotherapy, and the type of postremission therapy. Because of the poor outcome of patients in early (<12 months) first relapse, it is justified (for patients without HLA-compatible donors) to explore innovative approaches, such as new drugs or immunotherapies (Table 111-3). Patients with longer (>12 months) first CR generally relapse with drug-sensitive disease and may achieve a second remission with the original induction regimen. However, cure for these patients is uncommon, and treatment with novel approaches should be considered if SCT is not possible. It is not yet clear whether careful monitoring for residual disease byRT-PCR,FISH and quantitative PCR identifies patients destined to relapse who are more readily cured by salvage therapy given before overt clinical relapse.

CHRONIC MYELOID LEUKEMIA

INCIDENCE

The incidence of chronic myeloid leukemia (CML) is 1.3 per 100,000 people per year, and the age-adjusted incidence is higher in men than in women (1.7 versus 1.0). CML incidence decreased slightly between 1973 and 1991 (1.5 versus 1.3). The incidence of CML increases slowly with age until the middle forties, when it starts to rise rapidly.

DEFINITION

The diagnosis ofCML is established by identifying a clonal expansion of a hematopoietic stem cell possessing a reciprocal translocation between chromosomes 9 and 22. This translocation results in the head-to-tail fusion of the breakpoint cluster region (*BCR*) gene on chromosome 22q11 with the *ABL* (named after the abelson murine leukemia virus) gene located on chromosome 9q34. Untreated, the disease is characterized by the inevitable transition from a chronic phase to an accelerated phase and on to blast crisis.

ETIOLOGY

No clear correlation with exposure to cytotoxic drugs, such as alkylating agents, has been found, and there is no direct evidence of a viral etiology. Cigarette smoking has been shown to accelerate the progression to blast crisis and therefore has an adverse effect on survival inCML. The effect of radiation was demonstrated in the study of the atomic bomb survivors, where it has been estimated that the development of a CML cell mass of 10,000/uL takes 6.3 years. No increase in CML incidence was found in the survivors of the Chernobyl accident, suggesting that only large doses of radiation can induce CML.

PATHOPHYSIOLOGY

The product of the fusion gene resulting from the t(9;22) plays a central role in the development ofCML. This chimeric gene is transcribed into a hybrid*BCR*/*ABL* mRNA in which exon 1 of ABL is replaced by variable numbers of 5¢ BCR exons. Bcr/Abl fusion proteins, p210$_{BCR\text{-}ABL}$, are produced that contain NH_2-terminal domains of Bcr and the COOH-terminal domains of Abl. Bcr/Abl fusion proteins can transform hematopoietic progenitor cells in vitro. Furthermore, reconstituting lethally irradiated mice with bone marrow cells infected with retrovirus carrying the gene encoding the p210$_{BCR\text{-}ABL}$leads to the development of a myeloproliferative syndrome resembling CML in 50% of the mice. Specific antisense oligomers to the *BCR/ABL* junctions inhibit the growth of t(9;22)-positive leukemic cells without affecting normal colony formation.

The mechanism(s) by which p210$_{BCR\text{-}ABL}$promotes the transition from the benign state to the fully malignant one is still unclear. Messenger RNA for *BCR/ABL* can occasionally be detected in normal individuals. However, attachment of the*BCR*sequences to *ABL* results in three critical functional changes: (1) the Abl protein becomes constitutively active as a tyrosine kinase enzyme, (2) the DNA protein-binding activity of Abl is attenuated, and (3) the binding of Abl to cytoskeletal actin microfilaments is enhanced.

Disease Progression The events associated with transition to the acute phase are

poorly understood. Chromosomal instability of the malignant clone, resulting, for example, in the acquisition of an additional t(9;22), trisomy 8, or 17p- (p53 loss), is a fundamental characteristic ofCML. Acquisition of these additional genetic and/or molecular abnormalities is critical to the phenotypic transformation. The site of the breakpoint within the*BCR*gene may predict the time to development of blast crisis, but this claim has been refuted by others. Heterogeneous structural alterations of the p53 gene, as well as structural alterations and lack of protein production of the retinoblastoma gene, have been associated with disease progression in a subset of patients. Rare patients show alterations in *RAS*. Sporadic reports also document the presence of an altered *MYC* (named after the myelocytomatosis virus) gene or the appearance of p190*BCR-ABL*, the protein commonly found in adultALL and occasionally inAML, during the clinical evolution of small numbers of patients with CML. Progressive de novo DNA methylation at the *BCR/ABL* locus has also been shown to herald blastic transformation. Finally, interleukin (IL)-1b may be involved in the progression of CML to the blastic phase. Multiple pathways to disease transformation exist, but the exact timing and relevance of each of these remains unclear.

CLINICAL PRESENTATION

Symptoms The clinical onset of the chronic phase is generally insidious. Accordingly, some patients are diagnosed while still asymptomatic, during health screening tests; other patients present with fatigue, malaise, and weight loss or have symptoms resulting from splenic enlargement, such as early satiety and left upper quadrant pain or mass. Less common are features related to granulocyte or platelet dysfunction, such as infections, thrombosis, or bleeding. Occasionally, patients present with leukostatic manifestations due to severe leukocytosis or thrombosis such as vasoocclusive disease, cerebrovascular accidents, myocardial infarction, venous thrombosis, priapism, visual disturbances, and pulmonary insufficiency.

Progression ofCML is associated with worsening symptoms. Unexplained fever, significant weight loss, increasing dose requirement of the drugs controlling the disease, bone and joint pain, bleeding, thrombosis, and infections suggest transformation into accelerated or blastic phases. Fewer than 10 to 15% of newly diagnosed patients present with accelerated disease or with de novo blastic phase CML.

Physical Findings In most patients the abnormal finding on physical examination at diagnosis is minimal to moderate splenomegaly; mild hepatomegaly is found occasionally. Persistent splenomegaly despite continued therapy is a sign of disease acceleration. Lymphadenopathy and extramedullary myeloid tumors (granulocytic sarcomas) are unusual except late in the course of the disease; when they are present, the prognosis is poor.

Hematologic Findings Elevated white blood cell counts, with various degrees of immaturity of the granulocytic series, are present at diagnosis. Usually <5% circulating blasts and <10% blasts and promyelocytes are noted. Cycling of the counts may be observed in patients followed without treatment. Platelet counts are almost always elevated at diagnosis, and a mild degree of normochromic normocytic anemia is present. Leukocyte alkaline phosphatase is characteristically low inCMLcells. Serum levels of vitamin B_{12} and vitamin B_{12}-binding proteins are generally elevated. Phagocytic

functions are usually normal at diagnosis and remain normal during the chronic phase. Histamine production secondary to basophilia is increased in later stages, causing pruritus, diarrhea, and flushing.

At diagnosis, bone marrow cellularity, primarily of the myeloid and megakaryocytic lineages, with a greatly altered myeloid to erythroid ratio, is increased in almost all patients withCML. The marrow blast percentage is generally normal or slightly elevated. Marrow or blood basophilia, eosinophilia, and monocytosis may be present. While collagen fibrosis in the marrow is unusual at presentation, significant degrees of reticulin stain-measured fibrosis are noted in about half of the patients.

Disease acceleration is defined by the development of increasing degrees of anemia unaccounted for by bleeding or chemotherapy, cytogenetic clonal evolution, or blood or marrow blasts between 10 and 20%, blood or marrow basophils³20%, or platelet count<100,000/uL. *Blast crisis* is defined as acute leukemia, with blood or marrow blasts ³20%. Hyposegmented neutrophils may appear (Pelger-Huet anomaly). Blast cells can be classified as myeloid, lymphoid, erythroid, or undifferentiated, based on morphologic, cytochemical, and immunologic features. About half the cases are myeloid, one-third lymphoid, 10% erythroid, and the rest are undifferentiated.

Chromosomal Findings The cytogenetic hallmark ofCML, found in 90 to 95% of patients, is the t(9;22)(q34;q11). Originally, this was recognized by the presence of a shortened chromosome 22 (22q-), designated as the *Philadelphia chromosome*, that arises from the reciprocal 9;22 translocation. Some patients may have complex translocations (designated as *variant translocations*) involving three, four, or five chromosomes (usually including chromosomes 9 and 22). However, the molecular consequences of these changes appear similar to those resulting from the typical t(9;22).

PROGNOSTIC FACTORS

The clinical outcome of patients with CMLis variable. Death is expected in 10% of patients within 2 years and in about 20% yearly thereafter. The median survival time is ~4 years. Therefore, several prognostic models that identify different risk groups in CML have been developed. The most commonly used staging systems have been derived from multivariate analyses of prognostic factors. The Sokal index identified percentage of circulating blasts, spleen size, platelet count, cytogenetic clonal evolution, and age as the most important prognostic indicators. Two models, that of Tura and the combined model of Kantarjian, divide patients according to the number of negative prognostic factors. Age³60 years, spleen³10 cm below the costal margin, blasts³3% in blood or³5% in marrow, basophils³7% in blood or³3% in marrow, platelets³700,000/uL, or any of the characteristics of accelerated disease are associated with a very poor short-term prognosis and a threefold higher hazard rate, or risk of death per unit of time, in the first year. A prognostic scoring system to estimate the survival of CML patients treated with interferon (IFN) a has been developed.

TREATMENT

The goal of therapy inCML is to achieve prolonged, durable, nonneoplastic, nonclonal

hematopoiesis, which entails the eradication of any residual cells containing theBCR/ABL transcript. Hence the goal is complete molecular remission and cure (Table 111-4). A proposed treatment plan for the newly diagnosed patient with CML is presented inFig. 111-2.

Allogeneic SCT AllogeneicSCT is the only curative therapy forCML and, when feasible, is the treatment of choice. However, it is complicated by a high early mortality rate owing to the transplant procedure. When the outcome of all patients undergoing allogeneic SCT reported to the International Bone Marrow Transplant Registry was compared with the outcome of all patients treated with hydroxyurea or interferon (IFN) a by the German CML Study Group, the survival for the former group was statistically better, but only starting 5 years after transplant. When only low-risk patients (by Sokal's criteria) were evaluated, the benefit in survival for allogeneic SCT was seen after 6 years. Outcome of SCT depends on multiple factors including: (1) the patient (i.e., age and phase of disease); (2) the type of donor [i.e., syngeneic (monozygotic twins) or HLA-compatible allogeneic, related or unrelated]; (3) the preparative regimen; (4)GVHD; and (5) posttransplantation treatment.

The Patient As experience has been gained and safety and efficacy have been established, it has become clear that patients should be younger than 65 years and have a healthy and histocompatible donor. Furthermore, survival afterSCT in the accelerated and blastic phases of the disease is significantly diminished and is associated with a very high rate of relapse. The Seattle data demonstrate that SCT early in the chronic phase (1 to 2 years from diagnosis) is superior to later SCT. While overall survival, disease-free survival, and relapse rates are not influenced by priorIFN-atreatment, incidence and severity of acute and chronicGVHDcorrelate with prior IFN-a treatment in the unrelated donor and possibly also in the related donor setting. Therefore, because early SCT is more effective than late SCT, the decision to perform allogeneic SCT should probably be made within a year of diagnosis when IFN-a is the initial therapy; a 3-month hiatus is recommended between discontinuing IFN-a and initiating SCT.

The Donor Transplantation from a family donor, who is either fully matched or mismatched at only one HLA locus, should be considered standard therapy for any patient withCML who is a candidate for an HLA-related sibling transplant. SyngeneicSCT in patients with chronic phase CML has been reported from the Seattle group to result in 7-year disease-free survival in 55%, with a 30% relapse rate. With HLA-identical sibling SCT in the chronic phase, many groups have reported 5-year disease-free survival in 40 to 70% of patients, with a 25% relapse rate. SCT from an HLA-matched unrelated donor has been reported by the Seattle group to result in a 74% probability of surviving 3 years for patients transplanted in chronic phase less than 1 year from diagnosis and younger than 50 years. A 2-year disease-free (based on hematologic analyses) survival of 45%(±21%) for patients receiving SCT from unrelated individuals, matched or mismatched at only one locus, transplanted less than 1 year from diagnosis was reported by the National Marrow Donor Program. Patients age 40 to 50 years fared poorly (15 of 55 survived). The probability of 2-year disease-free (based on cytogenetic analyses) survival in a report on unrelated transplants from the Medical College of Wisconsin, using a standardized conditioning regimen and T cell depletion, was 52% for patients transplanted in chronic phase (regardless of the time from

diagnosis). Patients receiving transplants from unrelated individuals have higher rates of graft failure and acute and chronicGVHD and prolonged convalescence after treatment, compared to those who receive allogeneic transplants from related individuals. Peripheral blood is now being studied as a source of hematopoietic progenitor cells; it may offer rapid engraftment and less risk for the donor. Umbilical-cord blood may permit mismatched SCT with notably less GVHD; graft-versus-leukemia (GVL) effects do not appear to be impaired. A problem with cord blood is obtaining an appropriate number of progenitor cells to reconstitute hematopoiesis in an adult.

Preparative Regimens These regimens have been studied by several groups. A randomized study by the Seattle group compared cyclophosphamide and total-body irradiation with busulphan and cyclophosphamide. They found no significant differences in the 3-year probabilities of survival, relapse, event-free survival, speed of engraftment, or incidence of venoocclusive disease of the liver. Significantly more patients in the total-body irradiation arm experienced major elevations of creatinine, acuteGVHD, longer periods of fever, positive blood cultures, hospital admissions, and longer inpatient hospital stays. However, increased chronic GVHD, obstructive bronchiolitis and alopecia were noted with busulphan. Intravenous busulphan may permit better control of serum levels. Minitransplants in which the preparative regimen is aimed at eliminating host lymphocytes rather than bone marrow are being tested. Reduced toxicity with preserved antitumor efficacy is the goal.

Development and type of GVHD Development of grade I GVHD, as compared to no GVHD, decreases the risk of relapse. A lower relapse rate was observed also in patients with grade II GVHD but was accompanied by a substantially higher transplant-related mortality rate. The decreased relapse rate may be caused by aGVLeffect. Depletion of T lymphocytes from donor marrow can prevent GVHD but results in an increased risk of relapse, which exceeds the relapse rate after syngeneicSCT. Thus, T lymphocytes from the donor marrow mediate a significant antileukemic, or GVL, effect, and even syngeneic marrow may exhibit limited GVL activity inCML.

Posttransplantation Treatment Further support for the existence of an immunologically mediatedGVLeffect comes from the observation that donor leukocyte infusions (without prior conditioning orGVHDprophylaxis) can induce hematologic and cytogenetic remissions in patients withCML who have relapsed after allogeneicSCT.

The activity ofIFN-ain patients with early chronic-phaseCML was the basis for the use of IFN-a afterSCT, either to induce cytogenetic remissions in relapsed patients or to prevent relapse after SCT for high-risk patients. The main concern about IFN-a use after allogeneic SCT has been the development or worsening ofGVHD, because IFN-a acts as an immunomodulator. However, in published reports encompassing 52 allogeneic recipients who were free of GVHD and were either at high risk for relapse or had already relapsed, only 6 subsequently developed GVHD after IFN-a therapy was initiated. IFN-a has also been combined with mononuclear cells obtained from donor blood to induce cytogenetic remissions in relapsed patients. Cytogenetic remissions have been achieved, but the exact role of IFN-a as opposed to the mononuclear cells is unclear.IL-2, with or without IFN-a, is also being evaluated for its ability to restore complete cytogenetic remission in patients who suffer relapses after SCT.

IFN-ahas been used afterSCT to prevent relapse in patients with advanced disease at time of transplant (patients at high risk for relapse). CytogeneticCR has been maintained for as long as 2 years posttransplantation in small numbers of patients with blast crisis or second chronic phase. Similarly, IL-2 (2.5´10^6 to 6´10^6units/m^2per day) has been given to patients after T cell-depleted allogeneic SCT in an effort to induceGVLwithoutGVHD, and thus prevent relapse. Compared with historical control subjects, patients treated with IL-2 have a lower risk of disease relapse. A randomized trial is warranted.

Interferons When allogeneicSCT is not feasible,IFN-atherapy is the treatment of choice. The interferons are a complex group of naturally occurring proteins produced by eukaryotic cells in response to viruses, antigens, and mitogens. Three distinct groups of IFN species have been identified: IFN-a, -b, and -g. Although various interferons have become available for clinical investigation, most data have been generated with IFN-apreparations.

Interferons have potent, pleiotropic biologic effects, spanning a spectrum of antiviral, microbicidal, immunomodulatory, and antiproliferative properties. While interferons downregulate the expression of several oncogenes and cytokines, they also upregulate the expression ofIFNregulatory factor-1 (a transcriptional activator with antioncogenic activity), adhesion molecules, and the histocompatibility genes. Interferons also inhibit angiogenesis and induce a cellular immune response. However, their mode(s) of action are still unknown.

In seven randomized studies comparingIFN-aand chemotherapy, both modalities have been found to be effective in achieving hematologic remissions. However, patients treated with IFN-a survived longer than patients treated with hydroxyurea or busulphan. The 5-year survival rate was 51% with IFN-a and 42% with chemotherapy.

Patients develop both acute and chronic side effects fromIFN-atherapy. Acute side effects (flulike symptoms) appear early in the course of the treatment. Most flulike symptoms respond to acetaminophen, and tachyphylaxis develops within 1 to 2 weeks. Chronic reactions, such as fatigue and lethargy, depression, weight loss, myalgias, and arthralgias, occur in about half of the patients and may require dose reduction. Patients also report cough, postnasal drip, and dryness of the skin. Infrequently, immune-mediated thrombocytopenia and anemia develop. In addition, long-term therapy has been associated with late autoimmune side effects, such as hypothyroidism and occasionally generalized autoimmune phenomena.

The most important persistent side effects in patients withCML who are treated withIFN-aare neurologic. All patients treated with IFN-a are subject to some neurologic toxicity, the most common symptom being lethargy. Up to 20% of patients have neurologic side effects that are associated with compromised quality of life and reduced ability to carry out their regular activity, such as full-time work. In addition, at the required doses, impotence in men is not infrequent.

Hematologic remissions are generally achieved within 1 to 2 months of startingIFN-a. However, some patients have a cyclic response pattern with progressively lower peak

and nadir counts over a period of months. The increase in counts during the cycling that occurs in the first few months of therapy should not be confused with resistance. Cytogenetic responses generally start at 3 to 12 months, and complete cytogenetic responses may require 6 months to 4 years of therapy. However, most complete cytogenetic responses are achieved within 12 to 18 months; and in single-agent, single-arm studies they have been identified in up to 26% of patients.

The combination ofIFN-awith cytarabine has produced better results than those with IFN-a alone; cytogenetic responses occurred earlier, but the influence on survival is not yet known.

Chemotherapy Initial management of patients with chemotherapy is currently reserved for rapid lowering of white blood cell counts, reduction of symptoms, and reversal of symptomatic splenomegaly. Hydroxyurea, a ribonucleotide reductase inhibitor, induces rapid disease control. The initial dose is 1 to 4 g/d, and the dose should be reduced by half with each 50% reduction of the leukocyte count. Unfortunately, cytogenetic remissions with hydroxyurea are uncommon. Busulphan, an alkylating agent that acts on early progenitor cells, has a more prolonged effect. However, we do not recommend its use because of its serious side effects, which include unexpected, and occasionally fatal, myelosuppression in 5 to 10% of patients; pulmonary, endocardial, and marrow fibrosis; and an Addison-like wasting syndrome.

Homoharringtonine (HHT) is a plant alkaloid derived from a tree, *Cephalotaxus fortuneii* sp. *harringtonii*. HHT blocks peptide bond formation after binding of the aminoacyl-transfer RNA to the ribosome. In patients whose disease progressed during treatment withIFN-aor who were in later chronic phase (>1 year from diagnosis), HHT induced 72% complete hematologic responses and 22% complete or major cytogenetic responses. The use of HHT before IFN-a in early chronic phase resulted in a 92% complete hematologic response rate and a 27% major cytogenetic response rate. Toxicity is mainly related to myelosuppression.

Intensive combination chemotherapy has also been used in chronic phaseCML, with 30 to 50% of patients achieving complete cytogenetic responses. However these cytogenetic remissions have been short lived. Consequently, intensive combination chemotherapy regimens are being used today only to mobilize normal progenitors in the blood in order to collect circulating stem cells for autologous transplantation.

Autologous SCT Autologous SCT could potentially cureCML if a means to select the residual normal progenitors, which coexist with their malignant counterparts, could be developed. As a source of autologous hematopoietic stem cells for transplantation, blood offers certain advantages over marrow (e.g., faster engraftment and no general anesthesia). Normal hematopoietic stem cells appear with increased frequency in the blood of patients with CML during the recovery phase after chemotherapy andG-CSF.

A retrospective analysis of >200 autologousSCTperformed forCML at eight centers worldwide suggests that autologous SCT prolongs survival in chronic- or accelerated-phase patients when compared with conventional therapy. At transplant 93 patients were in chronic phase, 25 were in accelerated phase, and 114 were in blast crisis or second chronic phase. Patients received autologous bone marrow and/or blood

hematopoietic stem cells. In 42 cases the hematopoietic progenitors were subjected to ex vivo manipulation by long-term bone marrow culture, by incubation with recombinantIFN-g, or by chemotherapy. In 49 cases the hematopoietic progenitors were harvested during the recovery phase after various chemotherapy regimens. After autologous SCT, 29 of 93 (31%) patients in first chronic phase achieved complete cytogenetic remissions. The median duration of cytogenetic remission was 14 months, with a range of 2 to 68 months. Approaches to treat minimal residual disease after autologous transplantation, such as immune modulation, are currently being investigated.

Leukapheresis and Splenectomy Intensive leukapheresis may control the blood counts in chronic phaseCML; however, it is expensive and cumbersome. It is useful in emergencies where leukostasis-related complications such as pulmonary failure or cerebrovascular accidents are likely. It may also have a role in the treatment of pregnant women in whom it is important to avoid potentially teratogenic drugs.

Splenectomy was used inCML in the past because of the suggestion that evolution to the acute phase might occur in the spleen. However, this does not appear to be the case, and splenectomy is now reserved for symptomatic relief of painful splenomegaly unresponsive to chemotherapy or for significant anemia or thrombocytopenia associated with hypersplenism. Splenic radiation is used rarely to reduce the size of the spleen.

Minimal Residual Disease The correlation between residual cells with the t(9;22) and disease recurrence is not completely understood. In initial studies withRT-PCRused to predict disease recurrence afterIFN-atherapy, residual disease was found in all samples tested from patients with complete cytogenetic remissions. Later studies demonstrated the elimination of theBCR/ABL mRNA transcript after more prolonged IFN-a treatment in some cases. It is now possible to quantitate transcripts, and longer follow-up may indicate whether quantitation of the BCR/ABL transcript is useful for predicting cytogenetic and clinical relapse.

After allogeneicSCT,RT-PCRanalysis may be positive for residual disease during the first 6 months in patients who subsequently achieve a long-lasting remission. However, late persistence of RT-PCR positivity appears to indicate a reduced probability of cure. RT-PCR positivity at any single time point is not predictive of imminent relapse. After allogeneic SCT, patients are often divided according to RT-PCR results into one of three groups: (1) persistently positive, (2) intermittently negative, and (3) persistently negative. These three groups have low, intermediate, and high probability of maintaining remission and disease free-survival, respectively. Although these data suggest that patients who are persistently RT-PCR positive more than 6 months after allogeneic SCT need additional therapeutic interventions, this conclusion has not been rigorously established. The studies have used an assortment of techniques for measuring minimal residual disease, the level of sensitivity has been variable, and the follow-up durations of patients are short. Real-time RT-PCR may provide a more sensitive tool to predict relapse inCML and in other cancers. In patients who do not have any evidence forGVHD and are intermittently RT-PCR negative,GVL may be induced by alloreactive donor cells (without the side effects of GVHD) to suppress the proliferation of the leukemic cells.

Future Directions The synthetic inhibitor of theBCR/ABL kinase, STI571, induces selective inhibition in the growth of t(9;22)-bearing tumor cells in vitro and some responses in patients. Inhibition of *RAS* with a farnesyl transferase inhibitor that blocks its insertion into the membrane may have antitumor activity inCML on the basis of early clinical trials. Preclinical efforts to use BCR/ABL peptides as a tumor vaccine appear promising. The use of BCR/ABL antisense oligonucleotides to purge residual leukemic cells from autologous hematopoietic progenitors before reinfusion, as well as approaches to induceGVL in the setting of minimal residual disease without inducingGVHD, are underway.

Treatment of Blast Crisis The treatment for all forms of blast crisis is generally ineffective. Treatment is tailored to the phenotype of the blast cell. Myeloid crises and erythroid crisis are treated as forAML, but remissions occur in only a minority of cases and are generally short lived. Patients may present without having had a chronic phase. AML with a t(9;22) is probably blast crisis ofCML and carries a poor prognosis.

Lymphoid blast crisis is treated likeALL(Chap. 112) with vincristine (1.4 mg/m^2weekly) plus prednisone (60 mg/m^2orally qd) induction therapy with or without an anthracycline. About one-third of patients will reenter chronic phase after 2 to 3 weeks of treatment, but the remissions last only a median of ~4 months. EvenSCT is minimally effective during blast crises. Novel treatment approaches are needed.

112. MALIGNANCIES OF LYMPHOID CELLS - *James O. Armitage*, *Dan L. Longo*

Malignancies of lymphoid cells range from the most indolent to the most aggressive human malignancies. These cancers arise from cells of the immune system at different stages of differentiation, resulting in a wide range of morphologic, immunologic, and clinical findings. Advances in our understanding of the normal immune system have allowed a better understanding of these sometimes confusing disorders.

Some malignancies of lymphoid cells almost always present as leukemia (i.e., primary involvement of bone marrow and blood), while others almost always present as lymphomas (i.e., solid tumors of the immune system). However, other malignancies of lymphoid cells can present as either leukemia or lymphoma. In addition, the clinical pattern can change over the course of the illness. This change is more often seen in a patient who seems to have a lymphoma and then develops the manifestations of leukemia over the course of the illness.

BIOLOGY OF LYMPHOID MALIGNANCIES: CONCEPTS OF THE WHO CLASSIFICATION OF LYMPHOID MALIGNANCIES

The classification of lymphoid malignancy evolved steadily throughout the twentieth century. The distinction between leukemia and lymphoma was made early, and separate classification systems were developed for each. Leukemias were first divided into acute and chronic subtypes based on average survival. Chronic leukemias were easily subdivided into those of lymphoid or myeloid origin based on morphologic characteristics. However, in recent years, a spectrum of diseases that were formerly all called chronic lymphoid leukemia has become apparent (Table 112-1). The acute leukemias were usually malignancies of blast cells with few identifying characteristics. When cytochemical stains became available, it was possible to divide these objectively into myeloid malignancies and acute leukemias of lymphoid cells. Acute leukemias of lymphoid cells have been subdivided based on morphologic characteristics by the French-American-British (FAB) group (Table 112-2). Using this system, lymphoid malignancies of small uniform blasts (e.g., typical childhood acute lymphoblastic leukemia) were called L1, lymphoid malignancies with larger and more variable size cells were called L2, and lymphoid malignancies of uniform cells with basophilic and sometimes vacuolated cytoplasm were called L3 (e.g., typical Burkitt's lymphoma cells). Acute leukemias of lymphoid cells have also been subdivided based on immunologic (i.e., T vs. B) and cytogenetic abnormalities (Table 112-2). Major cytogenetic subgroups include the t(9;22) (e.g., Philadelphia chromosome-positive acute lymphoblastic leukemia) and the t(8;14) found in the L3 or Burkitt's leukemia.

Non-Hodgkin's lymphomas were separated from Hodgkin's disease by recognition of the Sternberg-Reed cells early in the twentieth century. The first systematic classification for non-Hodgkin's lymphomas was proposed by Gall and Mallory in the first half of the twentieth century and divided non-Hodgkin's lymphomas into giant follicular lymphoma, lymphosarcoma, and reticulum cell sarcoma. Unfortunately, this fairly simple system proved to be imprecise in its definitions and only marginally clinically useful. In the 1950s, Henry Rappaport and colleagues recognized the importance of growth pattern in subdividing non-Hodgkin's lymphomas and used pattern in addition to cell size and shape as the basis for a new classification that proved more clinically relevant. In the

1970s, it was recognized that non-Hodgkin's lymphomas were all tumors of lymphocytes and were derived from either T or B cells. This led to immunologically based classifications of lymphomas such as the Lukes-Collins classification in the United States and the Kiel classification proposed by Lennert and associates in Europe. In an attempt to unify terminology and improve the effectiveness of communication between pathologists and clinicians, the Working Formulation was proposed in 1982. Over the next two decades the Kiel classification dominated clinical practice in Europe, whereas the Working Formulation became the main classification system used in North America.

In the past two decades, increased understanding of the immune system and the genetic abnormalities associated with non-Hodgkin's lymphoma have led to the identification of several previously unrecognized types of lymphoma. The recognition of these new and clinically relevant lymphomas led to proposals for changing existing classifications. A new proposal that is part of the basis of the new World Health Organization classification of lymphoid malignancies takes into account morphologic, clinical, immunologic, and genetic information and attempts to divide non-Hodgkin's lymphomas and other lymphoid malignancies into clinical/pathological entities that have clinical and therapeutic relevance. This system is presented in Table 112-3. Clinical studies have shown that this new system is clinically relevant and has a higher degree of diagnostic accuracy than those used previously. The possibilities for subdividing lymphoid malignancies are extensive. However,Table 112-3 presents in bold those malignancies that occur in at least 1% of patients. Specific lymphoma subtypes will be dealt with in more detail below.

GENERAL ASPECTS OF LYMPHOID MALIGNANCIES

ETIOLOGY AND EPIDEMIOLOGY

Chronic lymphoid leukemia (CLL) is the most prevalent form of leukemia in western countries. It occurs most frequently in older adults and is exceedingly rare in children. Approximately 13,000 new cases are diagnosed in the United States each year, but because of the prolonged survival associated with this disorder, the total prevalence is many times higher. CLL is more common in men than in women and more common in whites than in blacks. This is an uncommon malignancy in Asia. The etiologic factors for typical CLL are unknown.

In contrast toCLL, acute lymphoid leukemias (ALLs) are predominantly cancers of children and young adults. The L3 or Burkitt's leukemia occurring in children in developing countries seems to be associated with infection by the Epstein-Barr virus (EBV) in infancy. However, the explanation for the etiology of more common subtypes of ALL is much less certain. Childhood ALL occurs more often in higher socioeconomic subgroups. Children with trisomy 21 (Down's syndrome) have an increased risk for childhood acute lymphoblastic leukemia as well as acute myeloid leukemia. Exposure to high-energy radiation in early childhood increases the risk of developing T cell acute lymphoblastic leukemia.

The etiology ofALL in adults is also uncertain. ALL is unusual in middle-aged adults but increases in incidence in the elderly. However, acute myeloid leukemia is still much more common in these patients. Environmental exposures including certain industrial

exposures, exposure to agricultural chemicals, and smoking might increase the risk of developing ALL as an adult.

The cell of origin of Hodgkin's disease has not been determined definitively, but molecular evidence suggests that most are of B cell origin. The incidence of Hodgkin's disease appears fairly stable, with approximately 8000 new cases diagnosed each year in the United States. Hodgkin's disease is more common in whites than in blacks and more common in males than in females. A bimodal distribution of age at diagnosis has been observed, with one peak incidence occurring in patients in their 20s and the other in those in their 80s. Patients in the younger age groups diagnosed in the United States largely have the nodular sclerosing subtype of Hodgkin's disease. Elderly patients, patients infected with HIV, and patients in third world countries more commonly have mixed-cellularity Hodgkin's disease or lymphocyte-depleted Hodgkin's disease. Infection by HIV is a risk factor for developing Hodgkin's disease. In addition, an association between infection byEBV and Hodgkin's disease has been demonstrated. A monoclonal or oligoclonal proliferation of EBV-infected cells in 20 to 40% of the patients with Hodgkin's disease has led to proposals for this virus having an etiologic role in Hodgkin's disease. However, the matter is not settled definitively.

For unknown reasons, non-Hodgkin's lymphomas have increased in frequency in the United States at the rate of 4% per year since 1950. Almost 60,000 new cases of non-Hodgkin's lymphoma were diagnosed in the United States in the year 2000. Non-Hodgkin's lymphomas are more frequent in the elderly and more frequent in men. Patients with both primary and secondary immunodeficiency states are predisposed to developing non-Hodgkin's lymphomas. These include patients with HIV infection; patients who have undergone organ transplantation; and patients with inherited immune deficiencies, the sicca syndrome, and rheumatoid arthritis.

The incidence of non-Hodgkin's lymphomas and the patterns of expression of the various subtypes differ geographically. T cell lymphomas are more common in Asia than in western countries, while certain subtypes of B cell lymphomas such as follicular lymphoma are more common in western countries. A specific subtype of non-Hodgkin's lymphoma known as the angiocentric nasal T/natural killer (NK) cell lymphoma has a striking geographic occurrence, being most frequent in Southern Asia and parts of Latin America. Another subtype of non-Hodgkin's lymphoma associated with infection by human T cell lymphotropic virus (HTLV) I is seen particularly in southern Japan and the Caribbean.

A number of environmental factors have been implicated in the occurrence of non-Hodgkin's lymphoma, including infectious agents, chemical exposures, and medical treatments. Several studies have demonstrated an association between exposure to agricultural chemicals and an increased incidence in non-Hodgkin's lymphoma. Patients treated for Hodgkin's disease can develop non-Hodgkin's lymphoma; it is unclear whether this is a consequence of the Hodgkin's disease or its treatment. However, the infectious etiology of non-Hodgkin's lymphoma is the area where evidence has been expanding most rapidly in recent years. Table 112-4 illustrates those infectious agents associated with the development of non-Hodgkin's lymphoma.HTLV-I infects T cells and leads directly to the development of adult T cell lymphoma (ATL) in a small percentage of infected patients. The cumulative lifetime risk of developing lymphoma in an infected

patient is 2.5%. The virus is transmitted by infected lymphocytes ingested by nursing babies of infected mothers, blood-borne transmission, or sexually. The median age of patients with ATL is about 56 years, emphasizing the long latency.

EBVis associated with the development of Burkitt's lymphoma in Central Africa and the occurrence of aggressive non-Hodgkin's lymphomas in immunosuppressed patients in western countries. EBV infection is strongly associated with the occurrence of extranodal nasal T/NKcell lymphomas in Asia and South America. Infection with HIV predisposes to the development of aggressive, B cell non-Hodgkin's lymphoma. This may be through overexpression of interleukin 6 by infected macrophages. Infection of the stomach by the bacterium *Helicobacter pylori* induces the development of gastric MALT (mucosa-associated lymphoid tissue) lymphomas. This association is supported by evidence that patients treated with antibiotics to eradicate *H. pylori* have regression of their MALT lymphoma. The bacterium does not transform lymphocytes to produce the lymphoma; instead, a vigorous immune response is made to the bacterium and the chronic antigenic stimulation leads to the neoplasia.

Chronic hepatitis C virus infection has been associated with the development of lymphoplasmacytic lymphoma. Human herpesvirus 8 is associated with primary effusion lymphoma in HIV-infected persons and multicentric Castleman's disease, a diffuse lymphadenopathy associated with systemic symptoms of fever, malaise, and weight loss.

In addition to infectious agents, a number of other diseases or exposures may predispose to developing lymphoma (Table 112-5).

IMMUNOLOGY

All lymphoid cells are derived from a common hematopoietic progenitor that gives rise to lymphoid, myeloid, erythroid, monocyte, and megakaryocyte lineages. Through the ordered and sequential activation of a series of transcription factors, the cell first becomes committed to the lymphoid lineage and then gives rise to B and T cells. About 75% of all lymphoid leukemias and 90% of all lymphomas are of B cell origin. A cell becomes committed to B cell development when it begins to rearrange its immunoglobulin genes. The sequence of cellular changes, including changes in cell-surface phenotype, that characterize normal B cell development are shown in Fig. 112-1. A cell becomes committed to T cell differentiation upon migration to the thymus and rearrangement of T cell antigen receptor genes. The sequence of the events that characterize T cell development are depicted in Fig. 112-2.

Although lymphoid malignancies often retain the cell-surface phenotype of lymphoid cells at particular stages of differentiation, this information is of little consequence. The so-called stage of differentiation of a malignant lymphoma does not predict its natural history. For example, the clinically most aggressive lymphoid leukemia is Burkitt's leukemia, which has the phenotype of a mature follicle center IgM-bearing B cell. Leukemias bearing the immunologic cell-surface phenotype of more primitive cells (e.g., pre-BALL, CD10+) are less aggressive and more amenable to curative therapy than the "more mature" appearing Burkitt's leukemia cells. Furthermore, the apparent stage of differentiation of the malignant cell does not reflect the stage at which the genetic

lesions that gave rise to the malignancy developed. For example, follicular lymphoma has the cell-surface phenotype of a follicle center cell, but its characteristic chromosomal translocation, the t(14;18), which involves juxtaposition of the antiapoptotic *bcl-2* gene next to the immunoglobulin heavy chain gene (see below), had to develop early in ontogeny as an error in the process of immunoglobulin gene rearrangement. Why the subsequent steps that led to transformation became manifest in a cell of follicle center differentiation is not clear.

The major value of cell-surface phenotyping is to aid in the differential diagnosis of lymphoid tumors that appear similar by light microscopy. For example, benign follicular hyperplasia may resemble follicular lymphoma; however, the demonstration that all the cells bear the same immunoglobulin light chain isotype strongly suggests the mass is a clonal proliferation rather than a polyclonal response to an exogenous stimulus.

GENETIC CONSIDERATIONS

Malignancies of lymphoid cells are associated with recurring genetic abnormalities. While specific genetic abnormalities have not been identified for all subtypes of lymphoid malignancies, it is presumed that they exist. Genetic abnormalities can be identified at a variety of levels including gross chromosomal changes (i.e., translocations, additions, or deletions); rearrangement of specific genes that may or may not be apparent from cytogenetic studies; and overexpression, underexpression, or mutation of specific oncogenes. Altered expression or mutation of specific proteins is particularly important. Many lymphomas contain balanced chromosomal translocations involving the antigen receptor genes; immunoglobulin genes on chromosomes 2, 14, and 22 in B cells; and T cell antigen receptor genes on chromosomes 7 and 14 in T cells. The rearrangement of chromosome segments to generate mature antigen receptors must create a site of vulnerability to aberrant recombination. B cells are even more susceptible to acquiring mutations during their maturation in germinal centers; the generation of antibody of higher affinity requires the introduction of mutations into the variable region genes in the germinal centers. Other nonimmunoglobulin genes, for example *bcl-6*, may acquire mutations as well.

In the case of diffuse large B cell lymphoma, the translocation t(14;18) occurs in approximately 30% of patients and leads to overexpression of the *bcl-2* gene found on chromosome 18. Some other patients without the translocation also overexpress the BCL-2 protein. This protein is involved in suppressing apoptosis -- i.e., the mechanism of cell death most often induced by cytotoxic chemotherapeutic agents. A higher relapse rate has been observed in patients whose tumors overexpress the BCL-2 protein, but not in those patients whose lymphoma cells show only the translocation. Thus, particular genetic mechanisms have clinical ramifications.

Table 112-6 presents the best documented translocations and associated oncogenes for various subtypes of lymphoid malignancies. In some cases, such as the association of the t(14;18) in follicular lymphoma, the t(2;5) in anaplastic large T/null-cell lymphoma, the t(8;14) in Burkitt's lymphoma, and the t(11;14) in mantle cell lymphoma, the great majority of tumors in patients with these diagnoses display these abnormalities. In other types of lymphoma where a minority of the patients have tumors expressing specific genetic abnormalities, the defects may have prognostic significance. No specific genetic

abnormalities have been identified in Hodgkin's disease.

In typical B cellCLL, trisomy 12 conveys a poorer prognosis. InALL in both adults and children, genetic abnormalities have important prognostic significance. Patients whose tumor cells display the t(9;22) have a much poorer outlook than patients who do not have this translocation. Other genetic abnormalities that occur frequently in adults with ALL include the t(4;11) and the t(8;14). The t(4;11) is associated with younger age, female predominance, high white cell counts, and L1 morphology. The t(8;14) is associated with older age, male predominance, frequent central nervous system (CNS) involvement, and L3 morphology. Both are associated with a poor prognosis. In childhood ALL, hyperdiploidy has been shown to have a favorable prognosis.

Approach to the Patient

Regardless of the type of lymphoid malignancy, the initial evaluation of the patient should include performance of a careful history and physical examination. These will help confirm the diagnosis, identify those manifestations of the disease that might require prompt attention, and aid in the selection of further studies to optimally characterize the patient's status to allow the best choice of therapy. It is difficult to overemphasize the importance of a carefully done history and physical examination. They might provide observations that lead to reconsidering the diagnosis, provide hints at etiology, clarify the stage, and allow the physician to establish rapport with the patient that will make it possible to develop and carry out a therapeutic plan.

For patients withALL, evaluation is usually completed after a complete blood count, chemistry studies reflecting major organ function, a bone marrow biopsy with genetic and immunologic studies, and a lumbar puncture. The latter is necessary to rule out occultCNSinvolvement. At this point, most patients would be ready to begin therapy. In ALL, prognosis is dependent upon the genetic characteristics of the tumor, the patient's age, the white cell count, and the patient's overall clinical status and major organ function.

InCLL, the patient evaluation should include a complete blood count, chemistry tests to measure major organ function, serum protein electrophoresis, and a bone marrow biopsy. However, some physicians believe that the diagnosis would not always require a bone marrow biopsy. Patients often have imaging studies of the chest and abdomen looking for pathologic lymphadenopathy. Patients with typical B cell CLL can be subdivided into three major prognostic groups. Those patients with only blood and bone marrow involvement by leukemia but no lymphadenopathy, organomegaly, or signs of bone marrow failure have the best prognosis. Those with lymphadenopathy and organomegaly have an intermediate prognosis, and patients with bone marrow failure, defined as hemoglobin<100 g/L (10 g/dL) or platelet count<100,000/uL, have the worst prognosis. The pathogenesis of the anemia or thrombocytopenia is important to discern. The prognosis is adversely affected when either or both of these abnormalities are due to progressive marrow infiltration and loss of productive marrow. However, either or both may be due to autoimmune phenomena or to hypersplenism that can develop during the course of the disease. These destructive mechanisms are usually completely reversible (glucocorticoids for autoimmune disease; splenectomy for hypersplenism) and do not influence disease prognosis.

Two popular staging systems have been developed to reflect these prognostic groupings (Table 112-7). Patients with typical B cellCLL can have their course complicated by immunologic abnormalities including autoimmune hemolytic anemia, autoimmune thrombocytopenia, and hypogammaglobulinemia. Patients with hypogammaglobulinemia benefit from regular (monthly)g globulin administration. Because of expense,g globulin is often withheld until the patient experiences a significant infection. These abnormalities do not have a clear prognostic significance and should not be used to assign a higher stage.

The initial evaluation of a patient with Hodgkin's disease or non-Hodgkin's lymphoma is similar. In both situations, the determination of an accurate anatomic stage is an important part of the evaluation. The staging system that is utilized is the Ann Arbor staging system originally developed for Hodgkin's disease (Table 112-8).

Evaluation of patients with Hodgkin's disease will typically include a complete blood count; erythrocyte sedimentation rate; chemistry studies reflecting major organ function; computed tomography (CT) scans of the chest, abdomen, and pelvis; and a bone marrow biopsy. A gallium scan is not necessary for primary staging, but when it is performed at the completion of therapy it allows evaluation of persistent radiographic abnormalities, particularly the mediastinum. In most cases, these studies will allow assignment of anatomic stage and the development of a therapeutic plan.

In patients with non-Hodgkin's lymphoma, the same evaluation described for patients with Hodgkin's disease is usually carried out. In addition, serum levels of lactate dehydrogenase (LDH) andb_2-microglobulin and serum protein electrophoresis are often included in the evaluation. Anatomic stage is assigned in the same manner as used for Hodgkin's disease. However, the prognosis of patients with non-Hodgkin's lymphoma is best assigned using the International Prognostic Index (IPI) (Table 112-9). This is a powerful predictor of outcome in all subtypes of non-Hodgkin's lymphoma. Patients are assigned an IPI score based on the presence or absence of five adverse prognostic factors and may have none or all five of these adverse prognostic factors.Figure 112-3 shows the prognostic significance of this score in 1300 patients with all types of non-Hodgkin's lymphoma.

CLINICAL FEATURES, TREATMENT, AND PROGNOSIS OF SPECIFIC LYMPHOID MALIGNANCIES

PRECURSOR CELL B CELL NEOPLASMS

Precursor B Cell Lymphoblastic Leukemia/Lymphoma The most common cancer in childhood is B cell acute lymphoblastic leukemia (ALL). Although this disorder can also present as a lymphoma in either adults or children, presentation as lymphoma is quite rare.

The malignant cells in patients with precursor B cell lymphoblastic leukemia are most commonly of pre-B cell origin. Patients typically present with signs of bone marrow failure such as pallor, fatigue, bleeding, fever, and infection related to peripheral blood cytopenias. Peripheral blood counts regularly show anemia and thrombocytopenia but

might show leukopenia, a normal leukocyte count, or leukocytosis based largely on the number of circulating malignant cells (seePlate V-24). Extranodal sites of disease are frequently involved in patients who present with leukemia, which might be manifested by lymphadenopathy, hepato- or splenomegaly,CNSdisease, testicular enlargement, and/or cutaneous infiltration.

The diagnosis is usually made by bone marrow biopsy, which shows infiltration by malignant lymphoblasts. Demonstration of a pre-B cell immunophenotype (Fig. 112-1) and, often, characteristic cytogenetic abnormalities (Table 112-6) confirm the diagnosis. An adverse prognosis in patients with precursor B cell ALL is predicted by a very high white cell count, the presence of symptomaticCNSdisease, and unfavorable cytogenetic abnormalities. For example, t(9;22) is frequently found in adults with B cell lymphoblastic leukemia and is associated with a very poor outlook.

TREATMENT

The treatment of patients with precursor B cell lymphoblastic leukemia involves remission induction with combination chemotherapy, a consolidation phase that includes administration of high-dose systemic therapy and treatment to eliminate disease in theCNS, and a period of continuing therapy to prevent relapse and effect cure. The overall cure rate in children is 85%, while about 50% of adults are long-term disease-free survivors. This reflects the high proportion of adverse cytogenetic abnormalities seen in adults with precursor B cell lymphoblastic leukemia.

Precursor B cell lymphoblastic lymphoma is a rare presentation of precursor B cell lymphoblastic malignancy. These patients often have a rapid transformation to leukemia, and similar treatment approaches as are used in patients presenting with leukemia are appropriate. In the few patients who present with the disease confined to lymph nodes, a high cure rate has been reported.

MATURE (PERIPHERAL) B CELL NEOPLASMS

B Cell Chronic Lymphoid Leukemia/Small Lymphocytic Lymphoma B cellCLL/small lymphocytic lymphoma represents by far the most common lymphoid leukemia, and when presenting as a lymphoma, it accounts for ~7% of non-Hodgkin's lymphomas. As the name implies, presentation can be as either leukemia or lymphoma. The major clinical characteristics of B cell CLL/small lymphocytic lymphoma are presented in Table 112-10.

The diagnosis of typical B cellCLL is made when an increased number of circulating lymphocytes (i.e.,>4 ´10^9/L and usually >10 ´10^9/L) is found (see Plate V-17) that are monoclonal B cells and display the CD5 antigen. Confirmation of bone marrow infiltration by the same cells confirms the diagnosis. The peripheral blood smear in such patients typically shows many "smudge" or "basket" cells, nuclear remnants of cells damaged by the physical shear stress of making the blood smear. If cytogenetic studies are performed, trisomy 12 is found in ~25 to 30% of patients. Abnormalities in chromosome 13 are also seen.

If the primary presentation is lymphadenopathy and a lymph node biopsy is performed,

pathologists usually have little difficulty in making the diagnosis of small lymphocytic lymphoma based on morphologic findings and immunophenotype. However, even in these patients ~70 to 75% will be found to have bone marrow involvement and the search for circulating monoclonal B lymphocytes is often positive.

The differential diagnosis of typical B cellCLL is extensive and presented in Table 112-1. Immunophenotyping will eliminate the T cell disorders and can often help sort out other B cell malignancies. For example, only mantle cell lymphoma and typical B cell CLL are usually CD5 positive. Typical B cell small lymphocytic lymphoma can be confused with other B cell disorders including lymphoplasmacytic lymphoma (i.e., the tissue manifestation of Waldenstrom's macroglobulinemia), nodal marginal zone B cell lymphoma, and mantle cell lymphoma. In addition, some small lymphocytic lymphomas have areas of large cells that can lead to confusion with diffuse large B cell lymphoma. An expert hematopathologist is vital for making this distinction.

Typical B cellCLL is often found incidentally when a complete blood count is done for another reason. However, complaints that might lead to the diagnosis include fatigue, frequent infections, and new lymphadenopathy. The diagnosis of typical B cell CLL should be considered in a patient presenting with an autoimmune hemolytic anemia or autoimmune thrombocytopenia. B cell CLL has also been associated with red cell aplasia. When this disorder presents as lymphoma, the most common abnormality is asymptomatic new lymphadenopathy, with or without splenomegaly. The staging systems used to predict prognosis in patients with typical B cell CLL are presented in Table 112-7. TheIPI for non-Hodgkin's lymphomas, which also predicts prognosis in these patients, is presented in Table 112-9. The evaluation of a new patient with typical B cell CLL/small lymphocytic lymphoma will include many of the studies included in Table 112-11, which describes the initial evaluation of a new patient with non-Hodgkin's lymphoma. In addition, particular attention needs to be given to detecting immune abnormalities such as autoimmune hemolytic anemia, autoimmune thrombocytopenia, hypogammaglobulinemia, and red cell aplasia.

TREATMENT

Patients whose presentation is typical B cellCLL with no manifestations of the disease other than bone marrow involvement and lymphocytosis (i.e., Rai stage O and Binet stage A;Table 112-7) can be followed without specific therapy for their malignancy. These patients have a median survival>10 years, and some will never require therapy for this disorder. If the patient has an adequate number of circulating normal blood cells and is asymptomatic, many physicians would not initiate therapy for patients in the intermediate stage of the disease manifested by lymphadenopathy and/or hepatosplenomegaly. However, the median survival for these patients is ~7 years, and most will require treatment in the first few years of follow-up. Patients who present with bone marrow failure (i.e., Rai stage III or IV or Binet stage C) will require initial therapy in almost all cases. These patients have a serious disorder with a median survival of only 1.5 years. It must be remembered that immune manifestations of typical B cell CLL should be managed independently of specific antileukemia therapy. For example, glucocorticoid therapy for autoimmune cytopenias and g globulin replacement for patients with hypogammaglobulinanemia should be used whether or not antileukemia therapy is given.

Patients who present primarily with lymphoma and have a lowIPIscore have a 5-year survival of ~75%, but those with a high IPI score have a 5-year survival of <40% and are more likely to require early therapy.

The most common treatments for patients with typical B cellCLL/small lymphocytic lymphoma have been the use of single-agent chlorambucil or single-agent fludarabine. Chlorambucil can be administered orally with few immediate side effects, while fludarabine is administered intravenously and is associated with significant immune suppression. However, fludarabine is by far the more active agent and is the only drug associated with a significant incidence of complete remission. For young patients presenting with leukemia requiring therapy, fludarabine is today the treatment of choice. Because fludarabine is an effective second-line agent in patients with tumors unresponsive to chlorambucil, the latter agent is often chosen in elderly patients who require therapy. Many patients who present with lymphoma will receive a combination chemotherapy regimen used in other lymphomas such as CVP (cyclophosphamide, vincristine, and prednisone), or CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone). Young patients with this disease can be candidates for bone marrow transplantation. Allogeneic bone marrow transplantation can be curative but is associated with a significant treatment-related mortality. The place of autologous transplantation in patients with this disorder remains uncertain.

Molecular analysis of immunoglobulin gene sequences inCLL has demonstrated that about half the patients have tumors expressing mutated immunoglobulin genes and half have tumors expressing unmutated or germ-line immunoglobulin sequences. Patients with unmutated immunoglobulins tend to have a more aggressive clinical course and are less responsive to therapy. Unfortunately, immunoglobulin gene sequencing is not routinely available. CD38 expression is said to be low in the better-prognosis patients expressing mutated immunoglobulin and high in poorer-prognosis patients expressing unmutated immunoglobulin, but this test has not been confirmed as a reliable means of distinguishing the two groups.

Extranodal Marginal Zone B Cell Lymphoma of MALT Type Extranodal marginal zone B cell lymphoma ofMALTtype makes up approximately 8% of non-Hodgkin's lymphomas. This small-cell lymphoma presents in extranodal sites. It was previously considered a small lymphocytic lymphoma or sometimes a pseudolymphoma. The recognition that the gastric presentation of this lymphoma was associated with *H. pylori* infection was an important step in recognizing it as a separate entity. The clinical characteristics of extranodal marginal zone B cell lymphoma of MALT type are presented in Table 112-10.

The diagnosis of extranodal marginal zone B cell lymphoma ofMALTtype can be made accurately by an expert hematopathologist based on a characteristic pattern of infiltration of small lymphocytes that are monoclonal B cells and CD5 negative. In some cases, transformation to diffuse large B cell lymphoma occurs, and both diagnoses may be made in the same biopsy. The differential diagnosis includes benign lymphocytic infiltration of extranodal organs and other small-cell B cell lymphomas.

Extranodal marginal zone B cell lymphoma ofMALTtype may occur in the stomach,

orbit, intestine, lung, thyroid, salivary gland, skin, soft tissues, bladder, kidney, andCNS. It may present as a new mass, be found on routine imaging studies, or be associated with local symptoms such as upper abdominal discomfort in gastric lymphoma. These lymphomas are localized to the organ in question in ~40% of cases and to the organ and regional lymph nodes in ~30% of patients. However, distant metastasis can occur -- particularly with transformation to diffuse large B cell lymphoma. Many patients who develop this lymphoma will have an autoimmune or inflammatory process such as Sjogren's syndrome (salivary gland MALT), Hashimoto's thyroiditis (thyroid MALT), or *Helicobacter* gastritis (gastric MALT).

Evaluation of patients with extranodal marginal zone B cell lymphoma ofMALTtype follows the pattern set forth inTable 112-11 for staging a patient with non-Hodgkin's lymphoma. In particular, patients with gastric lymphoma need to have studies performed to document the presence or absence of *H. pylori* infection. Endoscopic studies including ultrasound can help define the extent of gastric involvement. Most patients with extranodal marginal zone B cell lymphoma of MALT type have a good prognosis, with a 5-year survival of ~75%. In patients with a low IPIscore, the 5-year survival is ~90%, while it drops to ~40% in patients with a high IPI score.

TREATMENT

Extranodal marginal zone B cell lymphoma ofMALTtype is curable when localized. Local therapy such as radiation or surgery can effect cure, and this is one of the few times where surgery might be a reasonable primary therapy for a patient with non-Hodgkin's lymphoma. Patients with gastric MALT lymphomas who are infected with *H. pylori* can achieve remission in the majority of cases with eradication of the infection. These remissions can be durable. Patients who present with more extensive disease are most often treated with single-agent chemotherapy such as chlorambucil. Coexistent diffuse large B cell lymphoma must be treated with combination chemotherapy. The additional acquired mutations that mediate the histologic progression also convey *Helicobacter* independence to the growth.

Mantle Cell Lymphoma Mantle cell lymphoma makes up ~6% of all non-Hodgkin's lymphomas. Recognized as a separate entity only in the past decade, this lymphoma was previously placed in a number of other subtypes. Its existence was confirmed by the recognition that these lymphomas have a characteristic chromosomal translocation, t(11;14) between the immunoglobulin heavy chain gene on chromosome 14 and the *bcl-1* gene on chromosome 11, and regularly overexpress the BCL-1 protein. The clinical characteristics of mantle cell lymphoma are presented inTable 112-10.

The diagnosis of mantle cell lymphoma can be made accurately by an expert hematopathologist based on morphologic findings and proof that the tumor is a B cell lymphoma. As with all subtypes of lymphoma, an adequate biopsy is important. The differential diagnosis of mantle cell lymphoma includes other small-cell B cell lymphomas. In particular, mantle cell lymphoma and small lymphocytic lymphoma share a characteristic expression of CD5. Mantle cell lymphoma usually has a slightly indented nucleus.

The most common presentation of mantle cell lymphoma is with palpable

lymphadenopathy, frequently accompanied by systemic symptoms. Approximately 70% of patients will be stage IV at the time of diagnosis, with frequent bone marrow and peripheral blood involvement. Of the extranodal organs that can be involved, gastrointestinal involvement is particularly important to recognize. Patients who present with lymphomatosis polyposis in the large intestine usually have mantle cell lymphoma. The evaluation of patients with mantle cell lymphoma involves the studies presented in Table 112-11 for staging of patients with non-Hodgkin's lymphoma. Patients who present with gastrointestinal tract involvement often have Waldeyer's ring involvement, and vice versa. The 5-year survival for all patients with mantle cell lymphoma is ~25%, with only occasional patients who present with a highIPIscore surviving 5 years and ~50% of patients with a low IPI score surviving 5 years.

TREATMENT

Current therapies for mantle cell lymphoma are unsatisfactory. Patients with localized disease might be treated with combination chemotherapy followed by radiotherapy; however, these patients are exceedingly rare. For the usual presentation with disseminated disease, treatments are unsatisfactory, with the minority of patients achieving complete remission. Aggressive combination chemotherapy regimens followed by autologous or allogeneic bone marrow transplantation are frequently offered to younger patients. For the occasional elderly, asymptomatic patient, observation followed by single-agent chemotherapy might be the most practical approach. Combined used of rituximab (anti-CD20 antibody) and chemotherapy may be associated with better response rates.

Follicular Lymphoma Follicular lymphomas make up 22% of non-Hodgkin's lymphomas worldwide and at least 30% of non-Hodgkin's lymphomas diagnosed in the United States. This type of lymphoma can be diagnosed accurately on morphologic findings alone and has been the diagnosis in the majority of patients in therapeutic trials for "low-grade" lymphoma in the past. The clinical characteristics of follicular lymphoma are presented in Table 112-10.

Evaluation of an adequate biopsy by an expert hematopathologist is sufficient to make a diagnosis of follicular lymphoma. The tumor is composed of small cleaved and large cells in varying proportions organized in a follicular pattern of growth (see Plate V-30). Confirmation of B cell immunophenotype and the existence of the t(14;18) and abnormal expression of BCL-2 protein are confirmatory. The major differential diagnosis is between lymphoma and reactive follicular hyperplasia. The coexistence of diffuse large B cell lymphoma must be considered. Patients with follicular lymphoma are often subclassified into those with predominantly small cells, those with a mixture of small and large cells, and those with predominantly large cells. While this distinction cannot be made simply or very accurately, these subdivisions do have prognostic significance. Patients with follicular lymphoma with predominantly large cells have a higher proliferative fraction, progress more rapidly, and have a shorter overall survival with simple chemotherapy regimens.

The most common presentation for follicular lymphoma is with new, painless lymphadenopathy. Multiple sites of lymphoid involvement are typical, and unusual sites such as epitrochlear nodes are sometimes seen. However, essentially any organ can be

involved, and extranodal presentations do occur. Most patients do not have fevers, sweats, or weight loss, and anIPIscore of 0 or 1 is found in ~50% of patients. Fewer than 10% of patients have a high (i.e., 4 or 5) IPI score. The staging evaluation for patients with follicular lymphoma should include the studies included inTable 112-11 for the staging of patients with non-Hodgkin's lymphoma.

TREATMENT

Follicular lymphoma is one of the malignancies most responsive to chemotherapy and radiotherapy. In addition, as many as 25% of the patients undergo spontaneous regression -- usually transient -- when followed without therapy. In an asymptomatic patient, no initial treatment and watchful waiting can be an appropriate management strategy and is particularly likely to be adopted for older patients. For patients who do require treatment, single-agent chlorambucil or cyclophosphamide or combination chemotherapy withCVP orCHOP are most frequently used. With adequate treatment, between 50 and 75% of patients will achieve a complete remission. While most patients relapse (median response duration is about 2 years), at least 20% of complete responders will remain in remission for >10 years. For the rare patient with localized follicular lymphoma, involved field radiotherapy produces an excellent treatment result.

A number of new therapies have been shown to be active in the treatment of patients with follicular lymphoma. These include new cytotoxic agents such as fludarabine, interferona, monoclonal antibodies with or without radionuclides, and lymphoma vaccines. In patients treated with a doxorubicin-containing combination chemotherapy regimen, interferona given to patients in complete remission seems to prolong survival. The monoclonal antibody rituximab can cause objective responses in 35 to 50% of patients with relapsed follicular lymphoma, and radiolabeled antibodies appear to have response rates well in excess of 50%. Trials with tumor vaccines have been encouraging. Both autologous and allogeneic hematopoietic stem cell transplantation yield high complete response rates in patients with relapsed follicular lymphoma, and long-term remissions can occur.

Patients with follicular lymphoma with a predominance of large cells have a shorter survival when treated with single-agent chemotherapy but seem to benefit from receiving an anthracycline-containing combination chemotherapy regimen. When their disease is treated aggressively, the overall survival for such patients is no lower than for patients with other follicular lymphomas, and the failure-free survival is superior.

Patients with follicular lymphoma have a high rate of histologic transformation to diffuse large B cell lymphoma (~7% per year). This is recognized ~40% of the time during the course of the illness by repeat biopsy and is present in almost all patients at autopsy. This transformation is usually heralded by rapid growths of lymph nodes -- often localized -- and the development of systemic symptoms such as fevers, sweats, and weight loss. Although these patients have a poor prognosis, aggressive combination chemotherapy regimens can sometimes cause a complete remission in the diffuse large B cell lymphoma, usually leaving the patient with persisting follicular lymphoma.

Diffuse Large B Cell Lymphoma Diffuse large B cell lymphoma is the most common type of non-Hodgkin's lymphoma, representing approximately one-third of all cases.

This lymphoma makes up the majority of cases in previous clinical trials of "aggressive" or "intermediate-grade" lymphoma. The clinical characteristics of diffuse large B cell lymphoma are presented in Table 112-10.

The diagnosis of diffuse large B cell lymphoma can be made accurately by an expert hematopathologist when review of an adequate biopsy and proof of B cell immunophenotype are available (seePlate V-22). Cytogenetic and molecular genetic studies are not necessary for diagnosis, but some evidence has accumulated that patients who overexpress the BCL-2 protein might be more likely to relapse than others. Patients with prominent mediastinal involvement are sometimes diagnosed as a separate subgroup having primary mediastinal diffuse large B cell lymphoma. This latter group of patients has a younger median age (i.e., 37 years) and a female predominance (66%). Subtypes of diffuse large B cell lymphoma, including those with an immunoblastic subtype and tumors with extensive fibrosis, are recognized by pathologists but do not appear to have important, independent prognostic significance.

Diffuse large B cell lymphoma can present as either primary lymph node disease or at extranodal sites. More than 50% of patients will have some site of extranodal involvement at diagnosis, with the most common sites being the gastrointestinal tract and bone marrow, each being involved in 15 to 20% of patients. Essentially any organ can be involved, making a diagnostic biopsy imperative. For example, diffuse large B cell lymphoma of the pancreas has a much better prognosis than pancreatic carcinoma but would be missed without biopsy. Primary diffuse large B cell lymphoma of the brain is being diagnosed with increasing frequency.

The initial evaluation of patients with diffuse large B cell lymphoma involves the studies presented inTable 112-11 for staging of patients with non-Hodgkin's lymphoma. After a careful staging evaluation, ~50% of patients will be found to have stage I or II disease and ~50% will have widely disseminated lymphoma. Bone marrow biopsy shows involvement by lymphoma in about 15% of cases, with marrow involvement by small cells more frequent than with large cells.

TREATMENT

The initial treatment of all patients with diffuse large B cell lymphoma should be with a combination chemotherapy regimen. The most popular regimen in the United States isCHOP, although a variety of other anthracycline-containing combination chemotherapy regimens appear to be equally efficacious. Patients with stage I or nonbulky stage II can be effectively treated with three to four cycles of combination chemotherapy followed by involved field radiotherapy. The results are at least equal and probably superior to six to eight cycles of combination therapy, and cure rates of 60 to 70% in stage II disease and 80 to 90% in stage I disease can be expected.

For patients with bulky stage II, stage III, or stage IV, six to eight cycles of combination chemotherapy regimen such asCHOP are usually administered. A frequent approach would be to administer four cycles of therapy and then reevaluate. If the patient has achieved a complete remission after four cycles, two more cycles of treatment might be given and then therapy discontinued. Using this approach, ~60 to 70% of patients can be expected to achieve a complete remission, and 50 to 70% of complete responders

will be cured. The chances for a favorable response to treatment are predicted by theIPI. In fact, the IPI was developed specifically to predict outcome in patients with diffuse large-cell lymphoma. For the 35% of patients with a low IPI score of 0 to 1, the 5-year survival is >70%, while for the 20% of patients with a high IPI score of 4 to 5, the 5-year survival is ~20%. A number of other factors, including molecular features of the tumor, levels of circulating cytokines and soluble receptors, and other surrogate markers, have been shown to influence prognosis. However, they have not been validated as rigorously as the IPI and have not been uniformly applied clinically.

Because a large number of patients with diffuse large B cell lymphoma are either initially refractory to therapy or relapse after apparently effective chemotherapy,>50% of patients will be candidates for salvage treatment at some point. Alternative combination chemotherapy regimens can induce complete remission in as many as 50% of these patients, but long-term disease-free survival is seen in £10%. Autologous bone marrow transplantation has been shown to be superior to salvage chemotherapy at usual doses and leads to long-term disease-free survival in ~40% of patients whose lymphomas remain chemotherapy-sensitive after relapse.

Burkitt's Lymphoma/Leukemia Burkitt's lymphoma/leukemia is a rare disease in adults in the United States, making up <1% of non-Hodgkin's lymphomas, but it makes up ~30% of childhood non-Hodgkin's lymphoma. Burkitt's leukemia, or L3 ALL, makes up a small proportion of childhood and adult acute leukemias. The clinical features of Burkitt's lymphoma occurring in adults are presented inTable 112-10.

Burkitt's lymphoma can be diagnosed morphologically by an expert hematopathologist with a high degree of accuracy. The cells are homogeneous in size and shape (seePlate V-4). Demonstration of a very high proliferative fraction and the presence of the t(8;14) or one of its variants, t(2;8) (*c-myc* and the l light chain gene) or t(8;22) (*c-myc* and the k light chain gene), can be confirmatory. Burkitt's cell leukemia is recognized by the typical medium-sized cells with round nuclei, multiple nucleoli, and basophilic cytoplasm with cytoplasmic vacuoles. Demonstration of a B cell immunophenotype and one of the above-noted cytogenetic abnormalities is confirmatory.

The three distinct clinical forms of Burkitt's lymphoma that are recognized are endemic, sporadic, and immunodeficiency-associated. Endemic and sporadic Burkitt's lymphomas occur frequently in children in Africa, and the sporadic form in western countries. Immunodeficiency-associated Burkitt's lymphoma is seen in patients with HIV infection.

Pathologists sometimes have difficulty distinguishing between Burkitt's lymphoma and diffuse large B cell lymphoma. In the past, a separate subgroup of non-Hodgkin's lymphoma intermediate between the two was recognized. When tested, this subgroup could not be diagnosed accurately. Distinction between the two major types of B cell aggressive non-Hodgkin's lymphoma can sometimes be made based on the extremely high proliferative fraction seen in patients with Burkitt's lymphoma (i.e., essentially 100% of tumor cells are in cycle) caused by *c-myc* deregulation.

Most patients in the United States with Burkitt's lymphoma present with peripheral lymphadenopathy or an intraabdominal mass. The disease is typically rapidly progressive and has a propensity to metastasize to theCNS. Initial evaluation should

always include an examination of cerebral spinal fluid to rule out metastasis in addition to the other staging evaluations noted inTable 112-11. Once the diagnosis of Burkitt's lymphoma is suspected, a diagnosis must be made promptly and staging evaluation must be accomplished expeditiously. This is the most rapidly progressive human tumor, and any delay in initiating therapy can adversely affect the patient's prognosis.

TREATMENT

Treatment of Burkitt's lymphoma in both children and adults involves the use of intensive combination chemotherapy regimens incorporating administered high doses of cyclophosphamide. Prophylactic therapy to theCNS is mandatory and incorporated in all modern regimens. Burkitt's lymphoma was one of the first cancers shown to be curable by chemotherapy. Today, cure can be expected in 70% of both children and young adults when effective therapy is administered precisely. Salvage therapy has been generally ineffective in patients failing the initial treatment, emphasizing the importance of the initial treatment approach.

Other B Cell Lymphoid Malignancies *B-cell prolymphocytic leukemia* involves blood and marrow infiltration by large lymphocytes with prominent nucleoli. Patients typically have a high white cell count, splenomegaly, and minimal lymphadenopathy. The chances for a complete response to therapy are poor.

Hairy cell leukemia is a rare disease that presents predominantly in older males. Typical presentation involves pancytopenia, although occasional patients will have a leukemic presentation. Splenomegaly is usual. The malignant cells appear to have "hairy" projections on light and electron microscopy and show a characteristic staining pattern with tartrate-resistant acid phosphatase. Bone marrow is typically not able to be aspirated, and biopsy shows a pattern of fibrosis with diffuse infiltration by the malignant cells. Patients with this disorder are prone to unusual infections including infection by *Mycobacterium avium intracellulare*, and vasculitic syndromes have been described. Hairy cell leukemia is responsive to chemotherapy with interferona, pentostatin, or cladribine, with the latter being the usually preferred treatment. Clinical complete remissions with cladribine occur in the majority of patients, and long-term disease-free survival is frequent.

Splenic marginal zone lymphoma involves infiltration of the splenic white pulp by small, monoclonal B lymphocytes. This is a rare disorder that can present as leukemia as well as lymphoma. Definitive diagnosis is often made at splenectomy, which is also an effective therapy. This is an extremely indolent disorder, but when chemotherapy is required, the most usual treatment has been chlorambucil.

Lymphoplasmacytic lymphoma is the tissue manifestation of Waldenstrom's macroglobulinemia (Chap. 113). This type of lymphoma has been associated with chronic hepatitis C virus infection, and an etiologic association has been proposed. Patients typically present with lymphadenopathy, splenomegaly, bone marrow involvement, and occasionally peripheral blood involvement. The tumor cells do not express CD5. Patients often have a monoclonal IgM protein, high levels of which can dominate the clinical picture with the symptoms of hyperviscosity. Treatment of lymphoplasmacytic lymphoma can be aimed primarily at reducing the abnormal protein,

if present, but will usually also involve chemotherapy. Chlorambucil, fludarabine, and cladribine have been utilized. The median 5-year survival for patients with this disorder is ~60%.

Nodal marginal zone lymphoma, also known as *monocytoid B cell lymphoma*, represents ~1% of non-Hodgkin's lymphomas. This lymphoma has a slight female predominance and presents with disseminated disease (i.e., stage III or IV) in 75% of patients. Approximately one-third of patients have bone marrow involvement, and a leukemic presentation occasionally occurs. The staging evaluation and therapy should use the same approach as used for patients with follicular lymphoma. Approximately 60% of the patients with nodal marginal zone lymphoma will survive 5 years after diagnosis.

PRECURSOR CELL T CELL MALIGNANCIES

Precursor T Cell Lymphoblastic Leukemia/Lymphoma Precursor T cell malignancies can present either as ALL or as an aggressive lymphoma. These malignancies are more common in children and young adults, with males more frequently affected than females.

Precursor T cell ALL can present with bone marrow failure, although the severity of anemia, neutropenia, and thrombocytopenia is often less than in precursor B cell ALL. These patients sometimes have very high white cell counts, a mediastinal mass, lymphadenopathy, and hepatosplenomegaly. Precursor T cell lymphoblastic lymphoma is most often found in young men presenting with a large mediastinal mass and pleural effusions. Both presentations have a propensity to metastasize to theCNS, and CNS involvement is often present at diagnosis.

TREATMENT

Children with precursor T cell ALL seem to benefit from very intensive remission induction and consolidation regimens. The majority of patients treated in this manner can be cured. Older children and young adults with precursor T cell lymphoblastic lymphoma are also often treated with "leukemia-like" regimens. Patients who present with localized disease have an excellent prognosis. However, advanced age is an adverse prognostic factor. Adults with precursor T cell lymphoblastic lymphoma who present with highLDHlevels or bone marrow orCNSinvolvement are often offered bone marrow transplantation as part of their primary therapy.

MATURE (PERIPHERAL) T CELL DISORDERS

Mycosis Fungoides Mycosis fungoides is also known as *cutaneous T cell lymphoma*. This lymphoma is more often seen by dermatologists than internists. The median age of onset is in the mid-fifties, and the disease is more common in males and in blacks.

Mycosis fungoides is an indolent lymphoma with patients often having several years of eczematous or dermatitic skin lesions before the diagnosis is finally established. The skin lesions progress from patch stage to plaque stage to cutaneous tumors. Early in the disease, biopsies are often difficult to interpret, and the diagnosis may only become

apparent by observing the patient over time. In advanced stages, the lymphoma can metastasize to lymph nodes and visceral organs. A particular syndrome in patients with this lymphoma involves erythroderma and circulating tumor cells. This is known as Sezary's syndrome.

Rare patients with localized early stage mycosis fungoides can be cured with radiotherapy, often total-skin electron beam irradiation. More advanced disease has been treated with topical glucocorticoids, topical nitrogen mustard, phototherapy, psoralen with ultraviolet A (PUVA), electron beam radiation, interferon, and systemic cytotoxic therapy. Unfortunately, these treatments are palliative.

Adult T Cell Lymphoma/Leukemia Adult T cell lymphoma/leukemia is one manifestation of infection by theHTLV-I retrovirus. Patients can be infected through transplacental transmission, blood transfusion, and by sexual transmission of the virus. Patients who acquire the virus from their mother through breast milk are most likely to develop lymphoma, but the risk is still only 2.5% and the latency averages 55 years. Tropical spastic paraparesis, another manifestation of HTLV-I infection (Chap. 191), occurs after a shorter latency (1 to 3 years) and is most common in people who acquire the virus during adulthood from transfusion or sex.

The diagnosis of adult T cell lymphoma/leukemia is made when an expert hematopathologist recognizes the typical morphologic picture, a T cell immunophenotype (i.e., CD4 positive) of malignant cells has been demonstrated, and the existence of antibodies to HTLV-I is proven. Examination of the peripheral blood will usually reveal characteristic, pleomorphic abnormal CD4-positive cells with indented nuclei, which have been called "flower" cells (seePlate V-40).

A subset of patients have a smoldering clinical course and long survival, but most patients present with an aggressive disease manifested by lymphadenopathy, hepatosplenomegaly, skin infiltration, hypercalcemia, lytic bone lesions, and elevatedLDHlevels. The skin lesions can be papules, plaques, tumors, and ulcerations. Bone marrow involvement is not usually extensive, and anemia and thrombocytopenia are not usually prominent. Although treatment by combination chemotherapy regimens can result in objective responses, true complete remissions are unusual, and the median survival of patients is about 7 months.

Anaplastic Large T/Null Cell Lymphoma Anaplastic large T/null cell lymphoma was previously usually diagnosed as undifferentiated carcinoma or malignant histiocytosis. Discovery of the CD30, or Ki-1, antigen and the recognition that some patients with previously unclassified malignancies displayed this antigen led to the identification of a new type of lymphoma. Subsequently, discovery of the t(2;5) and the resultant frequent overexpression of the anaplastic lymphoma kinase (alk) protein confirmed the existence of this entity. This lymphoma accounts for ~2% of all non-Hodgkin's lymphomas. The clinical characteristics of patients with anaplastic large T/null cell lymphoma are presented inTable 112-10.

The diagnosis of anaplastic large T/null cell lymphoma is made when an expert hematopathologist recognizes the typical morphologic picture and a T cell or null cell immunophenotype is demonstrated along with CD30 positivity. Documentation of the

t(2;5) and/or overexpression of alk protein confirm the diagnosis. Some diffuse large B cell lymphomas can also have an anaplastic appearance but have the same clinical course or response to therapy as other diffuse large B cell lymphomas.

Patients with anaplastic large T/cell null cell lymphoma are typically young (median age, 33 years) and male (~70%). Some 50% of patients present in stage I/II, and the remainder with more extensive disease. Systemic symptoms and elevatedLDHlevels are seen in about one-half of patients. Bone marrow and the gastrointestinal tract are rarely involved, but skin involvement is frequent. Some patients with disease confined to the skin have a different and more indolent disorder that has been termed *cutaneous anaplastic large T/null cell lymphoma* and might be related to lymphomatoid papulosis.

TREATMENT

Treatment regimens appropriate for other aggressive lymphomas, such as diffuse large B cell lymphoma, should be utilized in patients with anaplastic large T/null cell lymphoma. Surprisingly, given the anaplastic appearance, this disorder has the best survival rate of any aggressive lymphoma. The 5-year survival is>75%. While traditional prognostic factors such as the IPIpredict treatment outcome, overexpression of the alk protein is an important prognostic factor, with patients overexpressing this protein having a superior treatment outcome.

Peripheral T Cell Lymphoma The peripheral T cell lymphomas make up a heterogenous morphologic group of aggressive neoplasms that share a mature T cell immunophenotype. They represent ~7% of all cases of non-Hodgkin's lymphoma. A number of distinct clinical syndromes are included in this group of disorders. The clinical characteristics of patients with peripheral T cell lymphoma are presented inTable 112-10.

The diagnosis of peripheral T cell lymphoma, or any of its specific subtypes, requires an expert hematopathologist, an adequate biopsy, and immunophenotyping. Most peripheral T cell lymphomas are CD4-positive, but a few will be CD8-positive, both CD4- and CD8-positive, or have anNK-cell immunophenotype. No characteristic genetic abnormalities have yet been identified, but translocations involving the T cell antigen receptor genes on chromosomes 7 or 14 may be detected. The differential diagnosis of patients suspected of having peripheral T cell lymphoma includes reactive T cell infiltrative processes. In some cases, demonstration of a monoclonal T cell population using T cell receptor gene rearrangement studies will be required to make a diagnosis.

The initial evaluation of a patient with a peripheral T cell lymphoma should include the studies inTable 112-11 for staging patients with non-Hodgkin's lymphoma. Unfortunately, patients with peripheral T cell lymphoma usually present with adverse prognostic factors, with >80% of patients having anIPIscore ³2 and >30% having an IPI score ³4. As this would predict, peripheral T cell lymphomas are associated with a poor outcome, and only 25% of the patients survive 5 years after diagnosis. Treatment regimens are the same as those used for diffuse large B cell lymphoma, but patients with peripheral T cell lymphoma have a poorer response to treatment. Because of this poor treatment outcome, hematopoietic stem cell transplantation is often considered early in the care of young patients.

A number of specific clinical syndromes are seen in the peripheral T cell lymphomas. *Angioimmunoblastic T cell lymphoma* is one of the more common subtypes, making up ~20% of T cell lymphomas. These patients typically present with generalized lymphadenopathy, fever, weight loss, skin rash, and polyclonal hypergammaglobunenemia. In some cases, it is difficult to separate patients with a reactive disorder from those with true lymphoma.

Extranodal T/NK cell lymphoma of nasal type has also been called *angiocentric lymphoma* and was previously termed *lethal midline granuloma*. This disorder is more frequent in Asia and South America than in the United States and Europe. Although most frequent in the upper airway, it can involve other organs. The course is aggressive, and patients frequently have the hemophagocytic syndrome. When marrow and blood involvement occur, distinction between this disease and leukemia might be difficult. Some patients will respond to aggressive combination chemotherapy regimens, but the overall outlook is poor.

Enteropathy-type intestinal T cell lymphoma is a rare disorder that occurs in patients with untreated gluten-sensitive enteropathy. Patients are frequently wasted and sometimes present with intestinal perforation. The prognosis is poor. *Hepatosplenicgd T cell lymphoma* is a systemic illness that presents with sinusoidal infiltration of the liver, spleen, and bone marrow by malignant T cells. Tumor masses generally do not occur. The disease is associated with systemic symptoms and is often difficult to diagnosis. Treatment outcome is poor. *Subcutaneous panniculitis-like T cell lymphoma* is a rare disorder that is often confused with panniculitis. Patients present with multiple subcutaneous nodules, which progress and can ulcerate. Hemophagocytic syndrome is common. Response to therapy is poor. The development of the hemophagocytic syndrome (profound anemia, ingestion of erythrocytes by monocytes and macrophages) in the course of any peripheral T cell lymphoma is generally associated with a fatal outcome.

HODGKIN'S DISEASE

Nodular Lymphocyte-Predominant Hodgkin's Disease Nodular lymphocyte predominant Hodgkin's disease is now recognized as an entity distinct from classic Hodgkin's disease. Previous classification systems recognized that biopsies from a subset of patients diagnosed as having Hodgkin's disease contained a predominance of small lymphocytes and rare Sternberg-Reed cells. In recent years, it was recognized that a subset of these patients had a nodular growth pattern and a clinical course that varied from that of patients with classic Hodgkin's disease. This is an unusual clinical entity and represents <5% of cases of Hodgkin's disease.

Nodular lymphocyte-predominant Hodgkin's disease has a number of characteristics that suggest its relationship to non-Hodgkin's lymphoma. These include a clonal proliferation of B cells and a distinctive immunophenotype; tumor cells express J chain and display CD45 and epithelial membrane antigen (ema) and do not express two markers normally found on Sternberg-Reed cells, CD30 and CD15. This lymphoma tends to have a chronic, relapsing course and sometimes transforms to diffuse large B cell lymphoma.

The treatment of patients with nodular lymphocyte-predominant Hodgkin's disease is controversial. Some clinicians favor no treatment and merely close follow-up. In the United States, most physicians will treat localized disease with radiotherapy and disseminated disease with regimens utilized for patients with classic Hodgkin's disease. Regardless of the therapy utilized, most series report a long-term survival of>80%.

Classical Hodgkin's Disease Hodgkin's disease occurs in ~8000 patients in the United States each year, and the disease does not appear to be increasing in frequency. Most patients present with palpable lymphadenopathy that is nontender; in most patients, these lymph nodes are in the neck, supraclavicular area, and axilla. More than half the patients will have mediastinal adenopathy at diagnosis, and this is sometimes the initial manifestation. Subdiaphragmatic presentation of Hodgkin's disease is unusual and more common in older males. Approximately one-third of patients present with fevers, night sweats, and/or weight loss -- B symptoms in the Ann Arbor staging classification (Table 112-8). Occasionally, Hodgkin's disease can present as a fever of unknown origin. This is more common in older patients who are found to have mixed-cellularity Hodgkin's disease in an abdominal site. Rarely, the fevers persist for days to weeks, followed by afebrile intervals and then recurrence of the fever. This pattern is known as *Pel-Epstein fever*. Hodgkin's disease can occasionally present with unusual manifestations. These include severe and unexplained itching, cutaneous disorders such as erythema nodosum and ichthyosiform atrophy, paraneoplastic cerebellar degeneration and other distant effects on theCNS, nephrotic syndrome, immune hemolytic anemia and thrombocytopenia, hypercalcemia, and pain in lymph nodes on alcohol ingestion.

The diagnosis of Hodgkin's disease is established by review of an adequate biopsy specimen by an expert hematopathologist. In the United States, most patients would be classified as having nodular sclerosing Hodgkin's disease, with a minority of patients having mixed-cellularity Hodgkin's disease. Lymphocyte-predominant and lymphocyte-depleted Hodgkin's disease are rare. Mixed-cellularity Hodgkin's disease or lymphocyte-depletion Hodgkin's disease are seen more frequently in patients infected by HIV (see Plate V-18). The differential diagnosis of a lymph node biopsy suspicious for Hodgkin's disease includes inflammatory processes, mononucleosis, non-Hodgkin's lymphoma, diphenylhydantoin-induced lymphadenopathy, and nonlymphomatous malignancies.

The staging evaluation for a patient with Hodgkin's disease would typically include a careful history and physical examination; complete blood count; erythrocyte sedimentation rate; serum chemistry studies includingLDH; chest radiograph;CT scan of the chest, abdomen, and pelvis; and bone marrow biopsy. Many patients would also have a gallium scan. If radiologic expertise is available, a bipedal lymphangiogram can be helpful. Gallium scans are most useful at the completion of therapy to document remission. Staging laparotomies were once popular for most patients with Hodgkin's disease but are now done rarely because of an increased reliance on systemic rather than local therapy.

TREATMENT

Patients with localized Hodgkin's disease are cured >90% of the time. In patients with good prognostic factors, extended field radiotherapy has a high cure rate. Increasingly, patients with all stages of Hodgkin's disease are treated initially with chemotherapy. Patients with localized or good-prognosis disease receive a brief course of chemotherapy followed by radiotherapy to sites of node involvement. Patients with more extensive disease or those with B symptoms receive a complete course of chemotherapy. The most popular chemotherapy regimens used in the treatment of Hodgkin's disease include doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) and mechlorethamine, vincristine, procarbazine, and prednisone (MOPP), or combinations of the drugs in these two regimens. Today, most patients in the United States receive ABVD. Long-term disease-free survival in patients with advanced disease can be achieved in >75% of patients who lack systemic symptoms and in 50 to 70% of patients with systemic symptoms.

Patients who relapse after primary therapy of Hodgkin's disease can frequently still be cured. Patients who relapse after initial treatment only with radiotherapy have an excellent outcome when treated with chemotherapy. Patients who relapse after an effective chemotherapy regimen are usually not curable with subsequent chemotherapy administered at standard doses. However, patients with a long initial remission can be an exception to this rule. Autologous bone marrow transplantation can cure half of patients who fail effective chemotherapy regimens.

Because of the very high cure rate in patients with Hodgkin's disease, long-term complications have become a major focus for clinical research. In fact, in some series of patients with early-stage disease, more patients died from late complications of therapy than from Hodgkin's disease itself. This is particularly true in patients with localized disease. The most serious late side effects include second malignancies and cardiac injury. Patients are at risk for the development of acute leukemia in the first 10 years after treatment with combination chemotherapy regimens that contain alkylating agents. The risk for development of acute leukemia appears to be greater after MOPP-like regimens than with ABVD. The development of carcinomas as a complication of treatment for Hodgkin's disease has become a major problem. These tumors usually occur[3]10 years after treatment and are associated more with radiotherapy than with chemotherapy. For this reason, young women treated with thoracic radiotherapy for Hodgkin's disease should institute screening mammograms 5 to 10 years after treatment, and all patients who receive thoracic radiotherapy for Hodgkin's disease should be discouraged from smoking. Thoracic radiation also accelerates coronary artery disease, and patients should be encouraged to minimize risk factors for coronary artery disease such as smoking and elevated cholesterol levels.

A number of other late side effects from the treatment of Hodgkin's disease are well known. Patients who receive thoracic radiotherapy are at very high risk for the eventual development of hypothyroidism and should be observed for this complication; intermittent measurement of thyrotropin should be made to identify the condition before it becomes symptomatic. Lhermitte's syndrome occurs in ~15% of patients who receive thoracic radiotherapy. This syndrome is manifested by an "electric shock" sensation into the lower extremities on flexion of the neck. Infertility is a concern for all patients undergoing treatment for Hodgkin's disease. In both women and men, the risk of permanent infertility is age-related, with younger patients more likely to recover fertility.

In addition, treatment withABVDrather thanMOPPincreases the chances to retain fertility.

LYMPHOMA-LIKE DISORDERS

The most common condition that pathologists and clinicians might confuse with lymphoma is reactive, atypical lymphoid hyperplasia. Patients might have localized or disseminated lymphadenopathy and might have the systemic symptoms characteristic of lymphoma. Underlying causes include a drug reaction to diphenylhydantoin or carbamezepine. Immune disorders such as rheumatoid arthritis and lupus erythematosus, viral infections such as cytomegalovirus andEBV, and bacterial infections such as cat-scratch disease may cause adenopathy (Chap. 63). In the absence of a definitive diagnosis after initial biopsy, continued follow-up, further testing, and repeated biopsies, if necessary, are the appropriate approach rather than instituting therapy.

Specific conditions that can be confused with lymphoma include *Castleman's disease*, which can present with localized or disseminated lymphadenopathy; some patients have systemic symptoms. The disseminated form is often accompanied by anemia and polyclonal hypergammaglobulinemia, and the condition seems to be related to an overproduction of interleukin 6, possibly produced by human herpesvirus 8. Patients with localized disease can be treated effectively with local therapy, while the initial treatment for patients with disseminated disease is usually with systemic glucocorticoids.

Sinus histiocytosis with massive lymphadenopathy (*Rosai-Dorfman's disease*) usually presents with bulky lymphadenopathy in children or young adults. The disease is usually nonprogressive and self-limited, but patients can manifest autoimmune hemolytic anemia.

Lymphomatoid papulosis is a cutaneous lymphoproliferative disorder that is often confused with anaplastic large-cell lymphoma involving the skin. The cells of lymphomatoid papulosis are similar to those seen in lymphoma and stain for CD30, and T cell receptor gene rearrangements are sometimes seen. However, the condition is characterized by waxing and waning skin lesions that usually heal, leaving small scars. In the absence of effective communication between the clinician and the pathologist regarding the clinical course in the patient, this disease will be misdiagnosed. Since the clinical picture is usually benign, misdiagnosis is a serious mistake.

113. PLASMA CELL DISORDERS - *Dan L. Longo*

GENERAL PRINCIPLES

The *plasma cell disorders* are monoclonal neoplasms related to each other by virtue of their development from common progenitors in the B lymphocyte lineage. Multiple myeloma, Waldenstrom's macroglobulinemia, primary amyloidosis (Chap. 319), and the heavy chain diseases comprise this group and may be designated by a variety of synonyms such as *monoclonal gammopathies*, *paraproteinemias*, *plasma cell dyscrasias*, and *dysproteinemias*. Mature B lymphocytes destined to produce IgG bear surface immunoglobulin molecules of both M and G heavy chain isotypes with both isotypes having identical idiotypes (variable regions). Under normal circumstances, maturation to antibody-secreting plasma cells is stimulated by exposure to the antigen for which the surface immunoglobulin is specific; however, in the plasma cell disorders the control over this process is lost. The clinical manifestations of all the plasma cell disorders relate to the expansion of the neoplastic cells, to the secretion of cell products (immunoglobulin molecules or subunits, lymphokines), and to some extent to the host's response to the tumor.**Normal development of B lymphocytes is discussed in Chap. 305.*

There are three categories of structural variation among immunoglobulin molecules that form antigenic determinants, and these are used to classify immunoglobulins (Chap. 305). *Isotypes* are those determinants that distinguish among the main classes of antibodies of a given species and are the same in all normal individuals of that species. Therefore, isotypic determinants are, by definition, recognized by antibodies from a distinct species (heterologous sera) but not by antibodies from the same species (homologous sera). There are five heavy chain isotypes (M, G, A, D, E) and two light chain isotypes (k, l). *Allotypes* are distinct determinants that reflect regular small differences between individuals of the same species in the amino acid sequences of otherwise similar immunoglobulins. These differences are determined by allelic genes; by definition, they are detected by antibodies made in the same species. *Idiotypes* are the third category of antigenic determinants. They are unique to the molecules produced by a given clone of antibody-producing cells. Idiotypes are formed by the unique structure of the antigen-binding portion of the molecule.

Antibody molecules (Fig. 305-8) are composed of two heavy chains (mol wt ~50,000) and two light chains (mol wt ~25,000). Each chain has a constant portion (limited amino acid sequence variability) and a variable region (extensive sequence variability). The light and heavy chains are linked by disulfide bonds and are aligned so that their variable regions are adjacent to one another. This variable region forms the antigen recognition site of the antibody molecule; its unique structural features form a particular set of determinants, or idiotypes, that are reliable markers for a particular clone of cells because each antibody is formed and secreted by a single clone. Each chain is specified by distinct genes, synthesized separately, and assembled into an intact antibody molecule after translation (Fig. 113-1). Because of the mechanics of the gene rearrangements necessary to specify the immunoglobulin variable regions (VDJ joining for the heavy chain, VJ joining for the light chain), a particular clone rearranges only one of the two chromosomes to produce an immunoglobulin molecule of only one light chain isotype and only one allotype (allelic exclusion). After exposure to antigen, the variable

region may become associated with a new heavy chain isotype (class switch). Each clone of cells performs these sequential gene arrangements in a unique way. This results in each clone producing a unique immunoglobulin molecule. In most cells, light chains are synthesized in slight excess, are secreted as free light chains by plasma cells, and are cleared by the kidney, but <10 mg of such light chains is excreted per day.

Electrophoretic analysis of components of the serum proteins permits determination of the amount of immunoglobulin in the serum (Fig. 113-2). The variety of immunoglobulins move heterogeneously in an electric field and form a broad peak in the gamma region. The gamma globulin region of the electrophoretic pattern is usually increased in the sera of patients and animals with plasma cell tumors. There is a sharp spike in this region called an *M component* (M for monoclonal). Less commonly, the M component may appear in the $beta_2$ or $alpha_2$globulin region. The antibody must be present at a concentration of at least 5 g/L (0.5 g/dL) to be detectable by this method. This corresponds to approximately 10_9cells producing the antibody. Confirmation that such an M component is truly monoclonal relies on the use of immunoelectrophoresis that shows a single light and heavy chain type. Hence immunoelectrophoresis and electrophoresis provide qualitative and quantitative assessment of the M component, respectively. Once the presence of an M component has been confirmed, electrophoresis provides the more practical information for managing patients with monoclonal gammopathies. In a given patient, the amount of M component in the serum is a reliable measure of the tumor burden. This makes the M component an excellent tumor marker, yet it is not specific enough to be used to screen asymptomatic patients. In addition to the plasma cell disorders, M components may be detected in other lymphoid neoplasms such as chronic lymphocytic leukemia and lymphomas of B or T cell origin; nonlymphoid neoplasms such as chronic myeloid leukemia, breast cancer, and colon cancer; a variety of nonneoplastic conditions such as cirrhosis, sarcoidosis, parasitic diseases, Gaucher's disease, and pyoderma gangrenosum; and a number of autoimmune conditions, including rheumatoid arthritis, myasthenia gravis, and cold agglutinin disease. A very rare skin disease known as lichen myxedematosus or papular mucinosis is associated with a monoclonal gammopathy. Highly cationic IgG is deposited in the dermis of patients with this disease. This organ specificity may reflect the specificity of the antibody for some antigenic component of the dermis.

The nature of the M component is variable in plasma cell disorders. It may be an intact antibody molecule of any heavy chain subclass, or it may be an altered antibody or fragment. Isolated light or heavy chains may be produced. In some plasma cell tumors such as extramedullary or solitary bone plasmacytomas, less than a third of patients will have an M component. In about 20% of myelomas, only light chains are produced and in most cases are secreted in the urine as Bence Jones proteins. The frequency of myelomas of a particular heavy chain class is roughly proportional to the serum concentration, and therefore IgG myelomas are more common than IgA and IgD myelomas.

MULTIPLE MYELOMA

Definition Multiple myeloma represents a malignant proliferation of plasma cells derived from a single clone. The terms *multiple myeloma* and *myeloma* may be used

interchangeably. The tumor, its products, and the host response to it result in a number of organ dysfunctions and symptoms of bone pain or fracture, renal failure, susceptibility to infection, anemia, hypercalcemia, and occasionally clotting abnormalities, neurologic symptoms, and vascular manifestations of hyperviscosity.

Etiology The cause of myeloma is not known. Myeloma occurred with increased frequency in those exposed to the radiation of nuclear warheads in World War II after a 20-year latency. A variety of chromosomal alterations have been found in patients with myeloma; 13q14 deletions, 17p13 deletions, and 11q abnormalities predominate. The most common translocation is t(11;14)(q13;q32), and evidence is strong that errors in switch recombination -- the genetic mechanism to change antibody heavy chain isotype -- participate in the transformation pathway. Overexpression of *myc* or *ras* genes has been noted in some cases. Mutations in p53 and Rb-1 have also been described, but no common molecular pathogenesis has yet emerged.

Myeloma has been seen more commonly than expected among farmers, wood workers, leather workers, and those exposed to petroleum products. The neoplastic event in myeloma may involve cells earlier in B cell differentiation than the plasma cell. Circulating B cells bearing surface immunoglobulin that share the idiotype of the M component are present in myeloma patients. Interleukin (IL) 6 may play a role in driving myeloma cell proliferation; a large fraction of myeloma cells exposed to IL-6 in vitro respond by proliferating. The IL-6 dependency of myeloma is controversial. Infection of marrow macrophages with human herpesvirus 8 has been noted in some cases leading to the hypothesis that viral IL-6 may contribute to the pathogenesis. This notion is also debated. It remains difficult to distinguish benign from malignant plasma cells on the basis of morphologic criteria in all but a few cases (see Plate V-27).

Incidence and Prevalence About 13,200 cases of myeloma were diagnosed in 2000, and 11,200 people died from the disease. Myeloma increases in incidence with age. The median age at diagnosis is 68 years; it is rare under age 40. The yearly incidence is around 4 per 100,000 and remarkably similar throughout the world. Males are slightly more commonly affected than females, and blacks have nearly twice the incidence of whites. In the age group over 25 the incidence is 30 per 100,000. Myeloma accounts for about 1% of all malignancies in whites and 2% in blacks; 13% of all hematologic cancers in whites and 33% in blacks.

Pathogenesis and Clinical Manifestations (Table 113-1) Bone pain is the most common symptom in myeloma, affecting nearly 70% of patients. The pain usually involves the back and ribs, and unlike the pain of metastatic carcinoma, which often is worse at night, the pain of myeloma is precipitated by movement. Persistent localized pain in a patient with myeloma usually signifies a pathologic fracture. The bone lesions of myeloma are caused by the proliferation of tumor cells and the activation of osteoclasts that destroy the bone. The osteoclasts respond to osteoclast activating factors (OAF) made by the myeloma cells [OAF activity can be mediated by several cytokines, includingIL-1, lymphotoxin, and tumor necrosis factor (TNF)]. However, production of these factors stops following administration of glucocorticoids or interferon (IFN)-a. The bone lesions are lytic in nature and are rarely associated with osteoblastic new bone formation. Therefore, radioisotopic bone scanning is less useful in diagnosis than is plain radiography. The bony lysis results in substantial mobilization of calcium

from bone, and serious acute and chronic complications of hypercalcemia may dominate the clinical picture (see below). Localized bone lesions may expand to the point that mass lesions may be palpated, especially on the skull (Fig. 113-3), clavicles, and sternum, and the collapse of vertebrae may lead to spinal cord compression.

The next most common clinical problem in patients with myeloma is susceptibility to bacterial infections. The most common infections are pneumonias and pyelonephritis, and the most frequent pathogens are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Klebsiella pneumoniae* in the lungs and *Escherichia coli* and other gram-negative organisms in the urinary tract. In about 25% of patients, recurrent infections are the presenting features, and over 75% of patients will have a serious infection at some time in their course. The susceptibility to infection has several contributing causes. First, patients with myeloma have diffuse hypogammaglobulinemia if the M component is excluded. The hypogammaglobulinemia is related to both decreased production and increased destruction of normal antibodies. Moreover, some patients generate a population of circulating regulatory cells in response to their myeloma that can suppress normal antibody synthesis. In the case of IgG myeloma, normal IgG antibodies are broken down more rapidly than normal because the catabolic rate for IgG antibodies varies directly with the serum concentration. The large M component results in fractional catabolic rates of 8 to 16% instead of the normal 2%. These patients have very poor antibody responses, especially to polysaccharide antigens such as those on bacterial cell walls. Most measures of T cell function in myeloma are normal, but a subset of CD4+ cells may be decreased. Granulocyte lysozyme content is low, and granulocyte migration is not as rapid as normal in patients with myeloma, probably the result of a tumor product. There are also a variety of abnormalities in complement functions in myeloma patients. All these factors contribute to the immune deficiency of these patients.

Renal failure occurs in nearly 25% of myeloma patients, and some renal pathology is noted in over half. Many factors contribute to this. Hypercalcemia is the most common cause of renal failure. Glomerular deposits of amyloid, hyperuricemia, recurrent infections, and occasional infiltration of the kidney by myeloma cells all may contribute to renal dysfunction. However, tubular damage associated with the excretion of light chains is almost always present. Normally, light chains are filtered, reabsorbed in the tubules, and catabolized. With the increase in the amount of light chains presented to the tubule, the tubular cells become overloaded with these proteins, and tubular damage results either directly from light chain toxic effects or indirectly from the release of intracellular lysosomal enzymes. The earliest manifestation of this tubular damage is the adult Fanconi syndrome (a type 2 proximal renal tubular acidosis), with increased loss of glucose, amino acids, and defects in the ability of the kidney to acidify and concentrate the urine. The proteinuria is not accompanied by hypertension, and the protein is nearly all light chains. Generally, very little albumin is in the urine because glomerular function is usually normal. When the glomeruli are involved, the proteinuria is nonselective. Patients with myeloma also have a decreased anion gap [i.e., $Na^+ - (Cl^- + HCO_3^-)$] because the M component is cationic, resulting in retention of chloride. This is often accompanied by hyponatremia that is felt to be artificial (pseudohyponatremia) because each volume of serum has less water as a result of the increased protein. Myeloma patients are susceptible to developing acute renal failure if they become dehydrated.

Anemia occurs in about 80% of myeloma patients. It is usually normocytic and normochromic and related both to the replacement of normal marrow by expanding tumor cells and to the inhibition of hematopoiesis by factors made by the tumor. In addition, mild hemolysis may contribute to the anemia. A larger than expected fraction of patients may have megaloblastic anemia due to either folate or vitamin B_{12}deficiency. Granulocytopenia and thrombocytopenia are very rare. Clotting abnormalities may be seen due to the failure of antibody-coated platelets to function properly or to the interaction of the M component with clotting factors I, II, V, VII, or VIII. Raynaud's phenomenon and impaired circulation may result if the M component forms cryoglobulins, and hyperviscosity syndromes may develop depending on the physical properties of the M component (most common with IgM, IgG3, and IgA paraproteins). Hyperviscosity is defined on the basis of the relative viscosity of serum as compared with water. Normal relative serum viscosity is 1.8 (i.e., serum is normally almost twice as viscous as water). Symptoms of hyperviscosity occur at a level of 5 to 6, a level usually reached at paraprotein concentrations of around 40 g/L (4 g/dL) for IgM, 50 g/L (5 g/dL) for IgG3, and 70 g/L (7 g/dL) for IgA.

Although neurologic symptoms occur in a minority of patients, they may have many causes. Hypercalcemia may produce lethargy, weakness, depression, and confusion. Hyperviscosity may lead to headache, fatigue, visual disturbances, and retinopathy. Bony damage and collapse may lead to cord compression, radicular pain, and loss of bowel and bladder control. Infiltration of peripheral nerves by amyloid can be a cause of carpal tunnel syndrome and other sensorimotor mono- and polyneuropathies.

Many of the clinical features of myeloma, e.g., cord compression, pathologic fractures, hyperviscosity, sepsis, and hypercalcemia, can present as medical emergencies. Despite the widespread distribution of plasma cells in the body, tumor expansion is dominantly within bone and bone marrow and, for reasons unknown, rarely causes enlargement of spleen, lymph nodes, or gut-associated lymphatic tissue.

Diagnosis and Staging The classic triad of myeloma is marrow plasmacytosis (>10%), lytic bone lesions, and a serum and/or urine M component. The diagnosis may be made in the absence of bone lesions if the plasmacytosis is associated with a progressive increase in the M component over time or if extramedullary mass lesions develop. There are two important variants of myeloma, solitary bone plasmacytoma and extramedullary plasmacytoma. These lesions are associated with an M component in fewer than 30% of the cases, they may affect younger individuals, and both are associated with median survivals of 10 or more years. Solitary bone plasmacytoma is a single lytic bone lesion without marrow plasmacytosis. Extramedullary plasmacytomas usually involve the submucosal lymphoid tissue of the nasopharynx or paranasal sinuses without marrow plasmacytosis. Both tumors are highly responsive to local radiation therapy. If an M component is present, it should disappear after treatment. Solitary bone plasmacytomas may recur in other bony sites or evolve into myeloma. Extramedullary plasmacytomas rarely recur or progress.

The most difficult differential diagnosis in patients with myeloma involves their separation from individuals with benign monoclonal gammopathies or monoclonal gammopathies of uncertain significance (MGUS). MGUS are vastly more common than

myeloma, occurring in 1% of the population over age 50 and in up to 10% over age 75. Patients with MGUS usually have <10% bone marrow plasma cells;<30 g/L (3 g/dL) of M components; no urinary Bence Jones protein; and no anemia, renal failure, lytic bone lesions, or hypercalcemia. When bone marrow cells are exposed to radioactive thymidine in order to quantitate dividing cells, patients with MGUS always have a labeling index <1%; patients with myeloma always have a labeling index >1%. Other discriminators include plasma cell acid phosphatase and b-glucuronidase, both of which are low in MGUS patients, and the salmon calcitonin stimulation test, which is positive only in patients with active ongoing bone destruction. With long-term follow-up, about 25% of patients with MGUS go on to develop myeloma. Typically, patients with MGUS require no therapy. Their survival is about 2 years shorter than age-matched controls without MGUS.

The clinical evaluation of patients with myeloma includes a careful physical examination searching for tender bones and masses. It is paradoxical that only a small minority of patients have an enlargement of the spleen and lymph nodes, the physiologic sites of antibody production. Chest and bone radiographs may reveal lytic lesions or diffuse osteopenia. A complete blood count with differential may reveal anemia. Erythrocyte sedimentation rate is elevated. Rare patients (~2%) may have plasma cell leukemia with more than 2000 plasma cells/uL. This may be seen in disproportionate frequency in IgD (12%) and IgE (25%) myelomas. Serum calcium, urea nitrogen, creatinine, and uric acid levels may be elevated. Protein electrophoresis and measurement of serum immunoglobulins are useful for detecting and characterizing M spikes, supplemented by immunoelectrophoresis, which is especially sensitive for identifying low concentrations of M components not detectable by protein electrophoresis. A 24-h urine specimen is necessary to quantitate protein excretion, and a concentrated aliquot is used for electrophoresis and immunologic typing of any M component. Serum alkaline phosphatase is usually normal even with extensive bone involvement because of the absence of osteoblastic activity. It is also important to quantitate serum b_2-microglobulin (see below). Serum soluble IL-6 receptor levels and C-reactive protein may reflect physiologic IL-6 levels in the patient.

The serum M component will be IgG in 53% of patients, IgA in 25%, and IgD in 1%; 20% of patients will have only light chains in serum and urine. Dipsticks for detecting proteinuria are not reliable at identifying light chains, and the heat test for detecting Bence Jones protein is falsely negative in about 50% of patients with light chain myeloma. Fewer than 1% of patients have no identifiable M component; these patients usually have light chain myelomas in which renal catabolism has made the light chains undetectable in the urine. IgD myeloma may also present as light chain myeloma. About two-thirds of patients with serum M components also have urinary light chains. The light chain isotype may have an impact on survival. Patients secreting lambda light chains have a significantly shorter overall survival than those secreting kappa light chains. It is not clear whether this is due to some genetically important determinant of cell proliferation or because lambda light chains are more likely to cause renal damage and form amyloid than are kappa light chains. The heavy chain isotype may have an impact on patient management as well. About half of patients with IgM paraproteins develop hyperviscosity compared with only 2 to 4% of patients with IgA and IgG M components. Among IgG myelomas, it is the IgG3 subclass that has the highest tendency to form both concentration- and temperature-dependent aggregates, leading to hyperviscosity

and cold agglutination at lower serum concentrations.

The staging system for patients with myeloma is a functional system for predicting survival and is based on a variety of clinical and laboratory tests, unlike the anatomic staging systems for solid tumors. Details of the staging system are given in Table 113-2. Based on the hemoglobin, calcium, M component, and degree of skeletal involvement, the total-body tumor burden is estimated to be low (stage I, $<0.6 \times 10^{12}$ cells/m^2), intermediate (stage II, 0.6 to 1.2×10^{12} cells/m^2), or high (stage III, $>1.2 \times 10^{12}$ cells/m^2), and the stages are further subdivided on the basis of renal function [A if serum creatinine <177 mol/L (<2 mg/dL), B if >177 (>2)]. Patients in stage IA have a median survival of more than 5 years and those in stage IIIB about 15 months. β_2-Microglobulin is a protein of 11,000 mol wt with homologies with the constant region of immunoglobulins that is the light chain of the class I major histocompatibility antigens (HLA-A, -B, -C) on the surface of every cell. Serum β_2-microglobulin is the single most powerful predictor of survival and can substitute for staging. Patients with β_2-microglobulin levels <0.004 g/L have a median survival of 43 months and those with levels >0.004 g/L only 12 months. It is also felt that once the diagnosis of myeloma is firm, histologic features of atypia may also exert an influence on prognosis. IL-6 may be an autocrine and/or paracrine growth factor for myeloma cells; elevated levels are associated with more aggressive disease. High labeling index and high levels of lactate dehydrogenase and thymidine kinase are also associated with poor prognosis.

Other factors that may influence prognosis are the number of cytogenetic abnormalities, % plasma cells in the marrow, performance status, and serum levels of IL-6, soluble IL-6 receptors, C-reactive protein, hepatocyte growth factor, C-terminal cross-linked telopeptide of collagen I, TGF-b, and syndecan-1.

TREATMENT

About 10% of patients with myeloma will have an indolent course demonstrating only very slow progression of disease over many years. Such patients only require antitumor therapy when the serum myeloma protein level rises above 50 g/L (5 g/dL) or progressive bone lesions develop. Patients with solitary bone plasmacytomas and extramedullary plasmacytomas may be expected to enjoy prolonged disease-free survival after local radiation therapy to a dose of around 40 Gy. There is a low incidence of occult marrow involvement in patients with solitary bone plasmacytoma. Such patients are usually detected because their serum M component falls slowly or disappears initially only to return after a few months. These patients respond well to systemic chemotherapy.

The vast majority of patients with myeloma require therapeutic intervention. In general such therapy is of two sorts: systemic chemotherapy to control the progression of myeloma, and symptomatic supportive care to prevent serious morbidity from the complications of the disease. All patients with stage II or III disease and stage I patients exhibiting Bence Jones proteinuria, progressive lytic bone lesions, vertebral compression fractures, recurrent infections, or rising serum M component should be treated with systemic combination chemotherapy. Therapy can prolong and improve the quality of life for myeloma patients.

The standard treatment has consisted of intermittent pulses of an alkylating agent [L-phenylalanine mustard (L-PAM, melphalan), cyclophosphamide, or chlorambucil] and prednisone administered for 4 to 7 days every 4 to 6 weeks. The alkylating agents appear to be roughly equally active, but resistance to one agent is often accompanied by resistance to the others. The usual doses are as follows: melphalan, 8 mg/m^2 per day; cyclophosphamide, 200 mg/m^2 per day; chlorambucil, 8 mg/m^2 per day; prednisone, 25 to 60 mg/m^2 per day. Melphalan is used most commonly, but because of their near equivalence in antitumor efficacy, we favor cyclophosphamide as the alkylating agent because it is less toxic to the marrow stem cell compartment and results in a lower incidence of acute myelodysplastic syndromes than do the other alkylating agents. Doses may need adjustment based on marrow tolerance. However, there are few constraints on the dose of the steroid pulse, and it appears that more is better. Patients responding to therapy generally have a prompt and gratifying reduction in bone pain, hypercalcemia, and anemia, and often have fewer infections. The serum M component lags substantially behind the symptomatic improvement, often taking 4 to 6 weeks to fall. This fall depends on the rate of tumor kill and the fractional catabolic rate of immunoglobulin, which in turn depends on the serum concentration (for IgG). Light chain excretion, with a functional half-life of approximately 6 h, may fall within the first week of treatment. However, since urine light chain levels may relate to renal tubular function, they are not a reliable measure of tumor cell kill. Calculations of tumor cell kill are made by extrapolation of the serum M component level and rely heavily on the assumption that every tumor cell produces immunoglobulin at a constant rate. About 60% of patients will achieve at least a 75% reduction in serum M component level and tumor cell mass in response to an alkylating agent and prednisone. Although this is a tumor reduction of less than one log, clinical responses may last many months. The important feature of the level of the M protein is not how far or how fast it falls, but the rate of its increase after therapy. Efforts to improve the fraction of patients responding and the degree of response have involved adding other active chemotherapeutic agents to the treatment program. Patients with more advanced disease may benefit most from such an approach. High-dose therapy with hematopoietic support is also being tested in younger patients. Sequential treatment with combination chemotherapy regimens followed by two successive high-dose melphalan treatments, each supported with peripheral blood stem cell transplants, have achieved complete responses in 50% of patients treated within a year of diagnosis. Complete responses are rare (<10%) with standard therapy. Long-term follow-up is not yet available. Allogeneic transplants may also produce high response rates, but treatment-related mortality may be as high as 40%.

The ideal duration of therapy has not been determined. Most physicians treat every 4 to 6 weeks for 1 or 2 years. Cessation of therapy is followed by relapse, usually within a year. Retreatment may be associated with a second response in up to 80% of patients. Maintenance therapy (e.g., with IFN-a) may prolong the duration of response, but this therapy is toxic and has generally not prolonged survival. The regrowth rate of the tumor during relapse accelerates with each relapse. This observation suggests that kinetic resistance to therapy (i.e., increase in cycling cells) is perhaps more important than drug resistance controlled by mdr-1 expression. Patients often respond to treatment, but the length of the response progressively shortens. Patients primarily resistant to initial therapy have a median survival of less than a year. High-dose pulsed steroids used alone (200 mg prednisone every other day or 1 g/m^2 per day methylprednisolone for 5

days) or VAD combination chemotherapy (vincristine, 0.4 mg/d in a 4-day continuous infusion; doxorubicin, 9 mg/m^2 per day in a 4-day continuous infusion; dexamethasone, 40 mg/d for 4 days per week for 3 weeks) may offer useful palliation in patients resistant to primary therapy. High-dose melphalan has activity in patients with refractory disease. Thalidomide, which inhibits angiogenesis, also produces responses in refractory cases, but at doses that may cause somnolence.

About 15% of patients die within the first 3 months after diagnosis; subsequently, the death rate is about 15% per year. The disease usually follows a chronic course for 2 to 5 years before developing an acute terminal phase, usually marked by the development of pancytopenia with a cellular marrow that is refractory to treatment. Widespread organ infiltration by myeloma cells occurs, and survival is less than 6 months. About 46% of patients die in the chronic phase of disease from progressive myeloma (16%) and renal failure (10%), sepsis (14%), or both (6%). Death in the acute terminal phase (26%) is chiefly from progressive myeloma (13%) and sepsis (9%). Five percent of patients die of acute leukemia, myeloblastic or monocytic. Although it has been debated that this is related to the primary disease, it appears more likely to be the result of chronic therapy with alkylating agents. Nearly 23% of patients die of myocardial infarction, chronic lung disease, diabetes, or stroke, all intercurrent illnesses related more to the age of the patient group than to the tumor.

Supportive care directed at the anticipated complications of the disease may be as important as primary antitumor therapy. The hypercalcemia generally responds well to glucocorticoid therapy, hydration, and natriuresis. Calcitonin may add to the inhibitory effects of steroids on bone resorption. Bisphosphonates (e.g., pamidronate 90 mg once a month) reduce osteoclastic bone resorption and preserve performance status and quality of life; antitumor effects are also possible. Treatments aimed at strengthening the skeleton, such as fluorides, calcium, and vitamin D, with or without androgens, have been suggested but are not of proven efficacy. Iatrogenic worsening of renal function may be prevented by the use of allopurinol during chemotherapy to avoid urate nephropathy and by maintaining a high fluid intake to prevent dehydration and to help excrete light chains and calcium. In the event of acute renal failure, plasmapheresis is approximately 10 times more effective at clearing light chains than peritoneal dialysis, and acutely reducing the protein load may result in functional improvement. Urinary tract infections should be watched for and treated early. Chronic dialysis probably should not be initiated in patients who have failed to respond to antitumor therapy. Plasmapheresis may be the treatment of choice for hyperviscosity syndromes. Although the pneumococcus is a dreaded pathogen in myeloma patients, pneumococcal polysaccharide vaccines may not elicit an antibody response. The advent of intravenous gamma globulin preparations raises some hope that prophylactic administration may prevent some serious infections, but this has not been tested. Chronic oral antibiotic prophylaxis is probably not warranted. Patients developing neurologic symptoms in the lower extremities, severe localized back pain, or problems with bowel and bladder control may need emergency myelography and radiation therapy for palliation. Most bone lesions respond to analgesics and chemotherapy, but certain painful lesions may respond most promptly to localized radiation. The chronic anemia may respond to hematinics (iron, folate, cobalamin), and some have responded to androgens. The pathogenesis of the anemia should be established and specific therapy instituted, where possible.

WALDENSTROM'S MACROGLOBULINEMIA

In 1948, Waldenstrom described a malignancy of lymphoplasmacytoid cells that secreted IgM. In contrast to myeloma, the disease was associated with lymphadenopathy and hepatosplenomegaly, but the major clinical manifestation was the hyperviscosity syndrome. The disease resembles the related diseases chronic lymphocytic leukemia, myeloma, and lymphocytic lymphoma. Waldenstrom's macroglobulinemia and IgM myeloma both follow a similar clinical course. The diagnosis of IgM myeloma is usually reserved for patients with lytic bone lesions and is important only because of the hazard of pathologic fractures.

The cause of macroglobulinemia is unknown. The disease is similar to myeloma in being slightly more common in men and occurring with increased incidence with age (median 64 years). There have been reports that the IgM in some patients with macroglobulinemia may have specificity for myelin-associated glycoprotein (MAG), a protein that has been associated with demyelinating disease of the peripheral nervous system and may be lost earlier and to a greater extent than the better known myelin basic protein in patients with multiple sclerosis. Sometimes patients with macroglobulinemia develop a peripheral neuropathy before the appearance of the neoplasm. There is speculation that the whole process begins with a viral infection that may elicit an antibody response that cross-reacts with a normal tissue component.

Like myeloma, the disease involves the bone marrow, but unlike myeloma, it does not cause bone lesions or hypercalcemia. Like myeloma, a serum M component is present in the serum in excess of 30 g/L (3 g/dL), but unlike myeloma, the size of the IgM paraprotein results in little renal excretion and only around 20% of patients excrete light chains. Therefore, renal disease is not common. The light chain isotype is kappa in 80% of the cases. Patients present with weakness, fatigue, and recurrent infections, similar to myeloma patients, but epistaxis, visual disturbances, and neurologic symptoms such as peripheral neuropathy, dizziness, headache, and transient paresis are much more common in macroglobulinemia. Physical examination reveals adenopathy and hepatosplenomegaly, and ophthalmoscopic examination may reveal vascular segmentation and dilatation of the retinal veins characteristic of hyperviscosity states. Patients may have a normocytic, normochromic anemia, but rouleaux formation and a positive Coombs' test are much more common than in myeloma. Malignant lymphocytes are usually present in the peripheral blood. About 10% of macroglobulins are cryoglobulins. These are pure M components and are not the mixed cryoglobulins seen in rheumatoid arthritis and other autoimmune diseases. Mixed cryoglobulins are composed of IgM or IgA complexed with IgG, for which they are specific. In both cases, Raynaud's phenomenon and serious vascular symptoms precipitated by the cold may occur, but mixed cryoglobulins are not commonly associated with malignancy. Patients suspected of having a cryoglobulin based on history and physical examination should have their blood drawn into a warm syringe and delivered to the laboratory in a container of warm water to avoid errors in quantitating the cryoglobulin.

TREATMENT

Control of serious hyperviscosity symptoms such as an altered state of consciousness

or paresis can be achieved acutely by plasmapheresis because 80% of the IgM paraprotein is intravascular. Fludarabine (25 mg/$m_2$per day for 5 days every 4 weeks) or cladribine (0.1 mg/kg per day for 7 days every 4 weeks) are highly effective single agents. About 80% of patients respond to chemotherapy, and their median survival is over 3 years. The absence of other serious organ toxicities results in a longer life span of patients with macroglobulinemia compared with those with myeloma.

POEMS SYNDROME

The features of this syndrome are *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*ultiple myeloma, and *s*kin changes (POEMS). Patients usually have a severe, progressive sensorimotor polyneuropathy associated with sclerotic bone lesions from myeloma. Polyneuropathy occurs in about 1.4% of myelomas, but the POEMS syndrome is only a rare subset of that group. Unlike typical myeloma, hepatomegaly and lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in one-third. The lymphadenopathy frequently resembles Castleman's disease histologically, a condition that has been linked toIL-6 overproduction. The endocrine manifestations include amenorrhea in women and impotence and gynecomastia in men. Hyperprolactinemia due to loss of normal inhibitory control by the hypothalamus may be associated with other central nervous system manifestations such as papilledema and elevated cerebrospinal fluid pressure and protein. Type 2 diabetes mellitus occurs in about one-third of patients. Hypothyroidism and adrenal insufficiency are occasionally noted. Skin changes are diverse: hyperpigmentation, hypertrichosis, skin thickening, and digital clubbing. Other manifestations include peripheral edema, ascites, pleural effusions, fever, and thrombocytosis.

The pathogenesis of the disease is unclear, but high circulating levels of the proinflammatory cytokinesIL-1, IL-6, andTNF have been documented and levels of the inhibitory cytokine transforming growth factorb (TGF-b) are lower than expected. Treatment of the myeloma may result in an improvement in the other disease manifestations.

HEAVY CHAIN DISEASES

The heavy chain diseases are rare lymphoplasmacytic malignancies. Their clinical manifestations vary with the heavy chain isotype. Patients secrete a defective heavy chain that usually has an intact Fc fragment and a deletion in the Fd region. Gamma, alpha, and mu heavy chain diseases have been described, but no reports of delta or epsilon heavy chain diseases have appeared. Molecular biologic analysis of these tumors has revealed structural genetic defects that may account for the aberrant chain secreted.

Gamma Heavy Chain Disease (Franklin's Disease) This disease affects people of widely different age groups and countries of origin. It is characterized by lymphadenopathy, fever, anemia, malaise, hepatosplenomegaly, and weakness. Its most distinctive symptom is palatal edema, resulting from node involvement of Waldeyer's ring, and this may progress to produce respiratory compromise. The diagnosis depends on the demonstration of an anomalous serum M component [often<20 g/L (<2 g/dL)] that reacts with anti-IgG but not anti-light chain reagents. *The M*

component is typically present in both serum and urine. Most of the paraproteins have been of the gamma$_1$subclass, but other subclasses have been seen. The patients may have thrombocytopenia, eosinophilia, and nondiagnostic bone marrow. Patients usually have a rapid downhill course and die of infection; however, some patients have survived 5 years with chemotherapy.

Alpha Heavy Chain Disease (Seligmann's Disease) This is the most common of the heavy chain diseases. It is closely related to a malignancy known as *Mediterranean lymphoma*, a disease that affects young people in parts of the world where intestinal parasites are common, such as the Mediterranean, Asia, and South America. The disease is characterized by an infiltration of the lamina propria of the small intestine with lymphoplasmacytoid cells that secrete truncated alpha chains. Demonstrating alpha heavy chains is difficult because the alpha chains tend to polymerize and appear as a smear instead of a sharp peak on electrophoretic profiles. Despite the polymerization, hyperviscosity is not a common problem in alpha heavy chain disease. Without J chain-facilitated dimerization, viscosity does not increase dramatically. Light chains are absent from serum and urine. The patients present with chronic diarrhea, weight loss, and malabsorption and have extensive mesenteric and para-aortic adenopathy. Respiratory tract involvement occurs rarely. Patients may vary widely in their clinical course. Some may develop diffuse aggressive histologies of malignant lymphoma. Chemotherapy may produce long-term remissions. Rare patients appear to have responded to antibiotic therapy, raising the question of the etiologic role of antigenic stimulation, perhaps by some chronic intestinal infection. Chemotherapy plus antibiotics may be more effective than chemotherapy alone.

Mu Heavy Chain Disease The secretion of isolated mu heavy chains into the serum appears to occur in a very rare subset of patients with chronic lymphocytic leukemia. The only features that may distinguish patients with mu heavy chain disease are the presence of vacuoles in the malignant lymphocytes and the excretion of kappa light chains in the urine. The diagnosis requires ultracentrifugation or gel filtration to confirm the nonreactivity of the paraprotein with the light chain reagents, because some intact macroglobulins fail to interact with these serums. The tumor cells seem to have a defect in the assembly of light and heavy chains, because they appear to contain both in their cytoplasm. There is no evidence that such patients should be treated differently from other patients with chronic lymphocytic leukemia (Chap. 112).

114. TRANSFUSION BIOLOGY AND THERAPY - *Jeffery S. Dzieczkowski*, *Kenneth C. Anderson*

BLOOD GROUP ANTIGENS AND ANTIBODIES

The study of red blood cell (RBC) antigens and antibodies forms the foundation of transfusion medicine. Serologic studies initially characterized these antigens, but now the molecular composition and structure of many are known. Antigens, either carbohydrate or protein, are assigned to a blood group system based upon the structure and the similarity of the determinant epitopes. Other cellular blood elements and plasma proteins are also antigenic and can result in *alloimmunization*, the production of antibodies directed against the blood group antigens of another individual. These antibodies are called *alloantibodies*.

Antibodies directed againstRBCantigens may result from "natural" exposure, particularly to carbohydrates that mimic some blood group antigens. Those antibodies that occur via natural stimuli are usually produced by a T cell-independent response (thus, generating no memory) and are IgM isotype. *Autoantibodies* (antibodies against autologous blood group antigens) arise spontaneously or as the result of infectious sequelae (e.g., from *Mycoplasma pneumoniae*) and are also often IgM. These antibodies are often clinically insignificant due to their low affinity for antigen at body temperature. However, IgM antibodies can activate the complement cascade and result in hemolysis. Antibodies that result from allogeneic exposure, such as transfusion or pregnancy, are usually IgG. IgG antibodies commonly bind to antigen at warmer temperatures and may hemolyze RBCs. Unlike IgM antibodies, IgG antibodies can cross the placenta and bind fetal erythrocytes bearing the corresponding antigen, resulting in hemolytic disease of the newborn, or *hydrops fetalis*.

Alloimmunization to leukocytes, platelets, and plasma proteins may also result in transfusion complications such as fevers and urticaria but generally does not cause hemolysis. Assay for these other alloantibodies is not routinely performed; however, they may be detected using special assays.

ABO ANTIGENS AND ANTIBODIES

The first blood group antigen system, recognized in 1900, was ABO, the most important in transfusion medicine. The major blood groups of this system are A, B, AB, and O. O typeRBCs lack A or B antigens. These antigens are carbohydrates attached to a precursor backbone, may be found on the cellular membrane either as glycosphingolipids or glycoproteins, and are secreted into plasma and body fluids as glycoproteins. H substance is the immediate precursor upon which the A and B antigens are added. This H substance is formed by the addition of fucose to the glycolipid or glycoprotein backbone. The subsequent addition of *N*-acetylgalactosamine creates the A antigen, while the addition of galactose produces the B antigen.

The genes that determine the A and B phenotypes are found on chromosome 9p and are expressed in a Mendelian codominant manner. The gene products are glycosyl transferases, which confer the enzymatic capability of attaching the specific antigenic carbohydrate. Individuals who lack the "A" and "B" transferases are phenotypically type

"O," while those who inherit both transferases are type "AB." Rare individuals lack the H gene, which codes for fucose transferase, and cannot form H substance. These individuals are homozygous for the silent h allele (hh) and have Bombay phenotype (O_h).

The ABO blood group system is important because essentially all individuals produce antibodies to the ABH carbohydrate antigen that they lack. The naturally occurring anti-A and anti-B antibodies are termed *isoagglutinins*. Thus, type A individuals produce anti-B, while type B individuals make anti-A. Neither isoagglutinin is found in type AB individuals, while type O individuals produce both anti-A and anti-B. Thus, persons with type AB are "universal recipients" because they do not have antibodies against any ABO phenotype, while persons with type O blood can donate to essentially all recipients because their cells are not recognized by any ABO isoagglutinins. The rare individuals with Bombay phenotype produce antibodies to H substance (which is present on all red cells except those of hh phenotype) as well as to both A and B antigens and are therefore compatible only with other hh donors.

In most people, A and B antigens are secreted by the cells and are present in the circulation. Nonsecretors are susceptible to a variety of infections (e.g., *Candida albicans*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*) as many organisms may bind to polysaccharides on cells. Soluble blood group antigens may block this binding.

RH SYSTEM

The Rh system is the second most important blood group system in pretransfusion testing. The Rh antigens are found on a 30- to 32-kDaRBCmembrane protein, which has no defined function. Although more than 40 different antigens in the Rh system have been described, five determinants account for the vast majority of phenotypes. The presence of the D antigen confers Rh "positivity," while people who lack the D antigen are Rh negative. Two allelic antigen pairs, E/e and C/c, are also found on the Rh protein. The three Rh genes, E/e, D, and C/c, are arranged in tandem on chromosome 1 and inherited as a haplotype, i.e., cDE or Cde. Two haplotypes can result in the phenotypic expression of two to five Rh antigens.

The D antigen is a potent alloantigen. About 15% of people lack this antigen. Exposure of these Rh-negative people to even small amounts of Rh-positive cells, by either transfusion or pregnancy, can result in the production of anti-D alloantibody.

OTHER BLOOD GROUP SYSTEMS AND ALLOANTIBODIES

More than 100 blood group systems are recognized, composed of more than 500 antigens. The presence or absence of certain antigens has been associated with various diseases and anomalies; antigens also act as receptors for infectious agents. Alloantibodies of importance in routine clinical practice are listed inTable 114-1.

Antibodies to *Lewis system* carbohydrate antigens are the most common cause of incompatibility during pretransfusion screening. The Lewis gene product is a fucosyl transferase and maps to chromosome 19. The antigen is not an integral membrane

structure but is adsorbed to the RBC membrane from the plasma. Antibodies to Lewis antigens are usually IgM and cannot cross the placenta. Lewis antigens may be adsorbed onto tumor cells and may be targets of therapy.

I system antigens are also oligosaccharides related to H, A, B, and Le. I and i are not allelic pairs but are carbohydrate antigens that differ only in the extent of branching. The i antigen is an unbranched chain that is converted by the I gene product, a glycosyltransferase, into a branched chain. The branching process affects all the ABH antigens, which become progressively more branched in the first 2 years of life. Some patients with cold agglutinin disease or lymphomas can produce anti-I autoantibodies that cause RBC destruction. Occasional patients with mononucleosis or *Mycoplasma* pneumonia may develop cold agglutinins of either anti-I or anti-i specificity. Most adults lack i expression; thus, finding a donor for patients with anti-i is not difficult. Even though most adults express I antigen, binding is generally low at body temperature. Thus, administration of warm blood prevents isoagglutination.

The *P system* is another group of carbohydrate antigens controlled by specific glycosyltransferases. Its clinical significance is in rare cases of syphilis and viral infection that lead to paroxysmal cold hemoglobinuria. In these cases, an unusual autoantibody to P is produced that binds to RBCs in the cold and fixes complement upon warming. Antibodies with these biphasic properties are called *Donath-Landsteiner antibodies*. The P antigen is also expressed on urothelial cells and may be a receptor for *Escherichia coli* binding.

The *MNSsU system* is regulated by genes on chromosome 4. M and N are determinants on glycophorin A, an RBC membrane protein, and S and s are determinants on glycophorin B. Anti-S and anti-s IgG antibodies may develop after pregnancy or transfusion and lead to hemolysis. Anti-U antibodies are rare but problematic; virtually every donor is incompatible because nearly all persons express U.

The *Kell* protein is very large (720 amino acids) and its secondary structure contains many different antigenic epitopes. The immunogenicity of Kell is third behind the ABO and Rh systems. The absence of the Kell precursor protein (controlled by a gene on X) is associated with acanthocytosis, shortened RBC survival, and a progressive form of muscular dystrophy that includes cardiac defects. This rare condition is called the *McLeod phenotype*. The K_x gene is linked to the 91-kDa component of the NADPH-oxidase on the X chromosome, deletion or mutation of which accounts for about 60% of cases of chronic granulomatous disease.

The *Duffy* antigens are codominant alleles, Fy_a and Fy_b, that also serve as receptors for *Plasmodium vivax*. More than 70% of persons in malaria-endemic areas lack these antigens, probably from selective influences of the infection on the population.

The *Kidd* antigens, Jk_a and Jk_b, may elicit antibodies transiently. A delayed hemolytic transfusion reaction that occurs with blood tested as compatible is often related to delayed appearance of anti-Jk_a.

PRETRANSFUSION TESTING

Pretransfusion testing of a potential recipient consists of the "type and screen." The "forward type" determines the ABO and Rh phenotype of the recipient'sRBC by using antisera directed against the A, B, and D antigens. The "reverse type" detects isoagglutinins in the patient's serum and should correlate with the ABO phenotype, or forward type.

The alloantibody screen identifies antibodies directed against otherRBCantigens. The alloantibody screen is performed by mixing patient serum with type O RBCs that contain the major antigens of most blood group systems and whose extended phenotype is known. The specificity of the alloantibody is identified by correlating the presence or absence of antigen with the results of the agglutination.

Cross matching is ordered when there is a high probability that the patient will require a packed RBC (PRBC) transfusion. Blood selected for cross matching must be ABO compatible and lack antigens for which the patient has alloantibodies. Nonreactive cross matching confirms the absence of any major incompatibility and reserves that unit for the patient.

In the case of Rh-negative patients, every attempt must be made to provide Rh-negative blood components to prevent alloimmunization to the D antigen. In an emergency, Rh-positive blood can be safely transfused to a Rh-negative patient who lacks anti-D; however, the recipient is likely to become alloimmunized and produce anti-D. Rh-negative women of child-bearing age who are transfused with products containing Rh-positiveRBCs should receive passive immunization with anti-D (RhoGam or WinRho) to reduce or prevent sensitization.

BLOOD COMPONENTS

Blood products intended for transfusion are routinely collected as whole blood (450 mL) in various anticoagulants. Most donated blood is processed into components:PRBCs, platelets, and fresh frozen plasma (FFP) or cryoprecipitate (Table 114-2). Whole blood is first separated into PRBCs and platelet-rich plasma by slow centrifugation. The platelet-rich plasma is then centrifuged at high speed to yield one unit of random donor (RD) platelets and one unit of FFP. Cryoprecipitate is produced by thawing FFP to precipitate the plasma proteins, which are then separated by centrifugation.

Apheresis technology is used for the collection of multiple units of platelets from a single donor. These single-donor apheresis platelets (SDAP) contain the equivalent of at least six units ofRDplatelets and have fewer contaminating leukocytes than pooled RD platelets.

Plasma may also be collected by apheresis. Plasma derivatives such as albumin, intravenous immunoglobulin, antithrombin, and coagulation factor concentrates are prepared from pooled plasma from many donors and are treated to eliminate infectious agents.

WHOLE BLOOD

Whole blood provides both oxygen-carrying capacity and volume expansion. It is the

ideal component for patients who have sustained acute hemorrhage of 25% or greater total blood volume loss. Whole blood is stored at 4°C to maintain erythrocyte viability, but platelet dysfunction and degradation of some coagulation factors occurs. In addition, 2,3-BPG levels fall over time, leading to an increase in the oxygen affinity of the hemoglobin and a decreased capacity to deliver oxygen to the tissues, a problem with all red cell storage. Whole blood is not readily available since it is routinely processed into components.

PACKED RED BLOOD CELLS

This product increases oxygen-carrying capacity in the anemic patient. Adequate oxygenation can be maintained with a hemoglobin content of 70 g/L in the normovolemic patient without cardiac disease; however, comorbid factors often necessitate transfusion at a higher threshold. The decision to transfuse should be guided by the clinical situation and not by an arbitrary laboratory value. In the critical care setting, liberal use of transfusions to maintain near normal levels of hemoglobin may have unexpected negative effects on survival. In most patients requiring transfusion, levels of hemoglobin of 100 g/L are sufficient to keep oxygen supply from being critically low.

PRBCs may be modified to prevent certain adverse reactions. Contaminating leukocytes are responsible for inducing fevers and causing alloimmunization to HLA antigens. Leukocytes can be removed by several methods. Bedside filtration is the most popular method and removes 99.9% of donor leukocytes. Leukoreduction may be done in the blood bank before storage of cellular components; this practice results in less cytokine release from the cells. Plasma, which may cause allergic reactions, can be removed from cellular blood components by washing.

PLATELETS

Thrombocytopenia is a risk factor for hemorrhage, and platelet transfusion reduces the incidence of bleeding. The threshold for prophylactic platelet transfusion is 10,000/uL. In patients without fever or infections, a threshold of 5000/uL may be sufficient to prevent spontaneous hemorrhage. For invasive procedures, 50,000/uL platelets is the usual target level.

Platelets are given either as pools prepared from five to eightRDs or as SDAPs from a single donor. In an unsensitized patient without increased platelet consumption [splenomegaly, fever, disseminated intravascular coagulation (DIC)], six to eight units of RD platelets (about 1 unit per 10 kg body weight) are transfused, and each unit is anticipated to increase the platelet count 5000 to 10,000/uL. Patients who have received multiple transfusions may be alloimmunized to many HLA- and platelet-specific antigens and have little or no increase in their posttransfusion platelet counts. Patients who may require multiple transfusions are best served by receiving SDAP and leukocyte-reduced components to lower the risk of alloimmunization.

Refractoriness to platelet transfusion may be evaluated using the corrected count increment (CCI):

where BSA is body surface area measured in square meters. The platelet count performed 1 h after the transfusion is acceptable if the CCI is 10 ´10^9/mL, and after 18 to 24 h an increment of 7.5 ´10^9/mL is expected. Patients who have suboptimal responses are likely to have received multiple transfusions and have antibodies directed against class I HLA antigens. Refractoriness can be investigated by detecting anti-HLA antibodies in the recipient's serum. Patients who are sensitized will often react with 100% of the lymphocytes used for the HLA-antibody screen, and HLA-matchedSDAPs should be considered for those patients who require transfusion. Although ABO-identical HLA-matched SDAPs provide the best chance for increasing the platelet count, locating these products is difficult. Platelet cross matching is available in some centers. Additional clinical causes for a low platelet CCI include fever, bleeding, splenomegaly,DIC, or medications in the recipient.

FRESH FROZEN PLASMA

FFPcontains stable coagulation factors and plasma proteins: fibrinogen, antithrombin, albumin, as well as proteins C and S. Indications for FFP include correction of coagulopathies, including the rapid reversal of coumadin; supplying deficient plasma proteins; and treatment of thrombotic thrombocytopenic purpura. FFP should not be routinely used to expand blood volume. FFP is an acellular component and does not transmit intracellular infections, e.g., cytomegalovirus (CMV). Patients who are IgA-deficient and require plasma support should receive FFP from IgA-deficient donors to prevent anaphylaxis (see below).

CRYOPRECIPITATE

Cryoprecipitate is a source of fibrinogen, factor VIII, and von Willebrand factor (vWF). It is ideal for supplying fibrinogen to the volume-sensitive patient. When factor VIII concentrates are not available, cyroprecipitate may be used since each unit contains approximately 80 units of factor VIII. Cryoprecipitate may also be used as a source of vWF for patients with dysfunctional (type II) or absent (type III) von Willebrand disease.

PLASMA DERIVATIVES

Plasma from thousands of donors may be pooled to derive specific protein concentrates, including albumin, intravenous immunoglobulin, antithrombin, and coagulation factors. In addition, donors who have high-titer antibodies to specific agents or antigens provide hyperimmune globulins, such as anti-D (RhoGam, WinRho), and antisera to hepatitis B virus (HBV), varicella-zoster virus,CMV, and other infectious agents.

ADVERSE REACTIONS TO BLOOD TRANSFUSION

Adverse reactions to transfused blood components occur despite multiple tests, inspections, and checks. Fortunately, the most common reactions are not life-threatening, although serious reactions can present with mild symptoms and signs. Some reactions can be reduced or prevented by modified (filtered, washed, or

irradiated) blood components. When an adverse reaction is suspected, the transfusion should be stopped and reported to the blood bank for investigation.

Transfusion reactions may result from immune and nonimmune mechanisms. Immune-mediated reactions are often due to preformed donor or recipient antibody; however, cellular elements may also cause adverse effects. Nonimmune causes of reactions are due to the chemical and physical properties of the stored blood component and its additives.

Infectious complications of transfusion have become less frequent, although fear of these complications remains a primary concern. The incidence of transfusion-related infections has been reduced substantially due to improved donor screening and testing of collected blood. Infections, like any adverse transfusion reaction, must be brought to the attention of the blood bank for appropriate studies (Table 114-3).

IMMUNE-MEDIATED REACTIONS

Acute Hemolytic Transfusion Reactions Immune-mediated hemolysis occurs when the recipient has preformed antibodies that lyse donor erythrocytes. The ABO isoagglutinins are responsible for the majority of these reactions, although alloantibodies directed against other RBC antigens, i.e., Rh, Kell, and Duffy, may result in hemolysis.

Acute hemolytic reactions may present with hypotension, tachypnea, tachycardia, fever, chills, hemoglobinemia, hemoglobinuria, chest and/or flank pain, and discomfort at the infusion site. Monitoring the patient's vital signs before and during the transfusion is important to identify reactions promptly. When acute hemolysis is suspected, the transfusion must be stopped immediately, intravenous access maintained, and the reaction reported to the blood bank. A correctly labeled posttransfusion blood sample and any untransfused blood should be sent to the blood bank for analysis. The laboratory evaluation for hemolysis includes the measurement of serum haptoglobin, lactate dehydrogenase (LDH), and indirect bilirubin levels.

The immune complexes that result inRBClysis can cause renal dysfunction and failure. Diuresis should be induced with intravenous fluids and furosemide or mannitol. Tissue factor released from the lysed erythrocytes may initiateDIC. Coagulation studies including prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen, and platelet count should be monitored in patients with hemolytic reactions.

Errors at the patient's bedside, such as mislabeling the sample or transfusing the wrong patient, are responsible for the majority of these reactions. The blood bank investigation of these reactions includes examination of the pre- and posttransfusion samples for hemolysis and repeat typing of the patient samples; direct antiglobulin test (DAT), sometimes called the direct Coombs test, of the posttransfusion sample; repeating the cross matching of the blood component; and checking all clerical records for errors. DAT detects the presence of antibody or complement bound toRBCs in vivo.

Delayed Hemolytic and Serologic Transfusion Reactions Delayed hemolytic transfusion reactions (DHTRs) are not completely preventable. These reactions occur in patients previously sensitized toRBCalloantigens who have a negative alloantibody

screen due to low antibody levels. When the patient is transfused with antigen-positive blood, an anamnestic response results in the early production of alloantibody that binds donor RBCs. The alloantibody is detectable 1 to 2 weeks following the transfusion, and the posttransfusionDAT may become positive due to circulating donor RBCs coated with antibody or complement. The transfused, alloantibody-coated erythrocytes are cleared by the extravascular reticuloendothelial system. These reactions are detected most commonly in the blood bank when a subsequent patient sample reveals a positive alloantibody screen or a new alloantibody in a recently transfused recipient.

No specific therapy is usually required, although additionalRBCtransfusions may be necessary. Delayed serologic transfusion reactions (DSTR) are similar toDHTR, as the DATis positive and alloantibody is detected; however, RBC clearance is not increased.

Febrile Nonhemolytic Transfusion Reaction The most frequent reaction associated with the transfusion of cellular blood components is a febrile nonhemolytic transfusion reaction (FNHTR). These reactions are characterized by chills and rigors and a 1°C or greater rise in temperature. FNHTR is diagnosed when other causes of fever in the transfused patient are ruled out. Antibodies directed against donor leukocyte and HLA antigens may mediate these reactions; thus, multiply transfused patients and multiparous women are felt to be at increased risk. Although antibodies may be demonstrated in the recipient's serum, investigation is not routinely done because of the mild nature of most FNHTR. The use of leukocyte-reduced blood products may prevent or delay sensitization to leukocyte antigens and thereby reduce the incidence of these febrile episodes. Cytokines released from cells within stored blood components may mediate FNHTR; thus, leukoreduction before storage may prevent these reactions. The incidence and severity of these reactions can be decreased in patients with recurrent reactions by premedicating with acetaminophen or other antipyretic agents.

Allergic Reactions Urticarial reactions are related to plasma proteins found in transfused components. Mild reactions may be treated symptomatically by temporarily stopping the transfusion and administering antihistamines (diphenhydramine, 50 mg orally or intramuscularly). The transfusion may be completed after the signs and/or symptoms resolve. Patients with a history of allergic transfusion reaction should be premedicated with an antihistamine. Cellular components can be washed to remove residual plasma for the extremely sensitized patient.

Anaphylactic Reaction This severe reaction presents after transfusion of only a few milliliters of the blood component. Symptoms and signs include difficulty breathing, coughing, nausea and vomiting, hypotension, bronchospasm, loss of consciousness, respiratory arrest, and shock. Treatment includes stopping the transfusion, maintaining vascular access, and administering epinephrine (0.5 to 1.0 mL of 1:1000 dilution SQ). Glucocorticoids may be required in severe cases.

Patients who are IgA-deficient may be sensitized to this Ig class and are at risk for anaphylactic reactions associated with plasma transfusion. Individuals with severe IgA deficiency should therefore receive only IgA-deficient plasma and washed cellular blood components. Patients who have anaphylactic or repeated allergic reactions to blood components should be tested for IgA deficiency.

Graft-Versus-Host Disease Graft-versus-host disease (GVHD) is a frequent complication of allogeneic bone marrow transplantation, in which viable lymphocytes from donor marrow attack and cannot be eliminated by an immunodeficient host. Transfusion-related GVHD is mediated by donor T lymphocytes that recognize host HLA antigens as foreign and mount an immune response, which is manifested clinically by the development of fever, a characteristic cutaneous eruption, diarrhea, and liver function abnormalities. GVHD can also occur when blood components that contain viable T lymphocytes are transfused to immunodeficient recipients or to immunocompetent recipients who share HLA antigens with the donor (e.g., a family donor). In addition to the aforementioned clinical features of GVHD, transfusion-associated GVHD (TA-GVHD) is characterized by marrow aplasia and pancytopenia. TA-GVHD is highly resistant to treatment with immunosuppressive therapies, including glucocorticoids, cyclosporine, antithymocyte globulin, and ablative therapy followed by allogeneic bone marrow transplantation. Clinical manifestations appear at 8 to 10 days, and death occurs at 3 to 4 weeks posttransfusion.

TA-GVHDcan be prevented by irradiation of cellular components (minimum of 2500 cGy) before transfusion to patients at risk. Patients at risk for TA-GVHD include fetuses receiving intrauterine transfusions, selected immunocompetent (e.g., lymphoma patients) or immunocompromised recipients, recipients of donor units known to be from a blood relative, and recipients who have undergone marrow transplantation. Directed donations by family members should be discouraged (they are not less likely to transmit infection); lacking other options, the blood products from family members should always be irradiated.

Transfusion-Related Acute Lung Injury This uncommon reaction results from the transfusion of donor plasma that contains high titer anti-HLA antibodies that bind recipient leukocytes. The leukocytes aggregate in the pulmonary vasculature and release mediators that increase capillary permeability. The recipient develops symptoms of respiratory compromise and signs of noncardiogenic pulmonary edema, including bilateral interstitial infiltrates on chest x-ray. Treatment is supportive, and patients usually recover without sequelae. Testing the donor's plasma for anti-HLA antibodies can support this diagnosis. The implicated donors are frequently multiparous women, and transfusion of their plasma component should be avoided.

Posttransfusion Purpura This reaction presents as thrombocytopenia 7 to 10 days after platelet transfusion and occurs predominantly in women. Platelet-specific antibodies are found in the recipient's serum, and the most frequently recognized antigen is HPA-1a found on the platelet glycoprotein IIIa receptor. The delayed thrombocytopenia is due to the production of antibodies that react to both donor and recipient platelets. Additional platelet transfusions can worsen the thrombocytopenia and should be avoided. Treatment with intravenous immunoglobulin may neutralize the effector antibodies, or plasmapheresis can be used to remove the antibodies.

Alloimmunization A recipient may become alloimmunized to a number of antigens on cellular blood elements and plasma proteins. Alloantibodies toRBCantigens are detected during pretransfusion testing, and their presence may delay finding antigen-negative crossmatch-compatible products for transfusion. Women of child-bearing age who are sensitized to certain RBC antigens (i.e., D, c, E, Kell, or

Duffy) are at risk for bearing a fetus with hemolytic disease of the newborn. Matching for D antigen is the only pretransfusion selection test to prevent RBC alloimmunization.

Alloimmunization to antigens on leukocytes and platelets can result in refractoriness to platelet transfusions. Once alloimmunization has developed, HLA-compatible platelets from donors who share similar antigens with the recipient may be difficult to find. Hence, prudent transfusion practice is directed at preventing sensitization through the use of leukocyte-reduced cellular components, as well as limiting antigenic exposure by the judicious use of transfusions and use ofSDAPs.

NONIMMUNOLOGIC REACTIONS

Fluid Overload Blood components are excellent volume expanders, and transfusion may quickly lead to volume overload. Monitoring the rate and volume of the transfusion, along with the use of a diuretic, can minimize this problem.

Hypothermia Refrigerated (4°C) or frozen (-18°C or below) blood components can result in hypothermia when rapidly infused. Cardiac dysrhythmias can result from exposing the sinoatrial node to cold fluid. Use of an in-line warmer will prevent this complication.

Electrolyte Toxicity RBCleakage during storage increases the concentration of potassium in the unit. Neonates and patients in renal failure are at risk for hyperkalemia. Preventive measures, such as using fresh or washed RBCs, are warranted for neonatal transfusions because this complication can be fatal.

Citrate, commonly used to anticoagulate blood components, chelates calcium and thereby inhibits the coagulation cascade. Hypocalcemia, manifested by circumoral numbness and/or tingling sensation of the fingers and toes, may result from multiple rapid transfusions. Because citrate is quickly metabolized to bicarbonate, calcium infusion is seldom required in this setting. If calcium or any other intravenous infusion is necessary, it must be given through a separate intravenous line.

Iron Overload Each unit ofRBCs contains 200 to 250 mg of iron. Symptoms and signs of iron overload affecting endocrine, hepatic, and cardiac function are common after 100 units of RBCs have been transfused (total body iron load of 20 g). Preventing this complication by using alternative therapies (e.g., erythropoietin) and judicious transfusion is preferable and cost effective. Deferoxamine and other chelating agents are available, but the response is often suboptimal.

Hypotensive Reactions Transient hypotension may be noted among transfused patients who take angiotensin-converting enzyme (ACE) inhibitors. Since blood products contain bradykinin that is normally degraded by ACE, patients on ACE inhibitors may have increased bradykinin levels that cause hypotension. The blood pressure typically returns to normal without intervention.

Immunomodulation Transfusion of allogeneic blood is immunosuppressive. Multiply transfused renal transplant recipients are less likely to reject the graft. However, in postoperative settings and in cancer patients, immune suppression is dangerous. The

use of leukocyte-depleted cellular products may reduce the immunosuppression, though controlled data have not been obtained.

INFECTIOUS COMPLICATIONS

Viral Infections

Hepatitis C virus (HCV) The use of an improved screening test for HCV antibodies has reduced the incidence of posttransfusion HCV infection to 1 in 103,000 transfusions. Infection with HCV may be asymptomatic or lead to chronic active hepatitis, cirrhosis, and liver failure.

Hepatitis B Virus Transfusion-associatedHBVinfection has been reduced with improved donor selection and screening, along with increased vaccination of the donor and recipient population. However, some data suggest that HBV is more commonly transmitted by transfusion thanHCV. Vaccination of individuals who require long-term transfusion therapy can prevent this complication.

Hepatitis G virus (HGV) This hepatotropic virus is transmitted by transfusion. Infection with HGV results in no apparent adverse effects. Routine testing is not available and does not appear to be warranted.

Human Immunodeficiency Virus Type 1 Intensive donor screening and testing has dramatically reduced the risk of HIV-1 infection by blood transfusion. Donated blood is tested for HIV-1 p24 antigen. Two antigen-positive seronegative donors have been identified. The risk of HIV-1 infection per transfusion episode is 1 in 676,000. A specific assay to detect antibodies to HIV-2 is also performed on donated blood. No cases of HIV-2 infection have been reported in the United States since 1992, and only three donors have been found to have HIV-2 antibodies.

Cytomegalovirus This ubiquitous virus infects 50% or more of the general population and is transmitted by the infected "passenger" white blood cells found in transfusedPRBCs or platelet components. Donated blood is not routinely tested for serologic evidence of donor exposure, but assays can be performed to identifyCMV-seronegative donors, if needed. Alternatively, cellular components that are leukocyte-reduced have a decreased risk of transmitting CMV, regardless of the serologic status of the donor. Groups at risk for CMV infections include immunosuppressed patients, CMV-seronegative transplant recipients, and neonates; these patients should receive seronegative or leukocyte-depleted components.

Human T lymphotropic virus (HTLV) type I Assays to detect HTLV-I and -II are used to screen all donated blood. HTLV-1 is associated with adult T cell leukemia/lymphoma and tropical spastic paraparesis in a small percentage of infected persons (Chap. 191). The reported risk of HTLV-I infection via transfusion is 1 in 641,000 transfusion episodes. HTLV-II is not clearly associated with any disease.

Parvovirus B-19 Blood components and products derived from pooled plasma can transmit this virus, the etiologic agent of erythema infectiosum, or fifth disease, in children. Parvovirus B-19 shows tropism for erythroid precursors and inhibits both

erythrocyte production and maturation. Pure red cell aplasia, presenting either as acute aplastic crisis or chronic anemia with shortenedRBCsurvival, may occur in individuals with an underlying hematologic disease, such as sickle cell disease or thalassemia. The fetus of a seronegative woman is at risk for developing hydrops if infected with this virus.

Bacterial Contamination Most bacteria do not grow well at cold temperatures; thus,PRBCs and FFPare not common sources of bacterial contamination. However, some gram-negative bacteria, notably *Yersinia* and *Pseudomonas* species, can grow at 1° to 6°C. Platelet concentrates, which are stored at room temperature, are more likely to be contaminated with skin contaminants such as gram-positive organisms, including coagulase-negative staphylococci.

Recipients of transfusions contaminated with bacteria may develop fever and chills, which can progress to septic shock andDIC. These reactions may occur abruptly, within minutes of initiating the transfusion, or after several hours. The onset of symptoms and signs is often sudden and fulminant, which aids in differentiating bacterial contamination from a FNHTR. The reactions, particularly those related to gram-negative contaminants, are the result of infused endotoxins formed within the contaminated stored component.

When contaminated transfusions are suspected (i.e., when there is sudden development of shock), the transfusion must be stopped immediately. Therapy is directed at supporting the recipient's blood pressure, cardiac output, oxygenation, and renal function. The laboratory investigation should include cultures of any untransfused component, along with the routine blood bank clerical checks and serologic studies. Broad-spectrum antibiotic coverage should be started immediately and may be adjusted based on culture and sensitivity.

Parasites Various parasites including those causing malaria, babesiosis, and Chagas' disease can be transmitted by blood transfusion rarely. Geographical migration and travel of donors can shift the incidence of these rare infections. Because these infections can prove fatal, they should be considered in the transfused patient in the appropriate clinical setting.

ALTERNATIVES TO TRANSFUSION

Alternatives to allogeneic blood transfusions that avoid homologous donor exposures with attendant immunologic and infectious risks remain attractive. Autologous blood is the best option when transfusion is anticipated. However, the cost:benefit ratio of autologous transfusion remains high. No transfusion is a zero-risk event; clerical errors and bacterial contamination remain potential complications even with autologous transfusions. Additional methods of autologous transfusion in the surgical patient include preoperative hemodilution, recovery of shed blood from sterile surgical sites, and postoperative drainage collection. Directed or designated donation from friends and family of the potential recipient has not been safer than volunteer donor component transfusions. Such directed donations may in fact place the recipient at higher risk for complications such asGVHD and alloimmunization.

Oxygen-carrying blood substitutes, such as perfluorocarbons and aggregated

hemoglobin solution, are presently in various stages of clinical trials. Granulocyte- and granulocyte-macrophage colony stimulating factor (G- or GM-CSF) are clinically useful to hasten leukocyte recovery in patients with leukopenia related to high-dose chemotherapy. Erythropoietin stimulates erythrocyte production in patients with anemia of chronic renal failure and other conditions, thus avoiding or reducing the need for transfusion. This hormone can also stimulate erythropoiesis in the autologous donor to enable additional donation. Thrombopoietin, a cytokine that promotes megakaryocyte proliferation and maturation, is being tested for its ability to reduce the need for platelet transfusion.

115. BONE MARROW AND STEM CELL TRANSPLANTATION - *Frederick R. Appelbaum*

Bone marrow transplantation is the generic term used to describe the collection and transplantation of hematopoietic stem cells. The procedure is usually carried out for one of two purposes: (1) to replace an abnormal but nonmalignant lymphohematopoietic system with one from a normal donor, or (2) to treat malignancy by allowing the administration of higher doses of myelosuppressive therapy than would otherwise be possible. The use of bone marrow transplantation has been steadily increasing, both because of the its demonstrated effectiveness in selected diseases and because of increasing availability of donors. The International Bone Marrow Transplant Registry estimates that about 50,000 transplants were performed during 1999.

THE HEMATOPOIETIC STEM CELL

Several features of the hematopoietic stem cell make bone marrow transplantation clinically feasible, including its remarkable regenerative capacity, its ability to home to the marrow space following intravenous injection, and the ability of the stem cell to be cryopreserved. Transplantation of a single stem cell can replace the entire lymphohematopoietic system of an adult mouse. In humans, transplantation of a few percent of a donor's bone marrow volume regularly results in complete and sustained replacement of the recipient's entire lymphohematopoietic system, including all red cells, granulocytes, B and T lymphocytes, and platelets, as well as cells comprising the fixed macrophage population, including Kupffer cells of the liver, pulmonary alveolar macrophages, osteoclasts, Langerhans cells of the skin, and brain microglial cells. The ability of the hematopoietic stem cell to home to the marrow following intravenous injection is mediated, at least in part, by the interaction of specific cell molecules, termed *selectins*, on bone marrow endothelial cells with their unique ligands, termed *integrins*, on early hematopoietic cells. Human hematopoietic stem cells can survive freezing and thawing with little, if any, damage, making it possible to remove and store a portion of the patient's own bone marrow for later reinfusion following treatment of the patient with high-dose myelotoxic therapy.

CATEGORIES OF BONE MARROW TRANSPLANTATION

Bone marrow transplantation can be described according to the relationship between the patient and the donor and by the anatomic source of stem cells. In approximately 1% of cases, patients have identical twins who can serve as donors. Syngeneic donors represent the best source of stem cells; unlike allogeneic donors, there is no risk of graft-versus-host disease (GVHD) and, unlike use of autologous marrow, there is no risk that the stem cells are contaminated with tumor cells.

Allogeneic transplantation involves a donor and recipient who are not immunologically identical. Following allogeneic transplantation immune cells transplanted with the marrow or developing from it can react against the patient, causingGVHD. Alternatively, if the immunosuppressive preparative regimen used to treat the patient before transplant is inadequate, immunocompetent cells of the patient can cause graft rejection. The risks of these complications are greatly influenced by the degree of matching between donor and recipient for antigens encoded by genes of the major

histocompatibility complex.

The human leukocyte antigen (HLA) molecules are responsible for binding antigenic proteins and presenting them to T cells. The antigens presented by HLA molecules may derive from exogenous sources (e.g., during active infections) or may be endogenous proteins produced by the cell. If individuals are not matched for HLA, T cells from one individual will react strongly to the mismatched HLA, or "major antigens," of the second. Even if the individuals are HLA-matched, the T cells of the donor may react to differing endogenous, or "minor antigens," presented by the HLA of the recipient. Reactions to minor antigens tend to be less vigorous. The genes of major relevance to transplantation include HLA-A, -B, -C, and -D; they are closely linked and therefore tend to be inherited as haplotypes, with only rare crossovers between them. Thus, the odds that any one full sibling will match a patient are one in four, and the probability that the patient has an HLA-identical sibling is $1 - (0.75)^n$ where n equals the number of siblings.

With current techniques, the risk of graft rejection is 1 to 3%, and the risk of severe, life-threatening acuteGVHD is approximately 15% following transplantation betweenHLA-identical siblings. The incidence of graft rejection and GVHD increases progressively with the use of family member donors mismatched for one, two, or three antigens. While survival following a one-antigen mismatched transplant is not markedly altered, survival following two- or three-antigen mismatched transplants is significantly impaired, and such transplants should only be performed as part of clinical trials.

The formation of the National Marrow Donor Program has allowed for the identification ofHLA-matched unrelated donors for many patients. The genes encoding HLA antigens are highly polymorphic, and thus the odds of any two unrelated individuals being HLA-identical are extremely low, somewhat less than 1 in 10,000. However, by identifying and typing >3 million volunteer donors, HLA-matched donors now can found for approximately 50% of patients for whom a search is initiated. It takes, on average, 3 to 4 months to complete a search and schedule and initiate an unrelated donor transplant. Results so far suggest thatGVHD is somewhat increased and survival somewhat poorer with such donors than with HLA-matched siblings.

Autologous transplantation involves the removal and storage of the patient's own stem cells with subsequent reinfusion after the patient receives high-dose myeloablative therapy. Unlike allogeneic transplantation, there is no risk ofGVHD or graft rejection with autologous transplantation. On the other hand, autologous transplantation lacks a graft-versus-tumor effect, and the autologous stem cell product can be contaminated with tumor cells that could lead to relapse. A variety of techniques have been developed to "purge" autologous products of tumor cells. Some use antibodies directed at tumor-associated antigens plus complement, antibodies linked to toxins, or antibodies conjugated to immunomagnetic beads. In vitro incubation with certain chemotherapeutic agents such as 4-hydroperoxycylophosphamide and long-term culture of bone marrow has also been shown to diminish tumor cell numbers in stem cell products. Another technique is positive selection of stem cells using antibodies to CD34, with subsequent column adherence or flow techniques to select normal stem cells while leaving tumor cells behind. All these approaches can reduce the number of tumor cells from 1000- to 10,000-fold and are clinically feasible; however, no prospective randomized trials have yet shown that any of these approaches results in a decrease in relapse rates or

improvements in disease-free or overall survival.

Bone marrow aspirated from the posterior and anterior iliac crests has traditionally been the source of hematopoietic stem cells for transplantation. Typically, anywhere from 1.5 to 5´10^8nucleated marrow cells per kilogram are collected for allogeneic transplantation. Several recent studies have found improved survival in the settings of both matched sibling and unrelated transplantation by transplanting higher numbers of bone marrow cells.

Hematopoietic stem cells circulate in the peripheral blood but in very low concentrations. Following the administration of certain hematopoietic growth factors, including granulocyte colony stimulating factor (G-CSF) or granulocyte-macrophage colony stimulating factor (GM-CSF), and during recovery from intensive chemotherapy, the concentration of hematopoietic progenitor cells in blood, as measured either by colony forming units or expression of the CD34 antigen, increases markedly. This has made it possible to harvest adequate numbers of stem cells from the peripheral blood for transplantation. Donors are typically treated with 4 or 5 days of hematopoietic growth factor, following which stem cells are collected in one or two 4-h pheresis sessions. In the autologous setting, transplantation of>2.5 ´10^6 CD34 cells per kilogram, a number easily collected in most circumstances, leads to rapid and sustained engraftment in virtually all cases. Compared to the use of autologous marrow, use of peripheral blood stem cells results in more rapid hematopoietic recovery, with granulocytes recovering to 500/uL by day 12 and platelets recovering to 20,000/uL by day 14. While this more rapid recovery diminishes the morbidity of transplantation, no studies show an improvement in survival.

Hesitation in studying the use of peripheral blood stem cells for allogeneic transplantation was because peripheral blood stem cell products contain as much as one log more T cells than are contained in the typical marrow harvest; in animal models, the incidence ofGVHD is related to the number of T cells transplanted. Nonetheless, phase II and now randomized phase III trials have shown that the use of growth factor-mobilized peripheral blood stem cells fromHLA-matched family members leads to faster engraftment without an increase in acute GVHD. Chronic GVHD may be increased with peripheral blood stem cells, but in trials conducted so far, this has been more than balanced by reductions in relapse rates and nonrelapse mortality, with the use of peripheral blood stem cells resulting in improved overall survival.

Umbilical cord blood contains a high concentration of hematopoietic progenitor cells, allowing for its use as a source of stem cells for transplantation. Cord blood transplantation from family members has been explored in the setting where the immediate need for transplantation precludes waiting the 9 or so months generally required for the baby to mature to the point of donating marrow. Use of cord blood in such settings results in somewhat slower engraftment than seen with marrow but a low incidence ofGVHD, perhaps reflecting the low number of T cells in cord blood. More recently, several banks have been developed to harvest and store cord blood for possible transplantation to unrelated patients from material that would otherwise be discarded. A summary of the first 272 unrelated cord blood transplants, facilitated by the New York Blood Center, reported engraftment in approximately 90% of patients but at a slower pace than seen with a marrow. Significant GVHD was seen in 40% of patients.

The risk of graft failure was related to the dose of cord blood cells per kilogram infused. The low cell content of most cord blood collections has limited the use of this approach as a source of stem cells for adult patients.

THE TRANSPLANT PREPARATIVE REGIMEN

The treatment regimen administered to patients immediately preceding transplantation is designed to eradicate the patient's underlying disease and, in the setting of allogeneic transplantation, immunosuppress the patient adequately to prevent rejection of the transplanted marrow. The appropriate regimen, therefore, depends on the disease setting and source of marrow. For example, when transplantation is performed to treat severe combined immunodeficiency and the donor is a histocompatible sibling, no treatment is required because no host cells require eradication and the patient is already too immunoincompetent to reject the transplanted marrow. For aplastic anemia, there is no large population of cells to eradicate and high-dose cyclophosphamide plus antithymocyte globulin is sufficient to immunosuppress the patient adequately to accept the marrow graft. In the setting of thalassemia and sickle cell anemia, high-dose busulfan is frequently added to cyclophosphamide in order to eradicate the hyperplastic host hematopoiesis. A variety of different regimens have been developed to treat malignant diseases. Most of these regimens included agents that have high activity against the tumor in question at conventional doses and have myelosuppression as their predominant dose-limiting toxicity. Therefore, these regimens commonly include busulfan, cyclophosphamide, melphalan, thiotepa, carmustine, etoposide, and total-body irradiation in various combinations.

THE TRANSPLANT PROCEDURE

Marrow is usually collected from the donor's posterior and sometimes anterior iliac crests with the donor under general or spinal anesthesia. Typically, 10 to 15 mL/kg of marrow is aspirated, placed in heparinized media, and filtered through 0.3- and 0.2-mm screens to remove fat and bony spicules. The collected marrow may undergo further processing depending on the clinical situation, such as the removal of red cells to prevent hemolysis in ABO-incompatible transplants, the removal of donor T cells to preventGVHD, or attempts to remove possible contaminating tumor cells in autologous transplantation. Marrow donation is a safe procedure, with only very rare complications reported.

Peripheral blood stem cells are collected by leukopheresis after the donor has been treated with hematopoietic growth factors or, in the setting of autologous transplantation, sometimes after treatment with a combination of chemotherapy and growth factors. Stem cells for transplantation are generally infused through a large-bore central venous catheter. Such infusions are usually well tolerated, although occasionally patients develop fever, cough, or shortness of breath. These symptoms usually resolve with slowing of the infusion. When the stem cell product has been cryopreserved using dimethyl sulfoxide, patients more often experience short-lived nausea or vomiting due to the odor and taste of the cryoprotectant.

ENGRAFTMENT

Peripheral blood counts usually reach their nadir several days to a week posttransplant as a consequence of the preparative regimen, then cells produced by the transplanted stem cells begin to appear in the peripheral blood. The rate of recovery depends on the source of stem cells, the use of posttransplant growth factors, and the form ofGVHDprophylaxis employed. If marrow is the source of stem cells, recovery to 100 granulocytes per microliter occurs by day 16 and 500/uL by day 22. Use ofG-CSF-mobilized peripheral blood stem cells speeds the rate of recovery by approximately 1 week when compared to marrow. Use of myeloid growth factor (G-CSF orGM-CSF) posttransplant can further accelerate recovery by 3 to 5 days, while use of methotrexate to prevent GVHD delays engraftment by a similar period. Following allogeneic transplantation, engraftment can be documented using fluorescence in situ hybridization of sex chromosomes if donor and recipient are sex-mismatched,HLA-typing if HLA-mismatched, or restriction fragment length polymorphism analysis if sex- and HLA-matched.

COMPLICATIONS FOLLOWING BONE MARROW TRANSPLANT

EARLY DIRECT CHEMORADIOTOXICITIES

The transplant preparative regimens commonly used cause a spectrum of acute toxicities that vary according to the specific regimen but frequently result in nausea, vomiting, and mild skin erythema (Fig. 115-1). Regimens that include high-dose cyclophosphamide can result in hemorrhagic cystitis, which can usually be prevented by bladder irrigation or therapy with the sulfhydryl compound, mercaptoethanesulfonate (MESNA); rarely, acute hemorrhagic carditis is seen. Most preparative regimens will result in oral mucositis, which typically develops approximately 5 to 7 days posttransplant and often requires narcotic analgesia. Use of a patient-controlled analgesic pump provides the greatest patient satisfaction and results in a lower cumulative dose of narcotic. Patients begin losing their hair 5 to 6 days posttransplant and by 1 week are usually profoundly pancytopenic.

Approximately 10% of patients will develop venoocclusive disease of the liver, a syndrome resulting from direct cytotoxic injury to hepatic-venular and sinusoidal endothelium, with subsequent deposition of fibrin and the development of a local hypercoagulable state. This chain of events results in the clinical symptoms of tender hepatomegaly, ascites, jaundice, and fluid retention. These symptoms can develop any time during the first month posttransplant, with the peak incidence at day 16. The mortality of venoocclusive disease is approximately 30%, with progressive hepatic failure culminating in a terminal hepatorenal syndrome. Both thrombolytic and antithrombotic agents, such as tissue plasminogen activator, heparin, and prostaglandin E, have been studied as therapy, but none has proven of consistent major benefit in controlled trials and all have significant toxicity. Early studies with defibrotide, a polydeoxyribonucleotide, seem encouraging.

Although most pneumonias developing posttransplant are caused by infectious agents, in approximately 5% of patients a diffuse interstitial pneumonia will develop that is thought to be the result of direct toxicity of the preparative regimen. Bronchoalveolar lavage typically shows alveolar hemorrhage, and biopsies are typically characterized by diffuse alveolar damage, although some cases may have a more clearly interstitial

pattern. High-dose glucocorticoids are often used as treatment, although randomized trials testing their utility have not been reported.

LATE DIRECT CHEMORADIOTOXICITIES

Late complications of the preparative regimen include decreased growth velocity in children and delayed development of secondary sex characteristics. These complications can be partly ameliorated with the use of appropriate growth and sex hormone replacement. Most men become azoospermic, and most postpubertal women will develop ovarian failure, which should be treated. Thyroid dysfunction, usually well compensated, is sometimes seen. Cataracts develop in 10 to 20% of patients and are most common in patients treated with total-body irradiation and those who receive glucocorticoid therapy posttransplant for treatment ofGVHD. Aseptic necrosis of the femoral head is seen in 10% of patients and is particularly frequent in those receiving chronic glucocorticoid therapy.

GRAFT-VERSUS-HOST DISEASE

GVHDis the result of allogeneic T cells that were either transferred with the donor's stem cell inoculum or develop from it, reacting with antigenic targets on host cells. GVHD developing within the first 3 months posttransplant is termed *acute GVHD*, while GVHD developing or persisting beyond 3 months posttransplant is termed *chronic GVHD*. Acute GVHD most often first becomes apparent between 2 and 4 weeks posttransplant and is characterized by an erythematous maculopapular rash; persistent anorexia or diarrhea, or both; and by liver disease with increased serum levels of bilirubin, alanine and aspartate aminotransferase, and alkaline phosphatase. Since many conditions can mimic acute GVHD, diagnosis usually requires skin, liver, or endoscopic biopsy for confirmation. In all these organs, endothelial damage and lymphocytic infiltrates are seen. In skin, the epidermis and hair follicles are damaged; in liver, the small bile ducts show segmental disruption; and in intestines, destruction of the crypts and mucosal ulceration may be noted. A commonly used rating system for acute GVHD is shown inTable 115-1. Grade I acute GVHD is of little clinical significance, does not affect the likelihood of survival, and does not require treatment. In contrast, grades II to IV GVHD are associated with significant symptoms and a poorer probability of survival and require aggressive therapy. The incidence of acute GVHD is higher in recipients of stem cells from mismatched or unrelated donors, in older patients, and in patients unable to receive full doses of drugs used to prevent the disease.

One general approach to the prevention of GVHDis the administration of immunosuppressive drugs early after transplant. Combinations of methotrexate and either cyclosporine or tacrolimus are among the most effective and widely used regimens. Prednisone, anti-T cell antibodies, mycophenolate mofetil, and other immunosuppressive agents have also been or are being studied in various combinations. A second general approach to GVHD prevention is removal of T cells from the stem cell inoculum. While effective in preventing GVHD, T cell depletion is associated with an increased incidence of graft failure and of tumor recurrent posttransplant; as yet, little evidence suggests that this approach improves cure rates in any specific setting.

Despite prophylaxis, significant acuteGVHDwill develop in ~30% of recipients of stem cells from matched siblings and in as many as 60% of those receiving stem cells from unrelated donors. The disease is usually treated with glucocorticoids, anti-thymocyte globulin, or monoclonal antibodies targeted against T cells or T cell subsets.

Between 20 and 50% of patients surviving >6 months after allogeneic transplantation will develop chronicGVHD. The disease is more common in older patients, in recipients of mismatched or unrelated stem cells, and in those with a preceding episode of acute GVHD. The disease resembles an autoimmune disorder with malar rash, sicca syndrome, arthritis, obliterative bronchiolitis, and bile duct degeneration and cholestasis. Single-agent prednisone or cyclosporine is standard treatment at present, although trials of other agents, including thalidomide, are under way. In most patients, chronic GVHD resolves, but it may require 1 to 3 years of immunosuppressive treatment before these agents can be withdrawn without the disease recurring. Because patients with chronic GVHD are susceptible to significant infection, they should receive prophylactic trimethoprim-sulfamethoxazole, and all suspected infections should be investigated and treated aggressively.

GRAFT FAILURE

While complete and sustained engraftment are usually seen posttransplant, occasionally marrow function either does not return or, after a brief period of engraftment, is lost. Graft failure after autologous transplantation can be the result of inadequate numbers of stem cells being transplanted, damage during ex vivo treatment or storage, or exposure of the patient to myelotoxic agents posttransplant. Infections with cytomegalovirus (CMV) or human herpes virus type 6 have also been associated with loss of marrow function. Graft failure after allogeneic transplantation can also be due to immunologic rejection of the graft by immunocompetent host cells. Immunologically based graft rejection is more common following use of less immunosuppressive preparative regimens, in recipients of T cell-depleted stem cell products, and in patients receiving grafts fromHLA-mismatched donors.

Treatment of graft failure usually involves removing all potentially myelotoxic agents from the patient's regimen and attempting a short trial of myeloid growth factor. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. Reinfusion of donor stem cells in such patients is usually unsuccessful unless preceded by a second immunosuppressive preparative regimen. Standard preparative regimens are generally tolerated poorly if administered within 100 days of a first transplant because of cumulative toxicities. However, use of regimens combining, for example, anti-CD3 antibodies with high-dose glucocorticoids have been successful in achieving engraftment in >50% of patients.

INFECTION

The general problem of infection in the immunocompromised host is discussed inChap. 136. Posttransplant patients, particularly recipients of allogeneic transplantation, require unique approaches. Early after transplantation, patients are profoundly neutropenic, and because the risk of bacterial infection is so great, most centers initiate antibiotic treatment once the granulocyte count falls to <500/uL. Fluconazole prophylaxis at a

dose of 200 to 400 mg/kg per day reduces the risk of candidal infections. Patients seropositive for herpes simplex should receive acyclovir prophylaxis. One approach to infection prophylaxis is shown inTable 115-2. Despite these prophylactic measures, most patients will develop fever and signs of infection posttransplant. The management of patients who become febrile despite bacterial and fungal prophylaxis is a difficult challenge and is guided by individual aspects of the patient and by the institution's experience.

Once patients engraft, the incidence of bacterial infection diminishes; however, patients, particularly allogeneic transplant recipients, remain at significant risk of infection. During the period from engraftment until about 3 months posttransplant, the most common causes of infection are gram-positive bacteria, fungi (particularly *Aspergillus*) and viruses includingCMV. CMV infection, which in the past was frequently seen and often fatal, can be prevented in seronegative patients by the use of seronegative blood products. The use of ganciclovir, either as prophylaxis beginning at the time of engraftment or initiated when CMV first reactivates as evidenced by development of antigenemia, can significantly reduce the risk of CMV disease in seropositive patients. Foscarnet is effective for some patients who develop CMV antigenemia or infection despite the use of ganciclovir or who cannot tolerate the drug.

Pneumocystis carinii pneumonia, once seen in 5 to 10% of patients, can be prevented by treating patients with oral trimethoprim-sulfamethoxazole for 1 week pretransplant and resuming the treatment once patients have engrafted.

The risk of infection diminishes considerably beyond 3 months after transplant unless chronicGVHDdevelops, requiring continuous immunosuppression. Most transplant centers recommend continuing trimethoprim-sulfamethoxazole prophylaxis while patients are receiving any immunosuppressive drugs and also recommend careful monitoring for lateCMVreactivation. In addition, most centers recommend prophylaxis against varicella zoster, using acyclovir for 1 year posttransplant.

TREATMENT OF SPECIFIC DISEASES USING BONE MARROW TRANSPLANTATION

NONMALIGNANT DISEASES

Immunodeficiency Disorders By replacing abnormal stem cells with cells from a normal donor, marrow transplantation can cure patients of a variety of immunodeficiency disorders including severe combined immunodeficiency, Wiskott-Aldrich syndrome, and Chediak-Higashi syndrome. The widest experience has been with severe combined immunodeficiency disease, where cure rates of 90% can be expected withHLA-identical donors and success rates of 50 to 70% have been reported using haplotype-mismatched parents as donors (Table 115-3).

Aplastic Anemia Transplantation from matched siblings after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin can cure up to 90% of patients younger than age 40 with severe aplastic anemia. Results in older patients and in recipients of mismatched family member or unrelated marrow are less favorable; therefore, a trial of immunosuppressive therapy is generally recommended for such

patients before considering transplantation. Transplantation is effective in all forms of aplastic anemia including, for example, the syndromes associated with paroxysmal nocturnal hemoglobinuria and Fanconi's anemia. Patients with Fanconi's anemia are abnormally sensitive to the toxic effects of alkylating agents and so less intensive preparative regimens must be used in their treatment (Chap. 109).

Hemoglobinopathies Marrow transplantation from anHLA-identical sibling following a preparative regimen of busulfan and cyclophosphamide can cure 70 to 90% of patients with thalassemia major. The best outcomes can be expected if patients are transplanted before they develop hepatomegaly or portal fibrosis and if they have been given adequate iron chelation therapy. Among such patients, the probabilities of 5-year survival and disease-free survival are 95 and 90%, respectively. Although prolonged survival can be achieved with aggressive chelation therapy, transplantation is the only curative treatment for thalassemia. Transplantation is being studied as a curative approach to patients with sickle cell anemia. Two-year survival and disease-free survival rates of 90 and 80%, respectively, have been reported following matched sibling transplantation. Decisions about patient selection and the timing of transplantation remain difficult, but transplantation seems to represent a reasonable option for younger patients who suffer repeated crises or other significant complications and who have not responded to other interventions (Chap 106).

Other Nonmalignant Diseases Theoretically, marrow transplantation should be able to cure any disease that results from an inborn error of the lymphohematopoietic system. Transplantation has been used successfully to treat congenital disorders of white blood cells such as Kostmann's syndrome, chronic granulomatous disease, and leukocyte adhesion deficiency. Congenital anemias such as Blackfan-Diamond anemia can also be cured with transplantation. Infantile malignant osteopetrosis is due to an inability of the osteoclast to resorb bone, and since osteoclasts derive from the marrow, transplantation can cure this rare inherited disorder.

Marrow transplantation has been used as treatment for a number of storage diseases caused by enzymatic deficiencies, such as Gaucher's disease, Hurler's syndrome, Hunter's syndrome, and infantile metachromatic leukodystrophy. Transplantation for these diseases has not been uniformly successful, but treatment early in the course of these diseases, before irreversible damage to extramedullary organs has occurred, increases the chance for success.

Transplantation is being explored as a treatment for severe acquired autoimmune disorders. These trials are based on studies demonstrating that transplantation can reverse autoimmune disorders in animal models and on the observation that occasional patients with coexisting autoimmune disorders and hematologic malignancies have been cured of both with transplantation.

MALIGNANT DISEASES

Acute Leukemia Allogeneic marrow transplantation cures 15 to 20% of patients who do not achieve complete response from induction chemotherapy for acute myeloid leukemia (AML) and is the only form of therapy that can cure such patients. Cure rates of 30 to 35% are seen when patients are transplanted in second remission or in first

relapse. The best results with allogeneic transplantation are achieved when applied during first remission, with disease-free survival rates averaging between 55 and 60%. Chemotherapy alone can cure a portion of AML patients, and so the relative merits of transplanting all patients during first remission versus only transplanting very high risk patients and those who relapse continue to be discussed. Autologous transplantation is also able to cure a portion of patients with AML. The rates of disease recurrence with autologous transplantation are higher than seen after allogeneic transplantation, and cure rates are generally somewhat less.

Similar to patients withAML, adults with acute lymphoblastic leukemia who do not achieve a complete response to induction chemotherapy can be cured in 15 to 20% of cases with immediate marrow transplantation. Cure rates improve to 30 to 50% in second remission, and therefore transplantation can be recommended for adults who have persistent disease after induction chemotherapy or who have subsequently relapsed. Transplantation in first remission results in cure rates around 55%. While transplantation appears to offer a clear advantage over chemotherapy for patients with high-risk disease, such as those with Philadelphia chromosome-positive disease, debate continues about whether adults with standard-risk disease would be transplanted in first remission or whether transplantation should be reserved until relapse. Autologous transplantation is associated with a higher relapse rate but a somewhat lower risk of nonrelapse mortality when compared to allogeneic transplantation. On balance, most experts recommend use of allogeneic stem cells if an appropriate donor is available.

Chronic Leukemia Allogeneic marrow transplantation is the only therapy shown to cure a substantial portion of patients with chronic myeloid leukemia. Five-year disease-free survival rates are 60 to 70% for patients transplanted during chronic phase, 30 to 40% for patients transplanted during accelerated phase, and 15 to 20% for patients transplanted in blast crisis. Time from diagnosis to transplantation influences outcome, with best results obtained among patients transplanted within 1 year of diagnosis. Use of unrelated donors results in moreGVHD and slightly worse survival than seen with matched siblings, although, at some large centers, 3-year disease-free survival rates of 70% have been reported. Autologous transplantation is being studied; however, few data suggest that this approach has curative potential in this disease. Given the excellent results obtained with matched sibling transplantation, most experts recommend early transplantation for younger patients with matched siblings. For older patients or those without matched siblings, it is not unreasonable to consider a trial of an interferon a-containing regimen to see if a major cytogenetic response can be achieved before making a decision about transplantation (Chap. 111).

Allogeneic transplantation has been used to only a limited extent for chronic lymphocytic leukemia, in large part because of the chronic nature of the disease and because of the age profile of patients. With allogeneic transplantation, complete remissions have been achieved in the majority of patients so far reported, with disease-free survival rates of approximately 50% at 3 years. However, treatment-related mortality has been substantial, and further follow-up is needed. There is even less experience with autologous transplantation in this disorder.

Myelodysplasia Between 40 and 50% of patients with myelodysplasia appear to be

cured with allogeneic marrow transplantation. Results are better among younger patients and those with less advanced disease. However, some patients with myelodysplasia can live for extended periods without intervention, and so transplantation is generally recommended only for patients with disease categorized as intermediate risk I or greater according to the International Prognostic Scoring System (Chap. 109).

Lymphoma Patients with disseminated intermediate- or high-grade non-Hodgkin's lymphoma who have not been cured by first-line chemotherapy and are transplanted in first relapse or second remission can still be cured in 40 to 50% of cases. This represents a clear advantage over results obtained with salvage chemotherapy. It is unsettled whether patients with high-risk disease benefit from transplantation in first remission. Most experts favor the use of autologous rather than allogeneic transplantation for patients with non-Hodgkin's lymphoma, because fewer complications occur with this approach and survival appears equivalent. The role of transplantation in patients with indolent non-Hodgkin's lymphoma is less well defined. Long-term remissions can be obtained in many patients with acceptable toxicity and results with transplantation in patients with recurrent disease generally appear better than one would expect with conventional-dose chemotherapy. However, late relapses are seen after transplantation, and no randomized study has confirmed its superiority.

The role of transplantation in Hodgkin's disease is similar to that in non-Hodgkin's lymphoma. With transplantation, 5-year disease-free survival ranges from 20 to 30% in patients who never achieve a first remission with standard chemotherapy and up to 60% for those transplanted in second remission. Transplantation has no defined role in first remission in Hodgkin's disease.

Myeloma Patients with myeloma who have progressed on first-line therapy can sometimes benefit from allogeneic or autologous transplantation. Autologous transplantation has been studied as part of the initial therapy of patients, and in randomized trials, both disease-free survival as well as overall survival were improved with this approach.

Solid Tumors Among women with metastatic breast cancer, between 15 and 20% disease-free survival rates at 3 years have been reported, with better results seen in younger patients who have responded completely to standard-dose therapy before undergoing transplantation. Randomized trials have not shown superior survival for patients treated for metastatic disease with high-dose chemotherapy plus stem cell support. Randomized trials evaluating transplantation as treatment for primary breast cancer are being conducted, but final results are not yet available.

Patients with testicular cancer who have failed first-line chemotherapy have been treated with autologous transplantation. Approximately 10 to 20% of such patients apparently have been cured with this approach.

The use of high-dose chemotherapy with autologous stem cell support is being studied for several other solid tumors, including ovarian cancer, small-cell lung cancer, neuroblastoma, and pediatric sarcomas. As in most other settings, the best results have been obtained in patients with limited amounts of disease and where the remaining

tumor retains sensitivity to conventional-dose chemotherapy. Few randomized trials of transplantation in these diseases have been completed.

Posttransplant Relapse Patients who relapse following autologous transplantation sometimes respond to further chemotherapy, particularly if the remission following transplantation was long. More options are available for patients who relapse following allogeneic transplantation. Of particular interest are the response rates seen with infusion of unirradiated donor lymphocytes. Complete responses in as many as 75% of patients with chronic myeloid leukemia, 40% in myelodysplasia, 25% inAML, and 15% in myeloma have been reported. Major complications of donor lymphocyte infusions include transient myelosuppression and the development ofGVHD. These complications appear to be dependent on the number of donor lymphocytes infused. The impressive responses seen with donor lymphocyte infusions in some patients has encouraged investigation into the use of "nonablative" transplant regimens as treatment for various malignancies. In this approach, preparative regimens and posttransplant immunosuppression are selected that allow for engraftment without regard to their direct antitumor activities. The antitumor effects are the result of a graft-versus-tumor effect arising from the transplanted stem cells or subsequent infusion of donor lymphocytes. While engraftment can be reliably achieved with this approach, with little toxicity, and complete responses are seen, neither the rate of complete responses nor their duration have yet been entirely determined for any specific disease category.

SECTION 3 -DISORDERS OF HEMOSTASIS

116. DISORDERS OF THE PLATELET AND VESSEL WALL - *Robert I. Handin*

Patients with platelet or vessel wall disorders usually bleed into superficial sites such as the skin, mucous membranes, or genitourinary or gastrointestinal tract. Bleeding begins immediately after trauma and either responds to simple measures such as pressure and packing or requires systemic therapy with glucocorticoids, desmopressin [1-desamino-8-D-arginine vasopressin (DDAVP)], plasma fractions, or platelet concentrates. The most common platelet/vessel wall disorders are (1) various forms of thrombocytopenia, (2) von Willebrand's disease (vWD), and (3) drug-induced platelet dysfunction. This chapter reviews the diagnosis and treatment of quantitative and qualitative platelet disorders as well as vessel wall defects that cause bleeding.*For further discussion of the physiology of normal hemostasis and the cardinal manifestations of bleeding arising from hemostatic disorders, see Chap. 62.*

PLATELET DISORDERS

Platelets arise from the fragmentation of megakaryocytes, which are very large, polyploid bone marrow cells produced by the process of endomitosis. They undergo from three to five cycles of chromosomal duplication without cytoplasmic division. After leaving the marrow space, about one-third of the platelets are sequestered in the spleen, while the other two-thirds circulate for 7 to 10 days. Normally, only a small fraction of the platelet mass is consumed in the process of hemostasis, so most platelets circulate until they become senescent and are removed by phagocytic cells. The normal blood platelet count is 150,000 to 450,000/ul. A decrease in platelet count stimulates an increase in the number, size, and ploidy of megakaryocytes, releasing additional platelets into the circulation. This process is regulated by thrombopoietin (TPO) binding to its megakaryocyte receptor, a proto-oncogene c-mpl. TPO (c-mpl ligand) is secreted continuously at a low level and binds tightly to circulating platelets. A reduction in platelet count increases the level of free TPO and thereby stimulates megakaryocyte and platelet production.

The platelet count varies during the menstrual cycle, rising following ovulation and falling at the onset of menses. It is also influenced by the patient's nutritional state and can be decreased in severe iron, folic acid, or vitamin B_{12}deficiency. Platelets are *acute-phase reactants*, and patients with systemic inflammation, tumors, bleeding, and mild iron deficiency may have an increased platelet count, a benign condition called *secondary* or *reactive thrombocytosis*. The cytokines interleukin (IL)-3, IL-6, and IL-11 may stimulate platelet production in acute inflammation. In contrast, the increase in platelet count that is characteristic of the myeloproliferative disorders such as polycythemia vera, chronic myelogenous leukemia, myeloid metaplasia, and essential thrombocytosis can cause either severe bleeding or thrombosis. In these patients, unregulated platelet production is secondary to a clonal stem cell abnormality affecting all the bone marrow progenitors.

THROMBOCYTOPENIA

Thrombocytopenia is caused by one of three mechanisms -- decreased bone marrow

production, increased splenic sequestration, or accelerated destruction of platelets. In order to determine the etiology of thrombocytopenia, each patient should have a careful examination of the peripheral blood film, an assessment of marrow morphology by examination of an aspirate or biopsy, and an estimate of splenic size by bedside palpation supplemented, if necessary, by ultrasonography or computed tomographic (CT) scan. Occasional patients have "pseudothrombocytopenia," a benign condition in which platelets agglutinate or adhere to leukocytes when blood is collected with EDTA as anticoagulant. This is a laboratory artifact, and the actual platelet count in vivo is normal. A scheme for classifying patients with thrombocytopenia based on these clinical observations and laboratory tests is outlined inFig. 116-1.

Impaired Production Disorders that injure stem cells or prevent their proliferation frequently cause thrombocytopenia. They usually affect multiple hematopoietic cell lines so that thrombocytopenia is accompanied by varying degrees of anemia and leukopenia. Diagnosis of a platelet production defect is readily established by examination of a bone marrow aspirate or biopsy, which should show a reduced number of megakaryocytes. The most common causes of decreased platelet production are marrow aplasia, fibrosis, or infiltration with malignant cells, all of which produce highly characteristic marrow abnormalities. Occasionally, thrombocytopenia is the presenting laboratory abnormality in these disorders. Cytotoxic drugs impair megakaryocyte proliferation and maturation and frequently cause thrombocytopenia. Rare marrow disorders such as congenital amegakaryocytic hypoplasia and *t*hrombocytopenia with *a*bsent *r*adii (TAR syndrome), produce a selective decrease in megakaryocyte production.

Splenic Sequestration Since one-third of the platelet mass is normally sequestered in the spleen, splenectomy will increase the platelet count by 30%. Postsplenectomy thrombocytosis is a benign self-limited condition that does not require specific therapy. In contrast, when the spleen enlarges, the fraction of sequestered platelets increases, lowering the platelet count. The most common causes of splenomegaly are portal hypertension secondary to liver disease and splenic infiltration with tumor cells in myeloproliferative or lymphoproliferative disorders (Chap. 63). Isolated splenomegaly is rare, and in most patients it is accompanied by other clinical manifestations of an underlying disease. Many patients with leukemia, lymphoma, or a myeloproliferative syndrome have both marrow infiltration and splenomegaly and develop thrombocytopenia from a combination of impaired marrow production and splenic sequestration of platelets.

Accelerated Destruction Abnormal vessels, fibrin thrombi, and intravascular prostheses can all shorten platelet survival and cause *nonimmunologic thrombocytopenia*. Thrombocytopenia is common in patients with vasculitis, the hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), or as a manifestation of disseminated intravascular coagulation (DIC). In addition, platelets coated with antibody, immune complexes, or complement are rapidly cleared by mononuclear phagocytes in the spleen or other tissues, inducing *immunologic thrombocytopenia*. The most common causes of immunologic thrombocytopenia are viral or bacterial infections, drugs, and a chronic autoimmune disorder referred to as *idiopathic thrombocytopenic purpura* (ITP). Patients with immunologic thrombocytopenia do not usually have splenomegaly and have an increased number of bone marrow

megakaryocytes.

DRUG-INDUCED THROMBOCYTOPENIA

Many common drugs can cause thrombocytopenia (Table 116-1). Cancer chemotherapeutic agents may depress megakaryocyte production. Ingestion of large quantities of alcohol has a marrow-depressing effect leading to transient thrombocytopenia, particularly in binge drinkers. Thiazide diuretics, used to treat hypertension or congestive heart failure, impair megakaryocyte production and can produce mild thrombocytopenia (50,000 to 100,000/uL), which may persist for several months after the drug is discontinued.

Most drugs induce thrombocytopenia by eliciting an immune response in which the platelet is an innocent bystander. The platelet is damaged by complement activation following the formation of drug-antibody complexes. Current laboratory tests can identify the causative agent in 10% of patients with clinical evidence of drug-induced thrombocytopenia. The best proof of a drug-induced etiology is a prompt rise in the platelet count when the suspected drug is discontinued. Patients with drug-induced platelet destruction may also have a secondary increase in megakaryocyte number without other marrow abnormalities.

Although most patients recover within 7 to 10 days and do not require therapy, occasional patients with platelet counts <10,000 to 20,000/uL have severe hemorrhage and may require temporary support with glucocorticoids, plasmapheresis, or platelet transfusions while waiting for the platelet count to rise. A patient who has recovered from drug-induced immunologic thrombocytopenia should be instructed to avoid the offending drug in the future, since only minute amounts of drug are needed to set up subsequent immune reactions. Certain drugs that are cleared from body storage depots quite slowly, such as phenytoin, may induce prolonged thrombocytopenia.

Heparin is a common cause of thrombocytopenia in hospitalized patients. Between 10 and 15% of patients receiving therapeutic doses of heparin develop thrombocytopenia and, occasionally, may have severe bleeding or intravascular platelet aggregation and paradoxical thrombosis. Heparin-induced thrombosis, sometimes called the "white clot syndrome," can be fatal unless recognized promptly. Most cases of heparin thrombocytopenia are due to drug-antibody binding to platelets; some are secondary to direct platelet agglutination by heparin. The offending antigen is a complex formed between heparin and the platelet-derived heparin neutralizing protein, platelet factor 4. Prompt cessation of heparin will reverse both thrombocytopenia and heparin-induced thrombosis. Low-molecular-weight heparin products have reduced the incidence of heparin-induced thrombocytopenia. They are effective antithrombotic agents (Chap. 118) and are less immunogenic. Unfortunately, 80 to 90% of the antibodies generated against conventional heparins cross-react with low-molecular-weight heparins, so only a minority of patients with preformed antibody can be treated with this product.

IDIOPATHIC THROMBOCYTOPENIC PURPURA

The immunologic thrombocytopenias can be classified on the basis of the pathologic mechanism, the inciting agent, or the duration of the illness. The explosive onset of

severe thrombocytopenia following recovery from a viral exanthem or upper respiratory illness (*acuteITP*) is common in children and accounts for 90% of the pediatric cases of immunologic thrombocytopenia. Of these patients, 60% recover in 4 to 6 weeks and>90% recover within 3 to 6 months. Transient immunologic thrombocytopenia also complicates some cases of infectious mononucleosis, acute toxoplasmosis, or cytomegalovirus infection and can be part of the prodromal phase of viral hepatitis and initial infection with HIV. Acute ITP is rare in adults and accounts for<10% of postpubertal patients with immune thrombocytopenia. Acute ITP is caused by immune complexes containing viral antigens that bind to platelet Fc receptors or by antibodies produced against viral antigens that cross-react with the platelet. In addition to these viral disorders, the differential diagnosis includes atypical presentations of aplastic anemia, acute leukemias, or metastatic tumor. A bone marrow examination is essential to exclude these disorders, which can occasionally mimic acute ITP.

Most adults present with a more indolent form of thrombocytopenia that may persist for many years and is referred to as *chronicITP*. Women age 20 to 40 are afflicted most commonly and outnumber men by a ratio of 3:1. They may present with an abrupt fall in platelet count and bleeding similar to patients with acute ITP. More often they have a prior history of easy bruising or menometrorrhagia. These patients have an autoimmune disorder with antibodies directed against target antigens on the glycoprotein IIb-IIIa or glycoprotein Ib-IX complex (Fig. 62-2). Although most antibodies function as opsonins and accelerate platelet clearance by phagocytic cells, occasional antibodies bind to epitopes on critical regions of these glycoproteins and impair platelet function. Platelet-associated IgG can be measured but specificity is a problem. High "background" level of IgG on normal platelets and elevations in plasma immunoglobulin levels or in circulating immune complexes will nonspecifically increase platelet-associated IgG. Few clinical situations require platelet-associated IgG testing.

A low platelet count may be the initial manifestation of systemic lupus erythematosus (SLE) or the first sign of a primary hematologic disorder. Thus, patients with chronicITPshould have a bone marrow examination and an antinuclear antibody determination. In addition, patients with hepatic or splenic enlargement, lymphadenopathy, or atypical lymphocytes should have serologic studies for hepatitis viruses, cytomegalovirus, Epstein-Barr virus, toxoplasma, and HIV. HIV infection is a common cause of immunologic thrombocytopenia. Thrombocytopenia can be the initial symptom of HIV infection or a complication of fully developed clinical AIDS.

TREATMENT

Treatment of patients withITP must take into account the age of the patient, the severity of the illness, and the anticipated natural history. Although adults have a higher incidence of intracranial bleeding than children, specific therapy may not be necessary unless the platelet count is <20,000/uL or there is extensive bleeding. Hemorrhage in patients with either acute or chronic ITP can usually be controlled with glucocorticoids but, in rare cases, may require temporary phagocytic blockade with intravenous immunoglobulin (IVIG) or anti-RhD (WinRho). Although antibody preparations are effective, they are expensive and should be reserved for patients with severe thrombocytopenia and clinical bleeding who are refractory to other measures. Emergency splenectomy is usually reserved for patients with acute or chronic ITP who

are desperately ill and have not responded to any medical measures. The treatment of symptomatic thrombocytopenia in patients with HIV infection is more complex because the administration of glucocorticoids or splenectomy may increase susceptibility to opportunistic infections. Splenectomy has been effective in the course of HIV before the onset of symptomatic AIDS. Treatment with zidovudine (AZT) and other antiviral agents that reduce viral load can improve the platelet count in patients with HIV-induced thrombocytopenia.

Symptomatic patients with chronicITP are usually placed on prednisone, 60 mg/d for 4 to 6 weeks. The drug is then decreased slowly over another few weeks. About 50% of patients with chronic ITP will normalize their platelet count on high doses of prednisone. However, the majority will have a fall in platelet count following steroid withdrawal. Patients with chronic ITP who fail to maintain a normal platelet count after a course of prednisone are eligible for elective splenectomy. These steroid-responsive but steroid-dependent patients are very likely to respond to splenectomy, and 70% will have a normal platelet count within 1 week after surgery. Some patients who do not respond to glucocorticoids may still respond to splenectomy. Occasionally, patients may fail to respond to splenectomy because of the failure to remove an accessory spleen. In other patients, a small, inactive accessory spleen may grow or new splenic foci may develop from splenic cells shed at the time of surgery and cause the late onset of thrombocytopenia. In either case, the presence of splenic tissue can be diagnosed by examination of the blood smear for Howell-Jolly bodies that appear in the red cells of asplenic individuals. Persistent splenic tissue can be confirmed by a radionuclide scan.

Patients still thrombocytopenic after splenectomy or who relapse months to years after initial therapy have received a variety of immunosuppressive drugs including azathioprine, cyclophosphamide, vincristine, vinblastine, and cyclosporine. Danazol has also been used with some success. Although each of these drugs may be beneficial, they have serious side effects and should be used judiciously.IVIG and anti-RhD are only transiently effective and expensive. IVIG can cause meningismus and headache, and some lots have carried hepatitis C virus. Anti-RhD can cause hemolysis. These drugs should be used to raise the platelet count temporarily and to support patients before surgery or labor and delivery; they are not substitutes for splenectomy. If a patient is not bleeding and maintains a platelet count >20,000/uL, consideration should be given to withholding therapy. Patients with severe chronic thrombocytopenia may live with their disease for two or three decades.

FUNCTIONAL PLATELET DISORDERS

As described inChap. 62, normal hemostasis requires three critical platelet reactions -- adhesion, aggregation, and granule release. Clinical bleeding can result from a failure of any of these important functions. Table 116-2 lists the major functional platelet disorders. Table 116-3 lists methods to assess platelet function.

Von Willebrand's Disease vWD is the most common inherited bleeding disorder, occurring in 1 in 800 to 1000 individuals. The von Willebrand factor (vWF) is a heterogeneous multimeric plasma glycoprotein with two major functions: (1) It facilitates platelet adhesion under conditions of high shear stress by linking platelet membrane receptors to vascular subendothelium; and (2) it serves as the plasma carrier for factor

VIII, the antihemophilic factor, a critical blood coagulation protein. Discrete domains in each vWF subunit mediate each of these important functions. The normal plasma vWF level is 10 mg/L. The vWF activity is distributed among a series of plasma multimers with estimated molecular weights ranging from 400,000 to >20 million. A single large vWF precursor subunit is synthesized in endothelial cells and megakaryocytes, where it is cleaved and assembled into the disulfide-linked multimers present in plasma, platelets, and vascular subendothelium. A modest reduction in plasma vWF concentration or a selective loss in the high-molecular-weight multimers decreases platelet adhesion and causes clinical bleeding.

AlthoughvWD is heterogeneous, certain clinical features are common to all the syndromes. With one exception (type III disease), all forms are inherited as autosomal dominant traits, and affected patients are heterozygous with one normal and one abnormalvWFallele. In mild cases, bleeding occurs only after surgery or trauma. More severely affected patients have spontaneous epistaxis or oral mucosal, gastrointestinal, or genitourinary bleeding. The laboratory findings are variable. The most diagnostic pattern is the combination of (1) a prolonged bleeding time, (2) a reduction in plasma vWF concentration, (3) a parallel reduction in biologic activity as measured with the ristocetin cofactor assay, and (4) reduced factor VIII activity. The variability in laboratory tests is related to both the heterogeneous nature of the defects in vWD and the fact that plasma levels are influenced by ABO blood group type, central nervous system disorders, systemic inflammation, and pregnancy. Since vWD is an autosomal dominant disorder, some vWF is produced by the remaining normal allele. Thus patients with mild defects may have laboratory values that fluctuate over time and may occasionally be within the normal range.

There are three major types ofvWD. Their mode of inheritance and laboratory findings are shown inFig. 116-2. Patients with *type I disease*, the most common abnormality, have a mild to moderate decrease in plasmavWF. In the milder cases, although hemostasis is impaired, the vWF level is just below normal (50% activity, or 5 mg/L). In type I disease, vWF antigen, factor VIII activity, and ristocetin cofactor activity are decreased with a normal spectrum of multimers detected by sodium dodecyl sulfate (SDS)-agarose gel electrophoresis.

The variant forms ofvWD(*type II disease*) are much less common and characterized by normal or near-normal levels of a dysfunctional protein. Patients with the *type IIa variant* of vWD have a deficiency in the high- and medium-molecular-weight forms ofvWFmultimer detected bySDS-agarose electrophoresis. This is due either to an inability to secrete the high-molecular-weight vWF multimers or to proteolysis of the multimers soon after they leave the endothelial cell and enter the circulation. Mutations in a localized region of the vWF A-2 domain have been identified in families with type IIa vWD (Fig. 116-3). The quantity of vWF antigen and the amount of associated factor VIII are usually normal. In the *type IIb variant*, high-molecular-weight multimers are also decreased; however, the decrease is due to the inappropriate binding of vWF to platelets. Intravascular platelet aggregates form that are rapidly cleared from the circulation, causing mild, variable thrombocytopenia. Mutations in a disulfide-bonded loop in the A-1 domain that binds to glycoprotein Ib-IX are the cause of the type IIb defect (Fig. 116-3). A few patients have a platelet membrane disorder that mimics type IIb vWD -- *platelet-type vWD*. It is due to mutations in the portion of glycoprotein Ib-IX

that interacts with vWF. Levels of total vWF antigen and factor VIII are normal.

Approximately 1 in 1 million individuals has a very severe form ofvWD that is phenotypically recessive (*type III disease*). Type III patients are usually the offspring of two parents (usually asymptomatic) with mild type I disease. Type III patients may inherit a different abnormality from each parent (a doubly heterozygous or compound heterozygous state) or be homozygous for a single defect. Type III patients have severe mucosal bleeding and no detectablevWFantigen or activity and, like patients with mild hemophilia, may have sufficiently low factor VIII that they have occasional hemarthroses. Major deletions in the vWF gene have been found in some type III families. Families with nonsense mutations and the combination of a deleted and nonsense mutant allele have also been described.

Type IIN disease is due to a defect in the factor VIII binding site ofvWF. Patients resemble those with mild hemophilia and have low levels of factor VIII. The presence of disease in both males and females in a family is a clue to the role of vWF in this disease.

TREATMENT

There are two therapeutic options. Factor VIII concentrates retain high-molecular-weightvWFmultimers (Humate-P, Alfanate), are highly purified and heat-treated to destroy HIV, and are appropriate treatments for all the inherited forms ofvWD. During surgery or after major trauma, patients should receive factor VIII concentrates twice daily for 2 or 3 days to assure optimal hemostasis. Minor bleeding episodes such as prolonged epistaxis or severe menorrhagia may respond to a single infusion. Recurrent menorrhagia, a major problem for women with severe vWD, can be treated effectively with oral contraceptive agents that suppress menses.

A second therapeutic option, which avoids the use of plasma, is the use ofDDAVP or desmopressin, a vasopressin analogue that has minimal blood pressure-elevating and fluid-retaining properties and raises the plasmavWFlevel in both normal individuals and patients with mildvWD. Patients with type I disease are the best candidates for DDAVP therapy. However, they must be tested for an adequate response before anticipated surgery, and vWF levels must be monitored closely during therapy, since the patient may develop tachyphylaxis when therapy is continued for more than 48 h. DDAVP should not be given to patients with variant forms of vWD without prior testing, since it may not improve multimer pattern or hemostasis in type IIa patients and may actually worsen the defect by depleting high-molecular-weight multimers, inducing intravascular platelet aggregation, and lowering the platelet count in type IIb patients. It is ineffective therapy for the severe (type III) form of vWD.

Acquired vWD Although most cases of vWDare inherited, acquired vWD may be caused by antibodies that inhibitvWFfunction or by lymphoid or other tumors that selectively adsorb vWF multimers onto their surfaces. Anti-vWF antibodies have developed in patients with severe vWD following multiple transfusions, as well as in patients with autoimmune and lymphoproliferative disorders. Adsorption of vWF to tumor surfaces has been documented in patients with Waldenstrom's macroglobulinemia and Wilms' tumor and inferred in other patients with lymphoma. Treatment of acquired vWD should

focus on the underlying disease, since plasma derivatives andDDAVPare often not effective and the disorder can be fatal.

Platelet Membrane Defects Receptors that modulate platelet adhesion and aggregation are located on the two major platelet surface glycoproteins.vWFfacilitates platelet adhesion by binding to glycoprotein Ib-IX, while fibrinogen links platelets into aggregates via sites on the glycoprotein IIb-IIIa complex. Two rare platelet defects are characterized by a loss of or a defect in these glycoprotein receptors. Patients with the *Bernard-Soulier syndrome* have markedly reduced platelet adhesion and cannot bind vWF to their platelets due to deficiency or dysfunction of the glycoprotein Ib-IX complex. They also have reduced levels of several other membrane proteins, mild thrombocytopenia, and extremely large, lymphocytoid platelets. Platelets from patients with *Glanzmann's disease* or *thrombasthenia* are deficient or defective in the glycoprotein IIb-IIIa complex. Their platelets do not bind fibrinogen and cannot form aggregates, although the platelets undergo shape change and secretion and are of normal size.

Both these disorders are autosomal recessive traits and are characterized by markedly impaired hemostasis and recurrent episodes of severe mucosal hemorrhage. Bernard-Soulier platelets react normally to all stimuli except ristocetin. In contrast, thrombasthenic platelets adhere normally and will agglutinate with ristocetin but will not aggregate with any of the agonists that require fibrinogen binding, such as adenosine diphosphate (ADP), thrombin, or epinephrine.

The only effective therapy for hemorrhagic episodes in these two disorders is transfusion with normal platelets. Alloimmunization will eventually limit the life span of infused platelets. In addition, a few patients have developed inhibitor antibodies with specificity for the missing protein. These antibodies bind to the protein that is expressed on the transfused normal platelets and impair their function.

Platelet Release Defects The most common mild bleeding disorders arise from the ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit platelet production of thromboxane A_2, an important mediator of platelet secretion and aggregation (Figs. 62-3 and62-4). These drugs inhibit cyclooxygenase, which converts arachidonic acid to a labile endoperoxide intermediate that is critical for thromboxane formation. Aspirin is the most potent agent, since it irreversibly acetylates the platelet enzyme so that a single dose impairs hemostasis for 5 to 7 days. The other agents are competitive and reversible inhibitors with more transient effects. Blocking thromboxane A_2synthesis partially inhibits platelet release and aggregation with weak agonists, such asADP and epinephrine, and produces a mild hemostatic defect. The administration of high doses of certain antibiotics, particularly penicillin, can coat the platelet surface, block platelet release, and impair hemostasis.

Patients generally have minimal symptoms such as easy bruising, and bleeding is usually confined to the skin. Occasional patients will have prolonged oozing after surgery, particularly with procedures involving mucous membranes such as periodontal, oral, or reconstructive plastic surgery. The antiplatelet effect of drugs such as aspirin is more dramatic when they are administered to patients with underlying defects such asvWD or hemophilia. Patients with drug-induced cyclooxygenase deficiency often have

a mildly prolonged bleeding time, and their platelets fail to aggregate when incubated with arachidonic acid, epinephrine, or low doses ofADP. Patients who have taken aspirin should be treated as if they have a mild hemostatic defect for the next 5 to 7 days. Platelet responses to collagen and thrombin are impaired at low doses but normal at higher doses. Symptomatic patients should be encouraged to use drugs such as acetaminophen that do not impair platelet function. Although most cases of cyclooxygenase deficiency are drug-induced, occasional patients have inherited disorders in platelet cyclooxygenase activity that impair thromboxane production or receptor level defects that prevent platelets from responding to thromboxane A_2.

Of the metabolic disorders that can perturb hemostasis, uremic platelet dysfunction is clinically the most important. The mechanism by which uremia impairs platelet function is not well understood, and retention of phenolic and guanidinosuccinic acids, excess prostacyclin production, or impairedvWF-platelet interactions have all been implicated. The degree of uremia correlates with bleeding symptoms and anemia. Bleeding can usually be reversed by dialysis and often improves after red cell transfusion or treatment with erythropoietin. In addition, factor VIII concentrate orDDAVP, both of which raise plasma vWF levels, can also improve hemostasis. Conjugated estrogens improve hemostasis and can be used as long-term therapy.

Storage Pool Defects Platelet granules have considerable amounts of adenine nucleotides, calcium, and adhesive glycoproteins such as thrombospondin, fibronectin, andvWF, all of which promote platelet adhesion and aggregation. Patients with defective platelet granules have a mild bleeding disorder. Platelet storage pool defects may be inherited as an isolated disorder or be part of systemic granule packaging defects such as oculocutaneous albinism or the Hermansky-Pudlak or Chediak-Higashi syndromes. Clinically, these patients cannot be distinguished from those with other functional platelet disorders, since they all have easy bruising, mucosal bleeding, and a prolonged bleeding time. They can be differentiated from patients with the cyclooxygenase defects because their platelets will usually aggregate in response to arachidonic acid. In addition, their platelets have decreased levels of specific granule constituents such asADP and serotonin and abnormalities in granule morphology that are best visualized by electron microscopy.

Occasionally, patients with acute or chronic leukemia or one of the myeloproliferative disorders develop an acquired storage pool disorder due to dysplastic megakaryocyte development. In addition, patients with liver disease and some patients withSLE or other immune complex-mediated disorders may have circulating platelets that have degranulated prematurely. Platelet degranulation and a transient storage pool disorder may occur after prolonged cardiopulmonary bypass. Fortunately, most patients with storage pool defects have only mildly impaired hemostasis. They can be treated with platelet transfusions. Occasional patients have responded toDDAVP.

VESSEL WALL DISORDERS

Bleeding from vascular disorders (nonthrombocytopenic purpura) is usually mild and confined to the skin and mucous membranes. The pathogenesis of bleeding is poorly defined in many of the syndromes, and classic tests of hemostasis, including the bleeding time and tests of platelet function, are usually normal. Vascular purpura arises

from damage to capillary endothelium, abnormalities in the vascular subendothelial matrix or extravascular connective tissues that support blood vessels, or from the formation of abnormal blood vessels. Several idiopathic disorders involve the vessel wall and can cause more severe bleeding and organ dysfunction.

THROMBOTIC THROMBOCYTOPENIC PURPURA

TTPis a fulminant, often lethal disorder that may be initiated by endothelial injury and subsequent release ofvWF and other procoagulant materials from the endothelial cell. Causes include pregnancy, metastatic cancer, mitomycin C, high-dose chemotherapy, HIV infection, and certain drugs, such as the antiplatelet angent ticlopidine. Characteristic findings include the microvascular deposition of hyaline fibrin thrombi, thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, fluctuating levels of consciousness, and evanescent focal neurologic deficits. The presence of hyaline thrombi in arterioles, capillaries, and venules without any inflammatory changes in the vessel wall is diagnostic. The presence of a severe Coombs-negative hemolytic anemia with schistocytes or fragmented red blood cells in the peripheral blood smear, coupled with thrombocytopenia, and minimal activation of the coagulation system help to confirm the clinical suspicion of TTP. This disorder should be distinguished from vasculitis andSLE, which can predispose patients to TTP. Platelet-associated IgG and complement levels are usually normal in TTP.

The treatment of acuteTTP has focused on the use of exchange transfusion or intensive plasmapheresis coupled with infusion of fresh frozen plasma. Patients with TTP become transiently deficient in a plasma enzyme that depolymerizes ultra-high-molecular-weightvWFreleased from endothelial cells. Therapy may remove abnormal forms of vWF and replenish the deficient enzyme. Overall mortality has been markedly reduced, and the majority of patients with TTP recover from this formerly fatal disorder. Most patients surviving the acute illness recover completely, with no residual renal or neurologic disease. Occasional patients with a chronic, relapsing form of TTP require maintenance plasmapheresis and plasma infusion, and a few patients are controlled only with glucocorticoids.

HEMOLYTIC-UREMIC SYNDROME

HUSis a disease of infancy and early childhood that closely resemblesTTP. Patients present with fever, thrombocytopenia, microangiopathic hemolytic anemia, hypertension, and varying degrees of acute renal failure. In many cases, onset is preceded by a minor febrile or viral illness, and an infectious or immune complex-mediated cause has been proposed. Epidemics related to infection with a specific strain of *Escherichia coli* (O157:H7) have been documented. As in TTP, disseminated intravascular coagulation is not found. In contrast to TTP, the disorder remains localized to the kidney, where hyaline thrombi are seen in the afferent arterioles and glomerular capillaries. Such thrombi are not present in other vessels, and neurologic symptoms, other than those associated with uremia, are uncommon. No therapy is proven effective; however, with dialysis for acute renal failure, the initial mortality is only 5%. Between 10 and 50% of patients have some chronic renal impairment.

HENOCH-SCHONLEIN PURPURA

Henoch-Schonlein, or anaphylactoid, purpura is a distinct, self-limited type of vasculitis that occurs in children and young adults. Patients have an acute inflammatory reaction in capillaries, mesangial tissues, and small arterioles that leads to increased vascular permeability, exudation, and hemorrhage. Vessel lesions contain IgA and complement components. The syndrome may be preceded by an upper respiratory infection or streptococcal pharyngitis or be associated with food or drug allergies. Patients develop a purpuric or urticarial rash on the extensor surfaces of the arms and legs and on the buttocks as well as polyarthralgias or arthritis, colicky abdominal pain, and hematuria from focal glomerulonephritis. Despite the hemorrhagic features, all coagulation tests are normal. A small number of patients may develop fatal acute renal failure, and 5 to 10% develop chronic nephritis. Glucocorticoids provide symptomatic relief of the joint and abdominal pains but do not alter the course of the illness.

METABOLIC AND INFLAMMATORY DISORDERS

Acute febrile illnesses may cause capillary fragility and skin bleeding. Immune complexes containing viral antigens or the viruses themselves may damage endothelial cells. In addition, certain pathogens such as the rickettsiae that cause Rocky Mountain spotted fever replicate in endothelial cells and damage them. Thrombocytopenia is also a frequent finding in acute infectious disorders and may contribute to skin bleeding. In addition, whenever the platelet count is<10,000/uL, gaps develop between endothelial cells, which allow the diapedesis of red cells into the dermis, forming petechiae. Drugs such as the sulfonamides, penicillin, and allopurinol may cause vascular inflammation, resulting in maculopapular or urticarial rashes. Some of these mechanisms are additive, and drug reactions in thrombocytopenic individuals cause an intensely hemorrhagic rash.

Occasionally, patients with diffuse polyclonal hyperglobulinemia will develop purpuric lesions on the lower limbs -- a benign condition referred to as *hyperglobulinemic purpura.* Vascular purpura may occur in patients with various monoclonal gammopathies, including Waldenstrom's macroglobulinemia, multiple myeloma, and cryoglobulinemia. These proteins markedly increase serum viscosity and may impair blood flow through capillaries and lead to retinal hemorrhage, central nervous system dysfunction, and skin necrosis. In addition, the globulins may impair platelet aggregation and adhesion and interfere with fibrin polymerization. Patients with mixed cryoglobulinemia develop a more extensive maculopapular lesion due to immune complex-mediated damage to the vessel wall. The mixed cryoglobulinemia (usually IgG and anti-IgG) may be associated with arthralgias, diffuse weakness, and unexplained nephritis. Plasmapheresis will temporarily lower the level of globulins, remove immune complexes, and improve symptoms in these patients. However, long-term management must include control of the underlying disease that produces the abnormal globulins or immune complexes.

Patients with *scurvy* (vitamin C deficiency) develop painful episodes of perifollicular skin bleeding as well as bleeding into muscles and, occasionally, into the gastrointestinal and genitourinary tracts. The diagnosis is confirmed by the presence of hyperkeratosis of skin, gum swelling, and low levels of the vitamin in leukocytes. Vitamin C is needed to

synthesize hydroxyproline, an essential constituent of collagen. Thus, collagen synthesis is impaired by scurvy. Patients with *Cushing's syndrome*, an excess production of glucocorticoids, or patients on large doses of glucocorticoids develop generalized protein wasting and may show skin bleeding or easy bruising due to atrophy of the supporting connective tissue around blood vessels. Aging causes a similar atrophy of perivascular connective tissue on the extensor surfaces of the hands and arms, leading to *senile purpura* -- dark purple, irregularly shaped hemorrhagic areas due to abnormal skin mobility that tears small blood vessels.

Patients with inherited disorders of the connective tissue matrix such as *Marfan's syndrome*, *Ehlers-Danlos syndrome*, and *pseudoxanthoma elasticum* also have easy bruising. In addition to having fragile skin vessels and easy bruising, patients with Ehlers-Danlos syndrome may develop aneurysms in intraabdominal vessels and apoplectic rupture and hemorrhage due to defects in the vascular collagen network. Primary vascular abnormalities can also lead to bleeding. Patients with *Osler-Weber-Rendu disease* (hereditary hemorrhagic telangiectasia), an inherited autosomal dominant disorder, have frequent episodes of nasal and gastrointestinal bleeding from abnormal telangiectatic capillaries. They may develop pulmonary arteriovenous fistulas. Two genetic defects have been identified in these patients both involving proteins that bind to transforming growth factor b (TGF-b); HHT-1 has mutations in endoglin, and HHT-2 has mutations in ALK-1. Patients with *angiodysplasia* of the colon have increased incidence of gastrointestinal bleeding. In the *Kasabach-Merritt syndrome*, patients may have very extensive and progressively enlarging vascular malformation that may involve large portions of their extremities. Bleeding is secondary to disseminated intravascular coagulation triggered by stagnant blood flow through the tortuous vessels.

117. DISORDERS OF COAGULATION AND THROMBOSIS - *Robert I. Handin*

Patients with congenital plasma coagulation defects characteristically bleed into muscles, joints, and body cavities hours or days after an injury. Most of the *inherited* plasma coagulation disorders are due to defects in single coagulation proteins, with the two X-linked disorders, factors VIII and IX deficiency, accounting for the majority. These patients may have severe bleeding and chronic disability and require specialized medical therapy. With rare exceptions, the known disorders prolong either the prothrombin time (PT), partial thromboplastin time (PTT), or both. If they are abnormal, quantitative assays of specific coagulation proteins are then carried out using the PT or PTT tests with plasma from congenitally deficient individuals as substrate. The corrective effect of varying concentrations of patient plasma is measured and expressed as a percentage of a normal pooled plasma standard. The interval range for most coagulation factors is from 50 to 150% of this average value, and the minimal level of most individual factors needed for adequate hemostasis is 25%.

Acquired coagulation disorders are both more frequent and more complex, arising from deficiencies of multiple coagulation proteins and simultaneously affecting both primary and secondary hemostasis. The most common acquired hemorrhagic disorders are (1) disseminated intravascular coagulation (DIC), (2) the hemorrhagic diathesis of liver disease, and (3) vitamin K deficiency and complications of anticoagulant therapy.

Although congenital and acquired bleeding disorders are relatively rare, venous and arterial thrombosis and embolism are common medical disorders that have been recognized for>100 years. Although risk factors such as atherosclerotic vascular disease, congestive heart failure, malignancy, and immobility predispose patients to thrombosis, specific coagulation defects have not yet been identified in most patients with thromboembolism. Several inherited coagulation abnormalities induce a hypercoagulable or prethrombotic state and predispose patients to thrombosis. These disorders affect young people, cause recurrent episodes of thromboembolism, and may involve multiple members of a single family. An understanding of the biochemical basis of thromboembolism is also important because anticoagulant and antithrombotic regimens are based on the premise that modifying critical coagulation reactions will reduce the incidence of thrombosis.**For further discussion of the physiology of normal hemostasis and the cardinal manifestations of the hemorrhagic and thrombotic disorders, see Chap. 62.*

FACTOR VIII DEFICIENCY -- HEMOPHILIA A

Pathogenesis and Clinical Manifestations The antihemophilic factor (AHF), or factor VIII coagulant protein, is a large (265-kDa), single-chain protein that regulates the activation of factor X by proteases generated in the intrinsic coagulation pathway (Figs. 62-5 and62-6). It is synthesized in liver and circulates complexed to the von Willebrand factor (vWF) protein. Factor VIII molecule is present in low concentration (10 ug/L) and is susceptible to proteolysis. The gene for factor VIII is on the X chromosome, and carrier detection and prenatal diagnosis are well established.

One in 10,000 males is born with deficiency or dysfunction of the factor VIII molecule. The resulting disorder, *hemophilia A*, is characterized by bleeding into soft tissues,

muscles, and weight-bearing joints. Symptomatic patients usually have factor VIII levels<5%, with a close correlation between the clinical severity of hemophilia and plasmaAHFlevel. Patients with <1%factor VIII activity have *severe* disease; they bleed frequently even without discernible trauma. Patients with levels of 1 to 5% have *moderate* disease with less frequent bleeding episodes. Those with levels>5% have *mild* disease with infrequent bleeding that is usually secondary to trauma. Occasional patients with factor VIII levels as high as 25% are discovered when they bleed after major trauma or surgery. The majority of patients with hemophilia A have factor VIII levels below<5%.

Hemophilic bleeding occurs hours or days after injury, can involve any organ, and, if untreated, may continue for days or weeks. This can result in large collections of partially clotted blood putting pressure on adjacent normal tissues and can cause necrosis of muscle (compartment syndromes), venous congestion (pseudophlebitis), or ischemic damage to nerves. Patients with hemophilia often develop femoral neuropathy due to pressure from an unsuspected retroperitoneal hematoma. They can also develop large calcified masses of blood and inflammatory tissue that are mistaken for cancers (pseudotumor syndrome).

Patients with severe hemophilia are usually diagnosed shortly after birth because of an extensive cephalhematoma or profuse bleeding at circumcision. However, young children with moderate disease may not bleed until they begin to walk or crawl, and individuals with mild hemophilia may not be diagnosed until they are adolescents or young adults. Typically, a hemophilia patient presents with pain followed by swelling in a weight-bearing joint, such as the hip, knee, or ankle. The presence of blood in the joint (*hemarthrosis*) causes synovial inflammation, and repetitive bleeding erodes articular cartilage and causes osteoarthritis, articular fibrosis, joint ankylosis, and eventually muscle atrophy. Bleeding may occur into any joint, but after a joint has been damaged, it may become a site for subsequent bleeding episodes.

Hematuria, without any genitourinary pathology, is also common. It is usually self-limited and may not require specific therapy. The most feared complications of hemophilia are oropharyngeal and central nervous system bleeding. Patients with oropharyngeal bleeding may require emergency intubation to maintain an adequate airway. Central nervous system bleeding can occur without antecedent trauma or without evidence of a specific lesion.

Patients suspected of having hemophilia should have a platelet count, bleeding time,PT, andPTT. Typically, the patient will have a prolonged PTT with all other tests normal. Because of the clinical similarity of factor VIII deficiency and factor IX deficiency, any male with an appropriate bleeding history and a prolonged PTT should have specific assays for factor VIII and factor IX.

TREATMENT

Tenets regarding the treatment of bleeding in hemophilia patients include the following: (1) Symptoms often precede objective evidence of bleeding. (2) Signs of bleeding may not appear until several days after well-documented trauma. The patients can generally be relied upon to identify early symptoms, usually pain. Early treatment is more

effective, less costly, and can be lifesaving. (3) Avoid the use of aspirin or aspirin-containing drugs, which impair platelet function and may cause severe hemorrhage. COX-2 inhibitors can be used, as they do not impair platelet function.

Plasma products enriched in factor VIII have revolutionized the care of hemophilia patients, reduced the degree of orthopedic deformity, and permitted virtually any form of elective and emergency surgery. The widespread use of factor VIII concentrates has also produced serious complications, including viral hepatitis, chronic liver disease, and AIDS. *Cryoprecipitate*, which contains about half the factor VIII activity of fresh-frozen plasma in one-tenth the original volume, is simple to prepare and is produced in hospital or regional blood banks.

Three developments have increased the safety of factor VIII therapy and have changed medical practice. First, heating of lyophilized factor VIII concentrates under carefully controlled conditions can inactivate HIV without destroying factor VIII activity. Second, highly purified factor VIII can be produced by adsorbing and eluting factor VIII from monoclonal antibody columns. Third, recombinant factor VIII is now available. Patients with hemophilia should receive either monoclonal purified or recombinant factor VIII to minimize viral infections and exposure to irrelevant proteins.

Each unit of factor VIII infused, defined as the amount present in 1 mL normal plasma, will raise the plasma level of the recipient by 2%/kg of body weight. Factor VIII has a half-life of 8 to 12 h, making it necessary to infuse it continuously or at least twice daily to sustain a chosen factor VIII level. In patients with mild hemophilia, an alternative treatment is desmopressin (DDAVP), which transiently increases the factor VIII level. DDAVP will increase the factor level two- to threefold. Although generally safe, it occasionally causes hyponatremia or may precipitate thrombosis in elderly patients.

An uncomplicated episode of soft tissue bleeding or an early hemarthrosis can be treated with one infusion of sufficient factor VIII concentrate to raise the factor VIII level to 15 or 20%. A more extensive hemarthrosis or retroperitoneal bleeding requires twice-daily or continuous infusions in order to keep the factor VIII level at 25 to 50% for at least 72 h. Life-threatening bleeding into the central nervous system or major surgery may require therapy for 2 weeks with levels kept at a minimum of 50% normal. Patients also need skilled orthopedic care, with immobilization of inflamed joints to promote healing and to prevent contractures, and physical therapy to strengthen muscles and maintain joint mobility.

Before surgery, every hemophilia patient should be screened for the presence of an inhibitor to factor VIII. Patients with hemophilia who do not have an inhibitor should receive factor VIII infusions just before surgery and will require daily monitoring so that the factor VIII level is maintained>50% for 10 to 14 days after surgery. When patients undergo joint replacement or other major orthopedic surgery, therapy should be continued for 3 weeks to permit wound healing and the institution of physical therapy.

Hemophilia patients also require treatment before dental procedures. Filling of a carious tooth can be managed by a single infusion of factor VIII concentrate coupled with the administration of 4 to 6 g of e-aminocaproic acid (EACA) four times daily for 3 to 4 days after the dental procedure. EACA is a potent antifibrinolytic agent that inhibits

plasminogen activators present in oral secretions and stabilizes clot formation in oral tissue. Alternatives include tranexamic acid, a longer-acting antifibrinolytic. EACA is also effective when used as a mouthwash. For major oral and periodontal surgery and extractions of permanent teeth, patients should probably be hospitalized briefly and also treated with factor VIII concentrates. Therapy should begin just before surgery and continue for at least 2 to 3 days.

Many centers have organized home-care programs so that patients can administer their own factor VIII infusions with the onset of symptoms. Occasional patients with very frequent bleeding receive regularly scheduled infusions. Despite the expense and inconvenience of "prophylactic" infusions, their use in early childhood has reduced or eliminated hemarthroses. Concern about transmission of AIDS has made some patients reluctant to treat themselves, despite the fact that current blood products carry a very low or no risk of transmitting HIV.

The prospects for correcting factor VIII deficiency by gene therapy are promising; some success has been achieved in dogs. Clinical studies in humans are underway.

Complications Most hemophilia patients have had multiple episodes of hepatitis, and a majority have elevated hepatocellular enzyme levels and abnormalities on liver biopsy. Ten to 20% of patients also have hepatosplenomegaly, and a small number develop chronic active or persistent hepatitis or cirrhosis. A few patients with hemophilia and end-stage liver disease have received liver transplants with cure of both diseases. Along with homosexuals and intravenous drug abusers, hemophilia patients are at high risk for AIDS because they frequently receive blood products; they can also present with the full range of AIDS-related syndromes, including diffuse lymphadenopathy and immune thrombocytopenia. Although up to 50% of multiply transfused hemophiliacs are HIV-positive and many have clinical AIDS, the advances in factor VIII concentrate production should prevent future HIV infection.

Despite frequent bleeding, severe iron-deficiency anemia is uncommon because most of the bleeding is internal and iron is effectively recycled. Mild iron deficiency from chronic epistaxis or gastrointestinal bleeding occurs in some patients. In addition, some patients have developed a mild Coombs-positive hemolytic anemia due to small amounts of anti-A and anti-B antibody that are present in intermediate purity factor VIII concentrates.

Following multiple transfusions, 10 to 20% of patients with severe hemophilia develop inhibitors to factor VIII. Inhibitors are usually IgG antibodies that rapidly neutralize factor VIII activity. Two types of inhibitors are found with different biologic characteristics and different clinical presentations. Patients with type I inhibitors have a typical anamnestic response and raise their antibody titer following exposure to factor VIII. Patients with a type II inhibitor have a low antibody titer that is not stimulated by factor VIII infusion. Patients with the type I inhibitor should not receive factor VIII. Control of bleeding may require the infusion of either porcine factor VIII concentrates, which may not be affected by inhibitors, or prothrombin complex concentrates, which contain trace quantities of activated coagulation factors and can bypass the block in coagulation produced by the inhibitor. Patients with low-titer type II antibodies may respond to higher doses of factor VIII.

Protocols to induce tolerance to human factor VIII use massive doses of the factor coupled with immunosuppression. Tolerance induction is expensive and not always effective; it should be reserved for severely affected patients.

Genetic Counseling and Carrier Detection It is possible to trace the defective allele in some families by examining the inheritance of restriction fragment length polymorphisms (RFLP) linked to the factor VIII gene. In addition, in families in which a specific mutation has been defined in the factor VIII gene, it can be readily detected by gene amplification and allele-specific oligonucleotide hybridization. For example, 45% of patients with severe hemophilia A have a chromosomal inversion arising from homologous recombination between sequences in intron 22 and an upstream gene. The inversion is readily detected by polymerase chain reaction (PCR) or Southern blotting. Precise diagnosis is possible early in pregnancy from either chorionic villus biopsy or amniocentesis.

Female carriers of hemophilia, who are heterozygotes, usually produce sufficient factor VIII from the factor VIII allele on their normal X chromosome for normal hemostasis. However, occasional hemophilia carriers will have factor VIII levels far below 50% due to random inactivation of normal X chromosomes in tissue producing factor VIII. These symptomatic carriers may bleed with major surgery or bleed occasionally with menses. Rarely, true female hemophiliacs arise from consanguinity within families with hemophilia or from concomitant Turner's syndrome or XO mosaicism in a carrier female.

FACTOR IX DEFICIENCY -- HEMOPHILIA B

Factor IX is a single-chain, 55-kDa proenzyme that is converted to an active protease (IXa) by factor XIa or by the tissue factor-VIIa complex. Factor IXa then activates factor X in conjunction with activated factor VIII. Factor IX is one of six proteins synthesized in the liver that require vitamin K for biologic activity. Vitamin K is a cofactor for a unique posttranslational modification that inserts a second carboxyl group onto certain glutamic acid residues on factor IX (Chap. 62). This modification permits calcium binding and adsorption onto phospholipid surfaces. Factor IX gene is on the X chromosome.

Factor IX deficiency or dysfunction (hemophilia B, Christmas disease) occurs in 1 in 100,000 male births. Accurate laboratory diagnosis is critical, since it is indistinguishable clinically from factor VIII deficiency (hemophilia A) but requires different treatment. Either fresh-frozen plasma or a plasma fraction enriched in the prothrombin complex proteins is used. Monoclonally purified or recombinant factor IX preparations are now available. In addition to the expected complications of hepatitis, chronic liver disease, and AIDS, the therapy of factor IX deficiency has a special hazard. Trace quantities of activated coagulation factors in prothrombin complex concentrates may activate the coagulation system and cause thrombosis and embolism. This is particularly common in immobilized surgical patients and patients with liver disease. As a result, some centers have returned to fresh-frozen plasma for factor IX-deficient surgical patients, while others have recommended the addition of small doses of heparin to the concentrate to activate antithrombin III during the infusion and reduce hypercoagulability. The recombinant or monoclonally purified products are less likely to be thrombogenic.

FACTOR XI DEFICIENCY

Factor XI is a 160-kDa dimeric protein activated to an active protease (XIa) by factor XIIa, in conjunction with high-molecular-weight kininogen and kallikrein (Figs. 62-5 and62-6). Factor XI deficiency is inherited as an autosomal recessive trait and is especially common in Ashkenazi Jews. In contrast to deficiency in factors VIII and IX, the correlation between factor level and propensity to bleed is not as precise, spontaneous bleeding is less, and hemarthroses are rare. Many patients with factor XI deficiency present with posttraumatic bleeding or with bleeding in the perioperative period, and occasional factor XI-deficient women have menorrhagia. Daily infusions of fresh-frozen plasma are sufficient, since the half-life of factor XI is approximately 24 h. The majority of defective factor XI alleles were accounted for by a limited number of mutations.

OTHER FACTOR DEFICIENCIES

Deficiencies in factors V, VII, X, and prothrombin (factor II) are exceedingly rare autosomal recessive disorders. Spontaneous or posttraumatic musculoskeletal bleeding or menorrhagia can occur with these deficiencies, but hemarthroses are uncommon. Fresh-frozen plasma is the appropriate therapy, although prothrombin concentrates may be employed for patients with severe prothrombin deficiency or decreases in factors VII and X as long as the risks of hepatitis and thrombosis are recognized.

Defects in the contact activation pathway involving Hageman factor (factor XII), high-molecular-weight kininogen, and prekallikrein cause laboratory abnormalities but no clinical bleeding. Despite dramatic prolongation of thePTT, often to greater than 100 s, deficient individuals have normal hemostasis and can undergo major surgery without plasma replacement therapy. Direct activation of factor IX by the tissue factor-VIIa complex may bypass this defective step in coagulation (Fig. 62-7). Recognition of these disorders is important because such patients should neither be treated inappropriately with plasma nor denied indicated surgery on the basis of these laboratory abnormalities.

AFIBRINOGENEMIA AND DYSFIBRINOGENEMIA

Fibrinogen is a 340-kDa dimeric molecule made up of two sets of three covalently linked polypeptide chains. Thrombin sequentially cleaves fibrinopeptides A and B from the Aa and Bb chains of fibrinogen to produce fibrin monomer, which then polymerizes to form a fibrin clot. Although fibrinogen is needed for platelet aggregation and fibrin formation, severe fibrinogen deficiency does not usually cause serious bleeding except after surgery. Patients with afibrinogenemia, who have no detectable fibrinogen in plasma or platelets, may have infrequent, mild bleeding episodes. Preliminary genetic analyses do not show any gross deletion or structural changes in the genes encoding the a,b, and g chains of fibrinogen despite the total absence of plasma fibrinogen.

Fibrinogen is an abundant plasma protein (2.5 g/L). Mutations have been identified that alter the release of fibrinopeptides from the Aa and Bb chains of fibrinogen, the rate of polymerization of fibrin monomers, and the sites for fibrin cross-linking. These dysfibrinogenemias are almost always inherited as autosomal dominant traits, so patients have nearly equal concentrations of normal and mutant fibrinogen in their

plasma. Patients with dysfibrinogenemia have a slightly prolongedPT andPTT, a prolonged thrombin time, and a disparity in levels of fibrinogen measured with functional and immunologic assays. Despite these abnormalities, most patients have no symptoms or only moderate bleeding. A few dysfibrinogenemias induce a hypercoagulable state and increase the risk of thrombosis, and others have been associated with an increased incidence of abortion (Chap. 118). Some patients with liver disease, hepatomas, AIDS, and lymphoproliferative disorders develop an acquired form of dysfibrinogenemia.

FACTOR XIII DEFICIENCY AND DEFECTIVE FIBRIN CROSS-LINKING

Factor XIII is a transglutaminase that stabilizes fibrin clots by forminge-amino-g-glutamyl cross-links between adjacent a andg chains of fibrin. Factor XIII deficiency is an extremely rare inherited syndrome. Patients usually bleed in the neonatal period from their umbilical stump or circumcision. In addition to hemorrhage, these patients may have poor wound healing, a high incidence of infertility among males and abortion among affected females, and a high incidence of intracerebral hemorrhage. These observations suggest that the enzyme may be important in other physiologic and pathologic processes beyond hemostasis, including placental implantation, spermatogenesis, and wound healing. Several drugs, including isoniazid, may bind to cross-linking sites on fibrinogen and mimic factor XIII deficiency by blocking enzyme activity. Normal hemostasis requires only 1% of normal enzyme activity, which can be achieved with a single infusion of fresh-frozen plasma or a purified factor XIII-rich product derived from human placenta called Fibrogammin. Factor XIII has a 14-day half-life.

VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin that plays a critical role in hemostasis. Dietary vitamin K is absorbed in the small intestine and stored in the liver. The vitamin is also synthesized by endogenous bacterial flora in the small intestine and colon; however, the quantity of endogenous vitamin K absorbed from the large intestine is debated. Following absorption and transport, vitamin K is converted to an active epoxide in liver microsomes and serves as a cofactor in the enzymatic carboxylation of glutamic acid residues on prothrombin complex proteins (Fig. 117-1).

The three major causes of vitamin K deficiency are inadequate dietary intake, intestinal malabsorption, and loss of storage sites due to hepatocellular disease. Neonatal vitamin K deficiency, which causes hemorrhagic disease of the newborn, has disappeared from western countries with the routine administration of vitamin K to all newborn infants. Although a 30-day supply of vitamin K is stored in the normal liver, acutely ill patients can become deficient within 7 to 10 days. Acute vitamin K deficiency is particularly common in patients recovering from biliary tract surgery who have no dietary intake of vitamin K, have T-tube drainage of bile, and are on broad-spectrum antibiotics. Vitamin K deficiency is also seen in chronic liver disease, particularly primary biliary cirrhosis, and in some malabsorption states (Chaps. 286 and298). The cephalosporins inhibit the reduction and recycling of vitamin K, much like coumarin.

With vitamin K deficiency, plasma levels of all the prothrombin complex proteins (factors II, VII, IX, X; proteins C and S) decrease. Factor VII and protein C, which have the

shortest half-lives, decrease first. Because of the rapid fall in factor VII, patients with mild vitamin K deficiency may have a prolongedPT and a normalPTT. Later, as the levels of the other factors fall, the PTT will also become prolonged. Parenteral administration of 10 mg vitamin K rapidly restores vitamin K levels in the liver and permits normal production of prothrombin complex proteins within 8 to 10 h. Severe hemorrhage can be treated with fresh-frozen plasma, which immediately corrects the hemostatic defect. If the cause of vitamin K deficiency cannot be eliminated, patients may need monthly injections. Purified prothrombin complex concentrates should be avoided because they contain trace quantities of activated forms of the prothrombin complex proteins and can cause thrombosis in patients with liver disease. They also carry an increased risk of hepatitis.

DISSEMINATED INTRAVASCULAR COAGULATION

DICcan be either an explosive and life-threatening bleeding disorder or a relatively mild or subclinical disorder. Although a long list of diseases can be complicated by DIC, it is most frequently associated with obstetric catastrophes, metastatic malignancy, massive trauma, and bacterial sepsis (Table 117-1). In each case, a tentative triggering mechanism has been identified. For example, tumors and traumatized or necrotic tissue release tissue factor into the circulation, while endotoxin from gram-negative bacteria activates several steps in the coagulation cascade. In addition to a direct effect on the activation of Hageman factor (factor XII), endotoxin induces the expression of tissue factor on the surface of monocytes and endothelial cells. These activated cell surfaces then accelerate coagulation reactions. These potent thrombogenic stimuli cause the deposition of small thrombi and emboli throughout the microvasculature. This early thrombotic phase of DIC is then followed by a phase of procoagulant consumption and secondary fibrinolysis. Continued fibrin formation and fibrinolysis lead to hemorrhage from the coagulation factor and platelet depletion and the antihemostatic effects of fibrin degradation products (Fig. 117-2).

The clinical presentation varies with the stage and severity of the syndrome. Most patients have extensive skin and mucous membrane bleeding and hemorrhage from surgical incisions or venipuncture or catheter sites. Less often, patients present with peripheral acrocyanosis, thrombosis, and pregangrenous changes in digits, genitalia, and nose -- areas where blood flow is markedly reduced by vasospasm or microthrombi. Some patients, particularly those with chronicDICsecondary to malignancy, have laboratory abnormalities without any evidence of thrombosis or hemorrhage.

The laboratory manifestations include thrombocytopenia and the presence of schistocytes or fragmented red blood cells that arise from cell trapping and damage within fibrin thrombi; prolongedPT andPTT and thrombin time and a reduced fibrinogen level from depletion of coagulation proteins; and elevated fibrin degradation products (FDP) from intense secondary fibrinolysis. The D dimer immunoassay, which specifically measures cross-linked fibrin derivatives, is a more specific FDP assay. The abnormality inDIC that predicts bleeding is the plasma fibrinogen level; low fibrinogen levels are associated with more bleeding.

TREATMENT

DIC, although sometimes indolent, can cause life-threatening hemorrhage and may require emergency treatment. This should include (1) an attempt to correct any reversible cause of DIC; (2) measures to control the major symptom, either bleeding or thrombosis; and (3) a prophylactic regimen to prevent recurrence in cases of chronic DIC. Treatment will vary with the clinical presentation. In patients with an obstetric complication such as abruptio placentae or acute bacterial sepsis, the underlying disorder is easy to correct, and prompt delivery of the fetus and placenta or treatment with appropriate antibiotics will reverse the DIC syndrome. In patients with metastatic tumor causing DIC, control of the primary disease may not be possible, and long-term prophylaxis may be necessary.

Patients with bleeding as a major symptom should receive fresh-frozen plasma to replace depleted clotting factors and platelet concentrates to correct thrombocytopenia. Those with acrocyanosis and incipient gangrene or other thrombotic problems need immediate anticoagulation with intravenous heparin. The use of heparin in the treatment of bleeding is still controversial. Although it is a logical way to reduce thrombin generation and prevent further consumption of clotting proteins, it should be reserved for patients with thrombosis or who continue to bleed despite vigorous treatment with plasma and platelets.

Patients who initially have mildDIC and may not be symptomatic may begin to bleed following surgery or chemotherapy. For example, mild DIC, without clinical bleeding, has been documented during saline- or prostaglandin-induced midtrimester abortions. Prophylactic treatment of patients with heparin may prevent progression of a mild DIC syndrome and has been used in the treatment of patients with acute promyelocytic leukemia and in some patients with a retained dead fetus who require surgical extraction. However, most patients with low-grade DIC can be managed with plasma and platelet replacement and do not require heparin. Chronic DIC does not respond to oral warfarin anticoagulants, but it can be controlled with long-term heparin infusion. Occasional patients with indolent tumors and severe DIC have been maintained on heparin administered by intermittent subcutaneous injection or continuous infusion with portable pumps.

Despite our detailed understanding of the pathophysiology ofDIC and a vigorous approach to therapy, treatment does not change the natural history of the underlying disorder. Therapy will only stabilize the patient, prevent exsanguination or massive thrombosis, and permit institution of definitive therapy.

COAGULATION DISORDERS IN LIVER DISEASE

Liver dysfunction is frequently accompanied by a hemostatic defect. The major causes of hemorrhage in patients with liver disease are shown in Table 117-2. Bleeding is usually due to an anatomic lesion that is exacerbated by a hemostatic defect. Most patients bleed from complications of portal hypertension, esophageal varices, or gastritis and peptic ulcer disease. Portal hypertension also causes splenomegaly, with splenic sequestration of platelets and thrombocytopenia, which contributes to the hemostatic defect (Chap. 298).

Patients with hepatocellular liver disease cannot store vitamin K optimally and may have

some degree of vitamin K deficiency. Cholestasis, a frequent feature of liver disease, impairs vitamin K absorption and further decreases liver vitamin K stores. Abnormalities in the g-carboxylation of prothrombin complex proteins independent of vitamin K and the production of abnormal proteins have also been described. Patients may also have decreased production of other coagulation proteins, including fibrinogen and factor V. The liver also produces inhibitors of coagulation such as antithrombin III and proteins C and S and is the clearance site for activated coagulation factors and fibrinolytic enzymes. Thus patients with liver disease are also "hypercoagulable" and predisposed to developingDIC or systemic fibrinolysis. Coagulation defects in advanced liver failure are often difficult to distinguish from those of DIC.

Each patient with hemorrhage and liver disease should have aPT,PTT, platelet count, and fibrinogen determination, although it is not always possible to determine the major hemostatic abnormality from a single set of laboratory values. It is helpful to have previous laboratory data available for patients with chronic liver disease who develop an acute complication. The degree of prolongation of the PT predicts the risk of bleeding. Most patients present with moderate prolongation of the PT and PTT, mild thrombocytopenia, and a normal fibrinogen level. However, they may also present with a more complex defect combining defective synthesis, abnormal clearance, and active consumption of coagulation proteins. Since vitamin K deficiency is so common, a single parenteral dose of vitamin K is given after initial laboratory studies have been obtained, even though this may only partially correct the laboratory abnormalities. The presence of severe thrombocytopenia or a low fibrinogen level suggests the additional complication ofDIC and may require further studies and therapy.

The safest replacement therapy for a patient with liver disease is fresh-frozen plasma, since it supplies all known coagulation factors. However, even this form of therapy has drawbacks, since large quantities of plasma may precipitate hepatic encephalopathy and cause fluid and sodium overload. Prothrombin complex concentrates should be avoided because they replace only the vitamin K-dependent factors, may be contaminated with hepatitis and AIDS virus, and contain trace quantities of activated coagulation proteins. Similarly, fibrinogen concentrates (or cryoprecipitate), rich in factor VIII and fibrinogen, should not be used without additional fresh-frozen plasma. Anticoagulation with heparin has been advocated to controlDIC, but this is particularly hazardous and not recommended in cirrhosis because heparin is metabolized erratically and may lead to severe bleeding.

FIBRINOLYTIC DEFECTS

Bleeding can also occur from defects in the fibrinolytic system. Patients with$\alpha_2$plasmin inhibitor deficiency or plasminogen activator inhibitor (PAI) 1 have rapid fibrinolysis following fibrin deposition after trauma or surgery and may experience recurrent hemorrhage. Similarly, patients with cirrhosis have an impaired clearance of tissue plasminogen activator (tPA) and systemic fibrinolysis that may contribute to their hemorrhagic defect. Rarely, patients with tumors such as metastatic prostatic cancer may develop diffuse bleeding from primary fibrinolysis rather thanDIC. Clues to the diagnosis include a disproportionately low fibrinogen level with a relatively normalPT andPTT and the presence of a normal or nearly normal platelet count. With rare exceptions, patients with primary fibrinolysis should have an elevated titer ofFDP but a

normal D dimer level. However, it is sometimes difficult or impossible to differentiate primary fibrinolysis from the secondary fibrinolysis accompanying DIC. Patients with clearly established primary fibrinolysis should not receive heparin; they require plasma therapy and, occasionally, fibrinolytic inhibitors such asEACA. However, EACA should not be given to patients suspected of having DIC unless they are also receiving heparin, since EACA can cause massive, often fatal, thrombosis in a patient with DIC.

CIRCULATING ANTICOAGULANTS

Circulating anticoagulants, or inhibitors, are usually IgG antibodies that interfere with coagulation reactions. Specific inhibitors inactivate individual coagulation proteins and may cause severe hemorrhage. They arise in 15 to 20%of patients with factor VIII or factor IX deficiency who have received plasma infusions. *Specific* inhibitors also occur in previously normal individuals. Although the most common target protein is factor VIII, inhibitors with specificity for each of the coagulation proteins occur. In addition to hemophiliacs, anti-factor VIII antibodies are seen in postpartum females, in patients on various drugs, as part of the spectrum of autoantibodies in systemic lupus erythematosus (SLE) patients, and in normal elderly individuals. Circulating anticoagulants also occur in patients with AIDS.

Nonspecific (lupus-like) inhibitors prolong coagulation tests by binding to phospholipids. They are assayed by their anticoagulant effect [lupus anticoagulant (LA) activity] or their ability to bind to the complex phospholipid cardiolipin [anticardiolipin antibody (ACLA) activity]. While most often encountered in patients withSLE, these nonspecific inhibitors may develop in patients with many other disorders and also in otherwise normal individuals.

The critical laboratory feature that identifies the presence of either type of inhibitor is the failure of normal plasma to correct a prolongedPT,PTT, or both. Plasma from patients with a specific inhibitor will progressively inactivate a coagulation protein and thus prolong whichever of these screening tests requires the participation of that clotting factor. This effect persists after dilution. Nonspecific inhibitors immediately prolong the PT and PTT and, at low dilution, block multiple coagulation reactions. However, these effects can be overcome by altering the quantity or type of phospholipid or by diluting the plasma.

Hemorrhage in patients with specific inhibitors may require treatment with massive plasma or concentrate infusion, the use of activated prothrombin complex concentrates to bypass the antibodies against factors VIII or IX, and plasmapheresis or exchange transfusion to lower antibody titer. Chronic immunosuppressive regimens have been particularly useful in otherwise normal individuals with an acquired factor VIII antibody. Many patients lose their antibody and recover within 6 to 12 months, although the acute mortality rate from uncontrollable bleeding may approach 10%.

Patients withLAactivity have normal hemostasis and will not bleed unless they have concomitant thrombocytopenia or prothrombin deficiency. Both thrombocytopenia and hypoprothrombinemia are secondary to autoantibodies that bind either to platelets or the prothrombin molecule. While these antibodies have no effect on function, they accelerate clearance of the coated platelets or the antibody-prothrombin complexes.

The presence ofLAactivity may predispose patients to venous and arterial thromboembolism and may cause midtrimester abortions. However, the risk of thrombosis is difficult to estimate and the appropriate therapy for individual patients difficult to choose. Tests for either LA orACLAactivity are not well standardized, and results vary among and within patients. The best predictor is a consistent prolongation of more than one coagulation test coupled with a high titer of ACLA activity. Second, the risk of thrombosis is increased in patients who haveSLEcompared with those with idiopathic LA or ACLA activity. Prophylactic therapy is not clearly beneficial, and treatments aimed at reducing the titer of antibody are not superior to conventional antithrombotic therapy.

Therapy should be individualized. Patients withSLE and eitherLA orACLAactivity who have had a thrombotic episode are at high risk for a recurrence and should receive long-term anticoagulant therapy. Women who have had more than one midtrimester abortion, especially those with SLE, should have a trial of anticoagulant therapy. Patients with a single thrombotic episode (stroke or pulmonary embolus) and no other risk factor except LA or ACLA activity should be treated. No consensus has been reached about treatment after an initial minor event [deep venous thrombosis (DVT)]. Asymptomatic patients with only laboratory abnormalities should not be treated. Glucocorticoids should be administered only in conjunction with antithrombotic agents and are not of proven efficacy.

INHERITED PRETHROMBOTIC DISORDERS

Coagulation is carefully regulated by a series of inhibitors that limit thrombin generation and fibrin formation and by the fibrinolytic system, which effectively removes fibrin thrombi (Figs. 62-5 and62-6). Inherited defects in the natural coagulation inhibitors (i.e., antithrombin, proteins C and S), abnormalities in the fibrinolytic system, and certain dysfibrinogenemias predispose patients to thrombosis (Table 62-5). A single point mutation in the factor V gene (factor V Leiden), which converts arginine 506 to glutamine and makes the molecule resistant to degradation by activated protein C, may account for 25% of inherited prethrombotic states. Antithrombin, protein C, and protein S defects are all autosomal dominant traits, so heterozygous individuals, who have a 50% reduction in protein concentration or a mixture of mutant and normal molecules, will have an increased risk of thrombosis. The patients have similar clinical presentations with a strong family history of thrombosis, episodes of recurrent venous thromboembolism, and symptoms by their early twenties. Any patient with this distinctive history should be tested for specific abnormalities.

ANTITHROMBIN DEFICIENCY

Antithrombin complexes with activated coagulation proteins and blocks their biologic activity (Fig. 62-5). The rate of this reaction is enhanced by heparin-like molecules within the vessel wall or on endothelial cells. Plasma antithrombin III content is 5 to 15 mg/L (50 to 150%), with values only slightly below normal increasing the risk of thrombosis. For optimal screening, the antithrombin III concentration is measured by immunoassay and the plasma antithrombin and heparin cofactor activity assessed with functional assays. The most common defect (1 in 2000 indidivuals) is mild (heterozygous)

antithrombin deficiency. Dysfunctional antithrombin molecules with mutations affecting either the serine protease or heparin-binding site or activation of inhibitor by heparin have also been described.

Patients with antithrombin deficiency who develop acute thrombosis or embolism can be treated with intravenous heparin, since there is usually sufficient normal antithrombin to act as a heparin cofactor. Following their first episode of thromboembolism, patients should be placed on oral anticoagulants for life to prevent recurrent thrombosis. Family studies should be conducted when an antithrombin-deficient individual is discovered, since up to half the members of a kindred may be affected. Asymptomatic individuals with antithrombin deficiency should receive prophylactic anticoagulation with heparin or plasma infusions to raise their antithrombin level before medical or surgical procedures that may increase their risk of thrombosis. Chronic oral anticoagulation is not recommended until individuals at risk have a thrombotic episode.

DEFICIENCIES OF PROTEINS C AND S

Protein C is a vitamin K-dependent hepatic protein that binds to the endothelial cell surface protein thrombomodulin and is converted to an active protease by thrombin (Fig. 62-5). Activated protein C, in conjunction with protein S, proteolyzes factors Va and VIIIa, which shuts off fibrin formation. Activated protein C may also stimulate fibrinolysis and accelerate clot lysis. Deficiencies of proteins C and S are usually autosomal dominant disorders, and deficiencies in the two proteins cause an identical syndrome of recurrent venous thrombosis and pulmonary embolism. Dysfunctional molecules have also been identified in some patients with thrombosis. Rare patients with homozygous protein C deficiency have fulminant neonatal intravascular coagulation and require prompt diagnosis and treatment.

The correlation between protein C and S levels and the risk of thrombosis is not as precise as for antithrombin III deficiency. In fact, some asymptomatic individuals with protein C "deficiency" have been discovered. In some well-studied protein C-deficient kindreds, asymptomatic individuals may have protein C levels as low as or lower than relatives with recurrent thrombosis. It is possible that an undiscovered cofactor is present in symptomatic patients. Finally, since a fraction of the available protein S is bound to C4b-binding protein and is unavailable for coagulation reactions, both free and total protein S levels or C4b-binding protein levels should be assessed for maximum accuracy.

Heterozygous patients with protein C or S deficiencies who develop acute thrombosis should be heparinized and then placed on oral anticoagulants. There are, however, two potential problems with the use of coumarin anticoagulants in these patients. First, these vitamin K antagonists (Fig. 117-1;Fig. 62-5), which lower the level of the procoagulant factors II, VII, IX, and X, may also reduce the concentration of proteins C and S sufficiently to nullify the desired antithrombotic effect. In addition, patients who are protein C-deficient may develop coumarin-induced skin necrosis; this defect may predispose patients to a rare but serious complication. Patients with homozygous protein C deficiency require periodic plasma infusions rather than oral anticoagulants to prevent recurrent intravascular coagulation and thrombosis.

RESISTANCE TO ACTIVATED PROTEIN C AND THE FACTOR V LEIDEN MUTATION

Some patients with familial or recurrent venous thromboembolism were found not to prolong theirPTT when activated protein C was added to their plasma. These patients were found to have an identical mutation in which arginine 506 in factor V is converted to glutamine. This amino acid substitution abolishes a protein C cleavage site in factor V and thus prolongs the thrombogenic effect of factor V activation. About 3% of the population worldwide is heterozygous for this mutation. The mutation is absent in certain populations, e.g., Asians, African Americans, and Native Americans. It may account for 25% of patients with recurrent deep venous thrombosis or pulmonary embolism.

Heterozygosity at this allele increases an individual's lifetime risk of venous thromboembolism sevenfold. The risk rises steadily with age. A homozygote has a twentyfold increased risk of thrombosis. Heterozygosity coupled with ingestion of oral contraceptives or pregnancy increases the risk at least fifteenfold. Coinheritance of factor V Leiden and another low-penetrance defect such as protein C or S deficiency is also additive. Many previous studies of risk factors predisposing patients to venous thromboembolism are being reevaluated to take into account this common mutation.

PROTHROMBIN GENE MUTATION

A specific point mutation in the prothrombin gene [conversion of G to A at position 20210 (G20210A)] also predisposes to venous thrombosis and embolism. This mutation is in the 3¢-untranslated region of the gene and results in a 30% increase in plasma prothrombin levels, either through more efficient translation or greater stability of the message. Heterozygotes account for ~18% of cases with family histories of venous thrombosis and 6% of patients with first episodes ofDVT.

The inheritance of multiple mutations increases the risk of thrombosis. The relationship between known mutations and the type of thrombosis is shown inTable 117-3. The fraction of patients withDVT with known mutations is shown in Table 117-4.

TREATMENT

Patients who develop venous thromboembolism without a clear predisposing factor, have a strong family history, present under the age 30, or have more than one episode should have assays for antithrombin III, proteins C and S, and factor V Leiden. Patients who present withDVT or pulmonary embolism during pregnancy or while using oral contraceptives have a 30% chance of having factor V Leiden.

Treatment recommendations for patients with the inherited prethrombotic disorders are still evolving. All patients should receive standard initial therapy with heparin, either conventional or low dose (Chap. 118), followed by 3 months of oral warfarin. This regimen should allow for maximal healing and reendothelialization of the thrombosed vessels and minimize recurrence in the damaged vascular beds. It is not clear which patients should go on to receive long-term (perhaps lifelong) anticoagulation, a judgment that depends on assessing the risk/benefit ratio.

Patients with antithrombin III deficiency who become symptomatic have a high likelihood of recurrent events and should be placed on lifelong anticoagulation. Patients with protein C or S deficiency or heterozygous factor V Leiden and prothrombin G20210A patients have a lower likelihood of recurrent disease. Long-term anticoagulation should be reserved until their second or subsequent episode of thromboembolism. Homozygous factor V Leiden patients should be placed on long-term anticoagulation after their initial episode, and all patients should receive replacement therapy or receive heparin prophylaxis during surgery or after trauma; women with these defects should avoid the use of oral contraceptives. The asymptomatic relatives of patients shown to have these disorders should be screened to determine if they have inherited the defective gene. If so, they should receive appropriate prophylaxis but not start anticoagulation until they are symptomatic. In the absence of a congenital defect predisposing a patient to thrombosis, recurring or migratory thrombophlebitis may indicate an underlying malignancy.

DYSFIBRINOGENEMIAS AND FIBRINOLYTIC DEFECTS

Recurrent venous thrombosis and embolism may be due to familial defects in fibrinogen or plasminogen or decreased synthesis or release oftPA. While most dysfibrinogenemias cause bleeding, several variants have excessively rapid release of fibrinopeptides and recurrent thromboembolism. Patients with this disorder and those with an abnormal plasminogen that resists activation by streptokinase and urokinase have been treated successfully with heparin and oral anticoagulants. Defects in tPA content or release have not been completely characterized. One group of patients with recurrent venous thrombosis and embolism failed to increase venous blood fibrinolytic activity when challenged with local ischemia or physical exercise. The other group had impaired fibrinolytic activity in extracts prepared from biopsied veins. Young patients with acute myocardial infarction may have impaired fibrinolysis due to increased plasma levels ofPAI, a serine protease inhibitor that binds to tPA and is derived from endothelial cells.

Many common illnesses are associated with an increased risk of thrombosis (Table 62-5). These patients are said to have a "hypercoagulable" or "prethrombotic" state. This increased risk is seen in patients with chronic congestive heart failure and metastatic cancer and in patients undergoing major surgery. The generation of tissue factor activity in damaged or ischemic tissue or metastatic tumor, coupled with venous stasis and endothelial injury, induces the formation of venous and, more rarely, arterial thrombi. Several hematologic disorders, paroxysmal nocturnal hemoglobinuria, essential thrombocythemia, and polycythemia vera predispose patients to venous and arterial thrombosis through diverse mechanisms related to increased blood viscosity and abnormal blood cells. Diseases that affect the endothelial cell, such as Behcet's syndrome, Kawasaki's disease, and homocystinuria, or the administration of drugs such as the oral contraceptives, which lower antithrombin III levels, or L-asparaginase, which inhibits production of multiple coagulation factors, may also predispose patients to thrombosis. Infusion of granulocyte-macrophage colony stimulating factor (GM-CSF) has been associated with thrombosis. Tamoxifen, an estrogen receptor antagonist, can cause venous thrombosis. The mechanism is unclear.

Plasma homocysteine levels influence the risk of both venous and arterial

thromboembolism. Individuals with the congenital homocystinuria syndrome have, in addition to their Marfanoid habitus, an increased incidence of strokes and coronary artery disease. These patients have well-recognized enzyme defects (Chap. 352), excrete homocysteine in their urine, and have very high plasma levels of the amino acid. Some patients with early-onset cerebral vascular events have mild homocystinuria that can be brought out by a methionine loading test. Epidemiologic studies show a relationship between homocysteine levels that are nearer to the normal range and coronary artery disease. Although this correlation is not yet definitive, the relationship remains intriguing and of potential clinical relevance. Vitamin B_{12}deficiency occurs in about 30% of people over age 70, produces elevated homocysteine levels, and may be a reversible cause of thrombotic disease.

118. ANTICOAGULANT, FIBRINOLYTIC, AND ANTIPLATELET THERAPY - *Robert I. Handin*

ANTICOAGULANT AND FIBRINOLYTIC THERAPY

Anticoagulation with heparin, followed by treatment with oral vitamin K antagonists, is the standard treatment for acute venous thrombosis and pulmonary embolism. In addition, chronic oral anticoagulation is used to prevent cerebral arterial embolism from cardiac sources such as ventricular mural thrombi or atrial thrombi or from an atherosclerotic, partially stenosed carotid or vertebral artery. Anticoagulants are also used, less successfully, to treat peripheral or mesenteric arterial thrombosis. These agents retard fibrin deposition on established thrombi and prevent the formation of new thrombi. The induction of a fibrinolytic state by the infusion of plasminogen activators such as recombinant tissue plasminogen activator (rtPA), streptokinase (SK), or urokinase (UK) has become an accepted mode of therapy for some thromboembolic disorders. Fibrinolytic therapy has been proposed for patients with massive pulmonary embolism and systemic hypotension and to restore the patency of acutely occluded peripheral and coronary arteries. Prompt fibrinolytic therapy can reduce both myocardial damage and mortality following acute coronary occlusion (Chap. 243), though mechanical interventions such as angioplasty and stent placement are also effective ways to restore vessel patency. Fibrinolytic therapy may also be effective in acute thrombotic strokes and in venoocclusive disease of the liver.

ACUTE ANTICOAGULATION WITH HEPARIN

Heparin is a naturally occurring mucopolysaccharide polymer with tetrasaccharide sequences that bind to and activate antithrombin III. It can dramatically reduce thrombin generation and fibrin formation in patients with acute venous and arterial thrombosis or embolism (Table 118-1). Heparin is administered to patients with acute thrombosis or embolism by giving an initial loading dose of 5000 to 10,000 units followed by a continuous intravenous infusion at a rate sufficient to keep the activated partial thromboplastin time (APTT) at 1.5 to 2 times the patient's preheparin APTT. This requires infusion of 800 to 1000 U.S.P. units per hour and is continued while patients are begun on oral anticoagulants and achieve appropriate prolongation of the prothrombin time. The usual duration of combined heparin-warfarin therapy is 5 to 7 days. Heparin is then discontinued, and the patient is maintained on warfarin. Alternatives to a continuous infusion include the administration of 5000 U.S.P. units of heparin four times a day either subcutaneously or intravenously. Unfractionated conventional heparin preparations are heterogeneous, with only 20% of the product biologically active. In addition, active heparin fractions may vary considerably in molecular weight. Biologically active, low-molecular-weight heparin (LMWH) preparations, while more expensive than unfractionated heparin, have several advantages: (1) they can be administered subcutaneously once or twice daily, (2) their pharmacokinetics are so predictable that APTT monitoring is not necessary, and (3) they are less immunogenic and less likely to cause thrombocytopenia. Many patients with deep venous thrombosis, a frequent cause for hospitalization, can be given LMWH as outpatients. Given their other advantages and equivalent efficacy, LMWH preparations have largely replaced unfractionated heparin (Table 118-1).

Patients with recurrent thromboembolism refractory to oral anticoagulants, pregnant women with thromboembolism, and patients with chronic disseminated intravascular coagulation (DIC) may be treated with daily injections ofLMWHpreparations such as enoxoparin or dalteparin. These agents are also effective in prevention of venous thrombosis in high-risk surgical and medical patients, including those with congestive heart failure, myocardial infarction, or cardiomyopathy.

The major complication of unfractionated heparin therapy is bleeding -- especially from surgical sites and into the retroperitoneum. Aspirin or aspirin-containing drugs impair platelet function. Thus, intramuscular injections in patients on both heparin and an antiplatelet drug may cause significant bleeding. Heparin's anticoagulant effect can be rapidly reversed by the administration of protamine sulfate. However, this is usually not necessary, since reduction or omission of a heparin dose usually improves hemostasis and stops bleeding. Thrombocytopenia occurs in ~10% of recipients and is usually mild, with the platelet count falling to 50,000 to 100,000/uL. Thrombocytopenia is more common in patients receiving heparin derived from beef lung as opposed to porcine intestinal mucosa.LMWH is less likely to cause either thrombocytopenia or bleeding. However, antibodies arising from exposure to unfractionated heparin often crossreact with LMWH. Thus, LMWH cannot usually be used to treat patients with established thrombocytopenia.

Heparin-induced thrombocytopenia (HIT) results from generation of an autoantibody to a complex of unfractionated heparin with the anti-heparin protein platelet factor 4 (PF-4). Heparin-PF-4-antibody complexes can bind to the platelet Fc receptor and cause platelet activation, agglutination, and arterial thrombosis. Recognition of the rare complication of thrombocytopenia and paradoxical thrombosis is critical, since discontinuing heparin can promptly reverse the syndrome and may be lifesaving. Heparin administration for >5 months also carries a risk of osteoporosis, perhaps through its activation of osteoclasts.LMWHcauses less osteoporosis on chronic administration.

CHRONIC ORAL ANTICOAGULATION

The coumarin anticoagulants, which include warfarin and dicumarol (dicoumarol), prevent the reduction of vitamin K epoxides in liver microsomes and induce a state of vitamin K deficiency (see Fig. 117-1). They slow thrombin generation and clot formation by impairing the biologic activity of the prothrombin complex proteins and are used to prevent the recurrence of venous thrombosis and pulmonary embolism. Although regimens employing loading doses of drug have been advocated, the simplest way to induce anticoagulation is to administer a single dose of a coumarin compound and monitor the prothrombin time (PT) until the desired prolongation is achieved. For example, treatment can be initiated with 5 mg/d of warfarin or equivalent, with the goal of prolonging the PT to 1.5 to 2 times the control value. Although the PT may reach this value after a few days of therapy, effective anticoagulation, with stable reduction of all the prothrombin complex proteins, requires at least 1 week of warfarin administration. Most patients require a daily maintenance dose of 2.5 to 7.5 mg of warfarin to remain anticoagulated.

Because commercial thromboplastins have different potencies, thePT can vary widely.

In an effort to standardize oral anticoagulation, the International Normalized Ratio (INR) method has been adopted by most hospital laboratories and clinicians. In this reporting method, the ratio of the patient's PT is compared to the mean PT for a group of normal individuals. The ratio is adjusted for the sensitivity of the laboratory's thromboplastin determined by the International Sensitivity Index (ISI). Thus, INR $=(PT_{patient}/PT_{normal})_{ISI}$. Use of the INR permits physicians to obtain the appropriate level of anticoagulation independent of laboratory reagents and to follow published recommendations for intensity of anticoagulation. The intensity of anticoagulation may be varied somewhat depending on the clinical indication (Table 118-2). Patients with chronic indwelling venous catheters have been maintained on 1 mg/d of warfarin to prevent clot formation at the catheter tip; such a dose has no effect on the PT.

Although warfarin anticoagulants reduce the recurrence of deep venous thrombosis and pulmonary or cerebral embolism, they may also cause bleeding. Any patient who takes oral anticoagulants requires frequent monitoring of thePT. Despite the most careful management, fluctuations in PT can occur. Various drugs that alter liver microsomal metabolism of coumarins or compete for albumin-binding sites can increase or decrease the potency of these drugs (Table 118-3).

The risk of bleeding increases and, up to a point, the risk of recurrent thrombosis declines with the duration of anticoagulation. Patients with a single uncomplicated thromboembolic event achieve maximal benefit after 3 to 6 months of anticoagulation. About 10% of patients on an oral anticoagulant for 1 year have a bleeding complication requiring medical supervision, and 0.5 to 1% have a fatal hemorrhage. The anticoagulant effects of coumarins can be reversed by infusion of fresh-frozen plasma or by the administration of vitamin K. Fresh-frozen plasma works immediately, but the effects last only a few hours. Vitamin K takes 8 to 12 h to become effective; after vitamin K administration, vitamin K antagonists are more difficult to use for reinduction of anticoagulation. In many cases, reduction or omission of several doses of warfarin improves hemostasis and stops hemorrhage. Despite the risk of bleeding, some patients may require lifelong anticoagulation.

Hemorrhagic skin necrosis is a rare complication. Some patients with this complication are deficient in protein C, an anticoagulant protein whose activity is reduced by vitamin K antagonists. Patients suspected of protein C deficiency should only begin oral anticoagulant therapy when combined with heparin or plasma infusions to restore protein C levels to normal. Patients with an inherited coumarin resistance may require extremely high doses to get an anticoagulant effect. Psychologically disturbed patients may surreptitiously ingest coumarin and present with unexplained bleeding and a prolongedPT. Plasma coumarin levels can be measured to confirm such ingestion.

FIBRINOLYTIC THERAPY

Fibrinolysis, an important part of the normal hemostatic process, is initiated by the release of either tissue plasminogen activator (tPA) or pro-urokinase (proUK) from endothelial cells. These agents preferentially activate plasminogen adsorbed onto fibrin clots, a mechanism that localizes the lytic process to sites that contain fibrin thrombi. Although fibrinolysis begins immediately after vascular injury, clot lysis and vessel recanalization may not be complete for 7 to 10 days. The fibrinolytic pathway is

important in normal hemostasis; defects can predispose patients to either hemorrhage or recurrent thrombosis (Chap. 117). Activators of the fibrinolytic system are frequently used to accelerate clot lysis in patients with thromboembolism (Fig. 118-1;Table 118-4).

The pharmacologic agents being used to accelerate clot lysis are either derived from natural products or are chemically modified derivatives. They differ with respect to fibrin specificity and some types of complications (Table 118-4). For example, many individuals have antistreptococcal antibodies that react withSK and reduce its potency and cause febrile reactions. All fibrinolytic agents cause hemorrhage. In addition totPA andproUK, several other agents are relatively "fibrin-specific" and preferentially activate plasminogen in the presence of fibrin. Although this makes it theoretically possible to achieve selective clot lysis, in practice the efficacy and toxicity of the "specific" and "nonspecific" fibrinolytic agents are similar. However, equivalent doses ofrtPAcost 10 times more than SK.

Some systemic fibrinolysis always occurs after the infusion of clinically effective doses of fibrin-specific agents. Fibrinogen level falls ~25%after infusion of lytic doses ofrtPA. In addition, both the fibrin-specific and -nonspecific agents can cause hemorrhage as they cannot differentiate between vital hemostatic plugs and pathologic thrombi. To minimize the risk of bleeding, systemic lytic therapy is not recommended for patients with recent surgery or a history of neurologic lesions, gastrointestinal bleeding, or hypertension.

The current indications for fibrinolytic therapy are listed inTable 118-5. Fibrinolytic therapy is currently recommended for patients with massive pulmonary embolism that is complicated by hypotension, hypoxemia, and right heart strain. It is also used for selected patients with peripheral arterial embolism or occlusion and for patients with extensive iliofemoral thrombophlebitis. While lytic therapy may hasten the resolution of venous thrombi, the long-term benefit still remains unproven, and no firm evidence proves that lytic therapy reduces postphlebitic complications. In contrast, fibrinolytic therapy may be of distinct benefit in patients with axillary vein thrombosis, a condition that does not usually respond to conventional anticoagulation. Fibrinolytic agents are also used to restore the patency of occluded venous catheters and dialysis shunts. For this indication the agents are instilled locally. The extensive literature on the use of fibrinolytic agents to treat patients with coronary artery disease and myocardial infarction is reviewed inChap. 243. When given within a few hours of infarction, fibrinolytic therapy reduces mortality and myocardial damage.

Although the doses and mode of administration may differ slightly, the general principles and complications are the same for all the fibrinolytic agents.SK andUK are the oldest and most extensively studied fibrinolytic agents. SK is a bacterial enzyme, and UK is a product of renal tubular epithelial cells. SK is an indirect plasminogen activator that interacts with circulating plasminogen to form an equimolar complex with proteolytic activity. The SK-plasminogen complex then activates additional plasminogen molecules that initiate fibrinolysis. In contrast, UK has intrinsic proteolytic activity and can activate plasminogen directly.

In the case ofSK, a loading dose of 250,000 units is usually given irrespective of body weight. Since patients may have antistreptococcal antibodies, the loading dose may need to be repeated. In addition, patients may develop acute allergic symptoms

including urticaria and, occasionally, serum sickness reactions. WithUK, a loading dose of 4400 units per kilogram body weight is administered over 10 to 30 min. Both regimens induce an intense lytic state as evidenced by a drop in fibrinogen, prolongation of the thrombin time, and a prolongation of the euglobulin lysis time -- an in vitro measure of fibrinolytic activity. After the initial loading dose, 100,000 units of SK or 4400 units of UK per kilogram body weight are administered hourly for 24 to 72 h. At the desired time, the lytic state is reversed by discontinuing UK or SK and by administering heparin for 7 to 10 days. Heparin can be started at the same time as the fibrinolytic agent. Fibrinolytic therapy should be initiated as soon as possible after the onset of thrombosis or embolism.

Fibrin-specific agents such asrtPA orproUKare also administered intravenously. Systemic infusion of 100 mg rtPA over 6 h restores coronary artery patency in ~75% of patients. Patients are then maintained on heparin for several days. ProUK given in a similar manner has almost identical effects, but large clinical trials suggest that rtPA is superior to other fibrinolytic agents in maintaining patency of acutely occluded coronary arteries.

ANTIPLATELET DRUG THERAPY

Antiplatelet drugs play a critical role in the management of patients with arterial vascular disease and thromboembolism. Aspirin is the most widely studied of these drugs because of its unique pharmacology. A single dose of aspirin irreversibly acetylates and inactivates the enzyme cyclooxygenase and thereby inhibits platelet production of thromboxane A_2. Although aspirin may also inactivate cyclooxygenase in other tissues, including endothelial cells, such cells recover rapidly by synthesizing new enzyme. Platelets, which are anucleate, cannot synthesize new enzyme and remain inactive for the rest of their life span. As little as one 160-mg tablet of aspirin daily or a 325-mg tablet every other day inhibits platelet thromboxane production and aggregation.

Patients with coronary artery disease who have unstable angina are at high risk for myocardial infarction (Chap. 243). The prompt administration of aspirin dramatically reduces progression to myocardial infarction in this group, although aspirin has no effect on the frequency, intensity, or duration of chronic angina. Aspirin also reduces the incidence of second infarction by 25% when administered to patients who have had a myocardial infarct. Daily aspirin therapy also reduces the incidence of first infarcts. The combination of aspirin and dipyridamole, when begun before surgery, may also increase the patency of coronary bypass grafts; the same combination reduces the incidence of cerebral emboli in patients on warfarin who have prosthetic intracardiac valves. Although dipyridamole has been a popular antithrombotic agent, it has little efficacy when given alone. Aspirin may be the active agent in the combination aspirin-dipyridamole trials.

Aspirin also reduces the frequency of transient ischemic attacks in patients with occlusive cerebrovascular disease. It has largely supplanted anticoagulation with the coumarin compounds in patients with transient ischemia. Aspirin also reduces the incidence of a second stroke by 25% when administered to men following a first stroke. Aspirin is also effective in maintaining the patency of arteriovenous cannulas inserted into patients with renal failure who require hemodialysis. Aspirin plus dipyridamole may

also slow the progression of some forms of glomerulonephritis, although these drugs are not widely used in the treatment of renal disease. Aspirin is not effective in maintaining the patency of vessels following percutaneous angioplasty or stent placement.

Although aspirin is clearly the most efficacious antiplatelet agent in clinical use today, a large number of new drugs are being tested that may supplement aspirin therapy. Ticlopidine, a potent inhibitor of platelet function, is effective as an alternative to aspirin in patients with cerebrovascular disease and is superior to aspirin or warfarin in maintaining coronary stent patency. Ticlopidine is more expensive than aspirin and causes some serious side effects, including neutropenia and occasional rare episodes of thrombotic thrombocytopenic purpura (TTP). A related drug, clopidogrel (Plavix), has been proposed as a substitute, but rare cases of TTP have also been noted with its use.

Monoclonal antibodies and both recombinant and chemically synthesized peptides that block either platelet adhesion or aggregation are being tested in clinical trials. A monoclonal antibody Fab fragment that blocks fibrinogen binding to platelet GpIIb/IIIa, thus inhibiting platelet aggregation (abciximab, RheoPro), is used in patients with coronary artery disease who undergo angioplasty. RheoPro is also being evaluated in other settings, e.g., as an adjunct to fibrinolytic therapy in patients with an acute myocardial infarction. A cyclic peptide based on the consensus fibronectin adhesion sequence RGD (arginine, glycine, aspartic acid) called eptifibatide (Integrilin) is as effective as RheoPro for maintaining patency after angioplasty and stent placement as is a small molecule inhibitor (Aggrestat). Orally active GpIIb/IIIa inhibitors have not been proven safe or effective.

The uses of antithrombotic therapy are evolving rapidly. However, aspirin is the current mainstay for chronic therapy and should be used (325 qd or qod) indefinitely in any patient who has had a coronary or cerebral thrombosis. It will reduce ischemic events by 25% or more. Patients undergoing angioplasty or stent placement should receive RheoPro/Integrilin or Aggrestat acutely, followed by 3 weeks of ticlopidine or clopidogrel.

PART SEVEN -INFECTIOUS DISEASES

SECTION 1 -BASIC CONSIDERATIONS IN INFECTIOUS DISEASES

119. INTRODUCTION TO INFECTIOUS DISEASES: HOST-PARASITE INTERACTIONS - *Lawrence C. Madoff*, *Dennis L. Kasper*

Despite decades of dramatic progress in their treatment and prevention, infectious diseases remain a major cause of death and debility and are responsible for worsening the living conditions of many millions of people around the world. Infections frequently challenge the physician's diagnostic skill and must be considered in the differential diagnoses of syndromes affecting every organ system.

CHANGING EPIDEMIOLOGY OF INFECTIOUS DISEASES

With the advent of antimicrobial agents, some medical leaders believed that infectious diseases would soon be eliminated and become of historic interest only. Indeed, the hundreds of chemotherapeutic agents developed since World War II, most of which are potent and safe, include drugs effective not only against bacteria but also against viruses, fungi, and parasites. Nevertheless, we now realize that as we developed antimicrobial agents, microbes developed the ability to elude our best weapons and to counterattack with new survival strategies. Antibiotic resistance occurs at an alarming rate among all classes of mammalian pathogens. Pneumococci resistant to penicillin and enterococci resistant to vancomycin have become commonplace. Even *Staphylococcus aureus* with reduced susceptibility to vancomycin has appeared. Such pathogens present real clinical problems in managing infections that were easily treatable just a few years ago. Diseases once thought to have been nearly eradicated from the developed world -- tuberculosis, cholera, and rheumatic fever, for example -- have rebounded with renewed ferocity. Newly discovered and emerging infectious agents appear to have been brought into contact with humans by changes in the environment and by movements of human and animal populations. An example of the propensity for pathogens to escape from their usual niche is the alarming 1999 outbreak in New York of encephalitis due to a flavivirus similar or identical to West Nile virus, which had never previously been isolated in the Americas.

Many infectious agents have been discovered only in recent decades. Ebola virus, hantavirus, the agent of human granulocytotropic ehrlichiosis, and retroviruses such as HIV humble us despite our deepening understanding of pathogenesis at the most basic molecular level. Even in developed countries, infectious diseases have made a resurgence. Between 1980 and 1996, mortality from infectious diseases in the United States increased by 64% to levels not seen since the 1940s.

The role of infectious agents in the etiology of diseases once believed to be noninfectious is being increasingly recognized. For example, it is now widely accepted that *Helicobacter pylori* is the causative agent of peptic ulcer disease and perhaps of gastric malignancy. Human papillomavirus is likely to be the most important cause of invasive cervical cancer. A new human herpesvirus (HHV-8) is believed to be the cause of most cases of Kaposi's sarcoma. Epstein-Barr virus is a cause of certain lymphomas and may play a role in the genesis of Hodgkin's disease. The possibility certainly exists

that other diseases of unknown cause, such as rheumatoid arthritis, sarcoidosis, or inflammatory bowel disease, have infectious etiologies. There is even evidence that atherosclerosis may have an infectious component.

Medical advances over infectious diseases have been hindered by changes in the patient population. Immunocompromised hosts now constitute a significant proportion of the seriously infected population. Physicians immunosuppress their patients to prevent the rejection of transplants and to treat neoplastic and inflammatory diseases. Some infections, most notably that caused by HIV, immunocompromise the host in and of themselves. Lesser degrees of immunosuppression are associated with other infections, such as influenza and syphilis. Infectious agents that coexist peacefully with immunocompetent hosts wreak havoc in those who lack a complete immune system. AIDS has brought to prominence once-obscure organisms such as *Pneumocystis carinii*, *Cryptosporidium parvum*, and *Mycobacterium avium*.

BIOTERRORISM

In recent years, the efforts of some governments and terrorist organizations to use biological weaponry have refocused public concern on the topic. To date, there is little evidence that biological weapons have ever been effectively used; indeed, their ease of use may be overstated. However, the ability of infectious agents to inflict widespread illness and thus to cause societal disruption and panic, together with the relatively low cost of these agents, has led to their being called a "poor man's nuclear arsenal."

Several pathogens have been considered likely candidates for biological warfare. *Bacillus anthracis*, which causes the zoonosis anthrax, is widely viewed as the leading contender. The hardy spores of the bacillus can be distributed by bombardment or other dispersal mechanisms. Inhalation of this pathogen results in severe pneumonia with a mortality rate of 95% in untreated persons. A World Health Organization report estimated that 50 kg of *B. anthracis* released upwind of a city with a population of 500,000 would result in up to 95,000 fatalities, with an additional 125,000 persons incapacitated. Moreover, the attack might go undetected until large numbers of seriously ill individuals presented with overt disease. In 1979, an accidental release from a military microbiology facility near Sverdlovsk in the former Soviet Union caused at least 66 deaths from inhalational anthrax along a 4-km-wide path downwind of the facility. The vast scope of the Soviet Union's biological warfare program, employing 60,000 people at its height, has only recently come to light. This endeavor is thought to be echoed by efforts in many other countries in the world today. In response to the perceived threat of anthrax as a biological weapon, the U.S. military recently decided to vaccinate more than 2 million of its members against this infection.

Smallpox, an ancient scourge caused by variola virus, has also been considered as a bioweapon owing to its contagiousness and high mortality rate and to the declining population of immunized persons. Indeed, one of the earliest accounts of biological warfare involved the distribution of smallpox-infected blankets to Native American tribes by British troops. Debate continues about whether to eradicate the two known existing stocks of the virus in U.S. and Russian government laboratories. Many investigators believe that additional undocumented stockpiles of the virus exist around the world.

Other infectious organisms that combine the virulence and stability necessary for biological weapons include *Yersinia pestis*, the agent of plague, and *Francisella tularensis*, the agent of tularemia. Viral hemorrhagic fever agents such as the Ebola and Marburg viruses as well as toxins such as that from *Clostridium botulinum* have also been considered as biological weapons. While some of the diseases caused by these agents can be effectively treated or prevented if sufficient resources exist to do so, it may also be possible for an aggressor to render organisms resistant to antibiotics or even to vaccines through genetic manipulation or other means.

HOST FACTORS IN INFECTION

For any infectious process to occur, the parasite and the host must first encounter each other. Factors such as geography, environment, and behavior thus influence the likelihood of infection. Though the initial encounter between a susceptible host and a virulent organism frequently results in disease, some organisms can be harbored in the host for years before disease becomes clinically evident. For a complete view, individual patients must be considered in the context of the population to which they belong. Infectious diseases do not often occur in isolation; rather, they spread through a group exposed from a point source (e.g., a contaminated water supply) or from individual to individual (e.g., via respiratory droplets). Thus, the clinician must be alert to infections prevalent in the community as a whole. A detailed history, including information on travel, behavioral factors, exposures to animals or potentially contaminated environments, and living and occupational conditions, must be elicited. For example, the likelihood of infection by *Plasmodium falciparum* can be significantly affected by altitude, climate, terrain, season, and even time of day. Antibiotic-resistant strains are localized to specific geographic regions, and a seemingly minor alteration in a travel itinerary can dramatically influence the likelihood of acquiring chloroquine-resistant malaria. If such important details in the history are overlooked, inappropriate treatment may result in the death of the patient. Likewise, the chance of acquiring a sexually transmitted disease can be greatly affected by a relatively minor variation in sexual practices, such as the method used for birth control. Knowledge of the relationship between specific risk factors and disease allows the physician to influence a patient's health even before the development of infection by modification of these risk factors and -- when a vaccine is available -- by immunization.

Many specific host factors influence the likelihood of acquiring an infectious disease. Age, immunization history, prior illnesses, level of nutrition, pregnancy, coexisting illness, and perhaps emotional state all have some impact on the risk of infection after exposure to a potential pathogen. The importance of individual host defense mechanisms, either specific or nonspecific, becomes apparent in their absence, and our understanding of these immune mechanisms is enhanced by studies of clinical syndromes developing in immunodeficient patients (Table 119-1). For example, the frequent occurrence of meningococcal disease in people with deficiencies in specific complement proteins of the "membrane attack complex" underscores the importance of an intact complement system in the prevention of meningococcal infection.

Medical care itself increases the patient's risk of acquiring an infection in several ways: (1) through contact with pathogens during hospitalization, (2) through breaching of the skin (with intravenous devices or surgical incisions) or mucosal surfaces (with

endotracheal tubes or bladder catheters), (3) through introduction of foreign bodies, (4) through alteration of the natural flora with antibiotics, and (5) through treatment with immunosuppressive drugs.

THE IMMUNE RESPONSE

Infection involves complicated interactions of parasite and host and inevitably affects both. In most cases, a pathogenic process consisting of several steps is required for the development of infections. Since the competent host has a complex series of barricades in place to prevent infection, the successful parasite must utilize specific strategies at each of these steps. The specific strategies used by bacteria, viruses, and parasites (Chaps. 120 and180) have some remarkable conceptual similarities, but the strategic details are unique not only for each class of organism but also for individual species within a class.

Once in the bloodstream or a normally sterile body site, the microorganism faces the host's tightly integrated cellular and humoral immune systems. Cellular immunity (Chap. 305), comprising T lymphocytes, macrophages, and natural killer cells, primarily recognizes and combats pathogens that proliferate intracellularly. Cellular immune mechanisms are important in immunity to all classes of infectious agents, including most viruses and many bacteria (e.g., *Mycoplasma*, *Chlamydia*, *Listeria*, *Salmonella*, and *Mycobacterium*), parasites (e.g., *Trypanosoma*, *Toxoplasma*, and *Leishmania*), and fungi (e.g., *Histoplasma*, *Cryptococcus*, and *Coccidioides*). Usually, T lymphocytes are activated by macrophages and B lymphocytes, which present foreign antigens along with the host's own major histocompatibility complex antigen. Activated T cells may then act in several ways to fight infection. Cytotoxic T cells may directly attack and lyse host cells that express foreign antigens. Helper T cells stimulate the proliferation of B cells and the production of immunoglobulins. B cells and T cells communicate with each other via a variety of signals, and often more than one signal is employed simultaneously. For example, costimulation through the CD40-CD40 ligand increases B cell responses, and costimulation via the B7-CD28 axis is required for activation of the CD4+ helper T cell. T cells elaborate cytokines (e.g., interferon), which directly inhibit the growth of pathogens or stimulate killing by host macrophages and cytotoxic cells. Cytokines also augment the host's immunity by stimulating the inflammatory response (fever, the production of acute-phase serum components, and the proliferation of leukocytes). Cytokine stimulation does not always result in a favorable response in the host; septic shock (Chap. 124) and toxic shock syndrome (Chaps. 139 and140) are among the conditions that are mediated by these inflammatory substances.

The reticuloendothelial system comprises monocyte-derived phagocytic cells that are located in the liver (Kupffer cells), lung (alveolar macrophages), spleen, kidney (mesangial cells), brain (microglia), and lymph nodes and that clear circulating microorganisms. Although these tissue macrophages and polymorphonuclear leukocytes (PMNs) are capable of killing microorganisms without help, they function much more efficiently when pathogens are first *opsonized* (Greek, "to prepare for eating") by components of the complement system such as C3b and/or by antibodies.

Extracellular pathogens, including most encapsulated bacteria, are attacked by the humoral immune system, which includes antibodies, the complement cascade, and

phagocytic cells. Antibodies are complex glycoproteins (also called immunoglobulins) that are produced by mature B lymphocytes, circulate in body fluids, and are secreted on mucosal surfaces. Antibodies specifically recognize and bind to foreign antigens. One of the most impressive features of the immune system is the ability to generate an incredible diversity of antibodies capable of recognizing virtually every foreign antigen yet not reacting with self. In addition to being exquisitely specific for antigens, antibodies come in different structural and functional classes: IgG predominates in the circulation and persists for many years after exposure; IgM is the earliest specific antibody to appear in response to infection; secretory IgA is important in immunity at mucosal surfaces, while monomeric IgA appears in the serum; and IgE is important in allergic and parasitic diseases. Antibodies may directly impede the function of an invading organism, neutralize secreted toxins and enzymes, or facilitate the removal of the antigen (invading organism) by phagocytic cells. Immunoglobulins participate in cell-mediated immunity by promoting the antibody-dependent cellular cytotoxicity functions of certain T lymphocytes. Antibodies also promote the deposition of complement components on the surface of the invader.

The complement system (Chap. 305) consists of a group of serum proteins functioning as a cooperative, self-regulating cascade of enzymes that adhere to -- and in some cases disrupt -- the surface of invading organisms. Some of these surface-adherent proteins (e.g., C3b) can then act as opsonins for destruction of microbes by phagocytes. The later, "terminal" components (C7, C8, and C9) can directly kill some bacterial invaders (notably, many of the neisseriae) by forming a "membrane attack complex" and disrupting the integrity of the bacterial membrane, thus causing bacteriolysis. Other complement components, such as C5a, act as chemoattractants forPMNs. Complement activation and deposition occur by either or both of two pathways: the classic pathway is activated primarily by immune complexes (i.e., antibody bound to antigen), and the alternative pathway is activated by microbial components, frequently in the absence of antibody. PMNs have receptors for both antibody and C3b, and antibody and complement function together to aid in the clearance of infectious agents.

PMNs, short-lived white blood cells that engulf and kill invading microbes, are first attracted to inflammatory sites by chemoattractants such as C5a, which is a product of complement activation at the site of infection. PMNs localize to the site of infection by adhering to cellular adhesion molecules expressed by endothelial cells. Endothelial cells express these receptors, called *selectins* (CD-62, ELAM-1), in response to inflammatory cytokines such as tumor necrosis factor (TNF) a and interleukin 1. The binding of these selectin molecules to specific receptors on PMNs results in the adherence of the PMNs to the endothelium. Cytokine-mediated upregulation and expression of intercellular adhesion molecule 1 (ICAM 1) on endothelial cells then take place, and this latter receptor binds to$b_2$integrins on PMNs, thereby facilitating diapedesis into the extravascular compartment. Once the PMNs are in the extravascular compartment, various molecules such as arachidonic acids further enhance the inflammatory process.

Approach to the Patient

The clinical manifestations of infectious diseases at presentation are myriad, varying from fulminant life-threatening processes to brief and self-limited conditions to indolent chronic maladies. The clinician must use all the skills of medicine to diagnose the

infection and prescribe appropriate treatment. First, a careful history is essential and must include details on underlying chronic diseases; medications; occupation; travel; and risk factors for exposure to certain types of pathogens, such as those associated with sexual contacts, family illnesses, illicit drug use, particular animals, blood transfusions, ingestion of contaminated liquids or foods, or bites of insect vectors. Since infectious diseases may involve many organ systems, a careful review of systems may elicit important clues as to the disease process. The physical examination must be thorough, and attention must be paid to seemingly minor details: a soft heart murmur that might indicate bacterial endocarditis; an evanescent skin rash that suggests rheumatic fever; or a retinal lesion that suggests disseminated candidiasis or cytomegalovirus (CMV) infection.

LABORATORY INVESTIGATIONS

Laboratory studies must be carefully considered and directed toward establishing an etiologic diagnosis in the shortest possible time, at the lowest possible cost, and with the least possible discomfort to the patient. Cultures must be performed in a manner that minimizes the likelihood of contamination with normal flora while maximizing the yield. A sputum sample is far more likely to be valuable when elicited with careful coaching by the clinician than when collected in a container simply left at the bedside with cursory instructions. Gram's stains of specimens should be interpreted carefully and the quality of the specimen assessed. The findings on Gram's staining should correspond to the results of culture; a discrepancy may suggest diagnostic possibilities such as infection due to fastidious or anaerobic bacteria.

The microbiology laboratory must be an ally in the diagnostic endeavor (Chap. 121). Astute laboratory personnel will suggest optimal culture and transport conditions or alternative tests to facilitate diagnosis. If informed about specific potential pathogens, an alert laboratory staff will allow sufficient time for these organisms to become evident in culture, even when present in small numbers or when slow-growing. The parasitology technician who is attuned to the specific diagnostic considerations relevant to a particular case may be able to detect the rare, otherwise-elusive egg or cyst in a stool specimen. In cases where a diagnosis appears difficult, serum should be stored during the early acute phase of the illness so that a diagnostic rise in titer of antibody to a specific pathogen can be detected later. Bacterial and fungal antigens can sometimes be detected in body fluids, even when cultures are negative or are rendered sterile by antibiotic therapy. Techniques such as the polymerase chain reaction allow the amplification of specific DNA sequences so that minute quantities of foreign nucleic acids can be recognized in host specimens.

TREATMENT

Optimal therapy for infectious diseases requires a broad knowledge of medicine and careful clinical judgment. Life-threatening infections such as bacterial meningitis or sepsis, viral encephalitis, or falciparum malaria must be treated immediately, often before a specific causative organism is identified. Antimicrobial agents must be chosen empirically and must be active against the range of potential infectious agents consistent with the clinical scenario. In contrast, good clinical judgment sometimes dictates withholding of antimicrobials in a self-limited process or until a specific

diagnosis is made. The dictum *primum non nocere* should be adhered to, and it should be remembered that all antimicrobials carry a risk (and a cost) to the patient. Direct toxicity may be encountered -- e.g., ototoxicity due to aminoglycosides, lipodystrophy due to HIV protease inhibitors, and hepatotoxicity due to antituberculous agents such as isoniazid and rifampin. Allergic reactions are common and can be serious. Since superinfection sometimes follows the eradication of the normal flora and colonization by a resistant organism, one invariable principle is that infectious disease therapy should be directed toward as narrow a spectrum of infectious agents as possible. Treatment specific for the pathogen should result in as little perturbation as possible of the host's microflora. With few exceptions, abscesses require surgical or percutaneous drainage for cure. Foreign bodies, including medical devices, must generally be removed in order to eliminate an infection of the device or of the adjacent tissue. Other infections, such as necrotizing fasciitis, peritonitis due to a perforated organ, gas gangrene, and chronic osteomyelitis, require surgery as the primary means of cure; in these conditions, antibiotics play only an adjunctive role.

The role of immunomodulators in the management of infectious diseases has received increasing attention. Glucocorticoids have been shown to be of benefit in the treatment of *Haemophilus influenzae* meningitis in children and in therapy for *P. carinii* pneumonia in patients with AIDS. The use of these agents in other infectious processes remains less clear and in some cases (in cerebral malaria and septic shock, for example) is detrimental. Other agents that modulate the immune response include prostaglandin inhibitors, specific lymphokines, andTNFinhibitors. Specific antibody therapy plays a role in the treatment and prevention of many diseases. Specific immunoglobulins have long been known to prevent the development of symptomatic rabies and tetanus. More recently,CMVimmune globulin has been recognized as important not only in preventing the transmission of the virus during organ transplantation but also in treating CMV pneumonia in bone marrow transplant recipients. There is a strong need for well-designed clinical trials to evaluate each new interventional modality.

PERSPECTIVE

The genetic simplicity of many infectious agents allows them to undergo rapid evolution and to develop selective advantages that result in constant variation in the clinical manifestations of infection. Moreover, changes in the environment and the host can predispose new populations to a particular infection. An epidemic of lethal respiratory failure -- later identified as hantavirus pulmonary syndrome -- on a Navajo reservation in the southwestern United States in 1993 caused nationwide alarm, exemplifying the fear that new plagues induce in the human psyche.

The potential for infectious agents to emerge in novel and unexpected ways requires that physicians and public health officials be knowledgeable, vigilant, and open-minded in their approach to unexplained illness. The emergence of antimicrobial-resistant pathogens (e.g., enterococci that are resistant to all known antimicrobial agents and cause infections that are essentially untreatable) has led some to conclude that we are entering the "postantibiotic era." Others have held to the perception that infectious diseases no longer represent as serious a concern to world health as they once did. The progress that science, medicine, and society as a whole have made in combating these maladies is impressive, and it is ironic that, as we stand on the threshold of an

understanding of the most basic biology of the microbe, infectious diseases are posing renewed problems. We are threatened by the appearance of new diseases such as AIDS, hepatitis C, and Ebola virus infection and by the reemergence of old foes such as tuberculosis, cholera, plague, and *Streptococcus pyogenes* infection. True students of infectious diseases were perhaps less surprised than anyone else by these developments. Those who know pathogens are aware of their incredible adaptability and diversity. As ingenious and successful as therapeutic approaches may be, our ability to develop methods to counter infectious agents so far has not matched the myriad strategies employed by the sea of microbes that surrounds us. Their sheer numbers and the rate at which they can evolve are daunting. Moreover, environmental changes, rapid global travel, population movements, and medicine itself -- through its use of antibiotics and immunosuppressive agents -- all increase the impact of infectious diseases. Although new vaccines, new antibiotics, improved global communication, and new modalities for treating and preventing infection will be developed, pathogenic microbes will continue to develop new strategies of their own, presenting us with an unending and dynamic challenge.

120. MOLECULAR MECHANISMS OF MICROBIAL PATHOGENESIS- *Gerald B. Pier*

Over the past two decades, molecular studies of microbial pathogenesis have yielded an explosion of information about the various microbial and host molecules that contribute to the processes of infection and disease. These processes can be classified into several stages: microbial encounter with and entry into the host; microbial growth after entry; avoidance of innate host defenses; tissue invasion and tropism; tissue damage; and transmission to new hosts. Virulence is the measure of an organism's capacity to cause disease and is a function of the pathogenic factors elaborated by microbes. These factors promote colonization (the simple presence of potentially pathogenic microbes in or on a host), infection (attachment and growth of pathogens and avoidance of host defenses), and disease (often, but not always, the activities of secreted toxins or toxic metabolites). In addition, the host's inflammatory response to infection greatly contributes to disease and its attendant clinical signs and symptoms. Knowledge of the molecular structures of the microbial surface, their interactions with the host, and the host response is critical to an understanding of the basic processes of infection and disease.

MICROBIAL ENTRY AND ADHERENCE

ENTRY SITES

A microbial pathogen can potentially enter any part of a host organism. In general, the type of disease produced by a particular microbe is often a direct consequence of its route of entry into the body. The most common sites of entry are body parts in contact with the external environment, including mucosal surfaces (particularly those of the respiratory, alimentary, and urogenital tracts) and the skin. Ingestion, inhalation, and sexual contact are typical routes of microbial entry. Other portals of entry include injuries to the skin (cuts, bites, burns, trauma) along with injection via natural (i.e., vector-borne) or artificial (i.e., needle-stick injury) routes. A few pathogens, such as *Schistosoma* spp., can penetrate unbroken skin. The conjunctiva can serve as an entry point for pathogens of the eye.

Microbial entry usually relies on the organism's biologic characteristics and reflects the presence of specific microbial factors needed for persistence and growth in a tissue. Fecal-oral spread via the alimentary tract requires a biology consistent with survival in the varied environments of the gastrointestinal tract (including the low pH of the stomach and the high bile content of the intestine) as well as in contaminated food or water outside the host. Organisms that gain entry via the respiratory tract are most often those that survive well in small moist droplets produced during sneezing and coughing; most such pathogens do not survive well once they dry out. Pathogens that enter by venereal routes often survive best on the warm moist environment of the urogenital mucosa. Many sexually transmitted human pathogens have restricted host ranges and do not infect other animals (e.g., *Neisseria gonorrhoeae*, *Treponema pallidum*, and HIV).

The biology of microbes entering through the skin is highly varied. Some of these organisms can survive in a broad range of environments, such as the salivary glands or alimentary tracts of arthropod vectors, the mouths of larger animals, soil, and water. A

complex biology allows protozoan parasites such as *Plasmodium*, *Leishmania*, and *Trypanosoma* spp. to undergo morphogenic changes that allow the organism to be transmitted to mammalian hosts during insect feeding for blood meals. Plasmodia are injected as infective sporozoites from the salivary glands during mosquito feeding. *Leishmania* parasites are regurgitated as promastigotes from the alimentary tract of sandflies and injected by bite into a susceptible host. Trypanosomes are first ingested from infected hosts by reduviid bugs; the pathogens then multiply in the gastrointestinal tract of the insects and are released in feces onto the host's skin during subsequent feedings. Most microbes that land directly on intact skin are destined to die, as survival on the skin or in hair follicles requires resistance to fatty acids, low pH, and other antimicrobial factors on skin. Once it is damaged (and particularly if it becomes necrotic), the skin can be a major portal of growth and entry for pathogens or their toxic products. Tetanus and burn wound infections are clear examples. After animal bites, pathogens resident in the animal's saliva gain access through the skin to the victim's tissues. Rabies is the paradigm for this pathogenic process; rabies virus grows in striated muscle cells at the site of inoculation.

MICROBIAL ADHERENCE

Once in or on a host, most microbes must anchor themselves to a tissue or tissue factor; the possible exceptions are organisms that directly enter the bloodstream and multiply there. Specific microbial ligands or adhesins for host receptors constitute a major area of study in the field of microbial pathogenesis. Adhesins comprise a wide range of surface structures, not only anchoring the microbe to a tissue and promoting cellular entry where appropriate but also eliciting host responses critical to the pathogenic process (Table 120-1). Most microbes produce multiple adhesins specific for multiple host receptors. These adhesins are often redundant, are serologically variable, and act additively or synergistically with other microbial factors to promote microbial sticking to host tissues. In addition, some microbes (such as *Mycobacterium tuberculosis* and *Legionella pneumophila*) adsorb host proteins (such as complement components) onto their surface and utilize the natural host protein receptor for microbial binding and entry into target cells.

All viral pathogens must bind to host cells, enter them, and replicate within them. Viral coat proteins serve as the ligands for cellular entry, and more than one ligand-receptor interaction may be needed; for example, HIV utilizes its envelope glycoprotein (gp) 120 to enter host cells by binding to both CD4 and one of several receptors for chemokines. Similarly, the measles virus H glycoprotein binds to both CD46 and the membrane-organizing protein moesin. The gC protein on herpes simplex virus binds to heparin sulfate; this step is followed by attachment to cells mediated by the viral gD (and possibly gH) protein. CD46 has now been shown to be the cellular receptor for human herpesvirus type 6. Eukaryotic parasites use complicated surface glycoproteins as adhesins, some of which are lectins with specificity for carbohydrates on host cells.

Among the microbial adhesins studied in greatest detail are bacterial pili and flagella. *Pili* or *fimbriae* are commonly used by gram-negative bacteria for attachment to host cells and tissues. In electron micrographs, these hairlike projections (up to several hundred per cell) may be confined to one end of the organism (polar pili) or distributed more evenly over the surface. An individual cell may have pili with a variety of functions.

Most pili are made up of a major pilin protein subunit (molecular weight, 17,000 to 30,000) that polymerizes to form the pilus. Many strains of *Escherichia coli* express mucus-binding type 1 pili, whose binding to host tissues is inhibited by D-mannose. Other strains produce the Pap (pyelonephritis-associated) or P pilus adhesin that mediates binding to digalactose (gal-gal) residues on globosides of the human P blood groups. These pili have proteins located at the tips of the main pilus unit that are critical to the binding specificity of the whole pilus unit. Immunization with the mannose-binding FimH tip protein of type 1 pili prevents experimental *E. coli* bladder infections in mice and monkeys. *E. coli* cells causing diarrheal disease express pilus-like receptors for enterocytes on the small bowel, along with other receptors termed *colonization factors*.

A common type of pilus found in *Neisseria* spp., *Moraxella* spp., *Vibrio cholerae*, and *Pseudomonas aeruginosa* mediates adherence of these organisms to target surfaces. These pili tend to have a relatively conserved amino-terminal region and a more variable carboxyl-terminal region. For some species such as *N. gonorrhoeae* and *Neisseria meningitidis*, the pili are critical for attachment to mucosal epithelial cells. For others, such as *P. aeruginosa*, the pili only partially mediate the cells' adherence to host tissues. *V. cholerae* cells appear to use two different types of pili for intestinal colonization. Whereas interference with this stage of colonization would appear to be an effective antibacterial strategy, attempts to develop pilus-based vaccines for human diseases have not been highly successful to date.

Flagella are long appendages attached at either one or both ends of the bacterial cell (polar flagella) or distributed over the entire cell surface (peritrichous flagella). Flagella, like pili, are composed of a polymerized or aggregated basic protein. In flagella, the protein subunits form a tight helical structure and vary serologically with the species. Spirochetes such as *T. pallidum* and *Borrelia burgdorferi* have axial filaments similar to flagella running down the long axis of the center of the cell, and they "swim" by rotation around these filaments. Some bacteria can glide over a surface in the absence of obvious motility structures.

Other bacterial structures involved in adherence to host tissues include specific staphylococcal and streptococcal proteins that bind to human extracellular matrix proteins such as fibrin, fibronectin, laminin, and collagen. Fibronectin appears to be a commonly used receptor for various pathogens; a particular sequence, Arg-Gly-Asp or RGD, is critical for bacterial binding. Surface lipoteichoic acids may also promote streptococcal adherence to mucosal surfaces. The surface lipopolysaccharide (LPS) of *P. aeruginosa* mediates binding to the cystic fibrosis transmembrane conductance regulator (CFTR) on airway epithelial cells. Coagulase-negative staphylococci readily colonize prosthetic devices and catheters commonly used in medical care; the surface capsular polysaccharide of these organisms promotes binding to the prosthetic material. It has been reported that *Staphylococcus aureus* produces the same capsular polysaccharide and may also use this material to colonize prosthetic devices.

FUNGAL ADHESINS

Several fungal adhesins have been described that mediate colonization of epithelial surfaces, particularly adherence to structures like fibronectin, laminin, and collagen. The product of the *Candida albicans INT1* gene, int1p, bears similarity to mammalian

integrins that bind to extracellular matrix proteins. Transformation of normally nonadherent *Saccharomyces cerevisiae* with this gene allows these yeast cells to adhere to human epithelial cells. Disruption of *INT1* in *C. albicans* diminishes but does not eliminate epithelial cell adhesion; this result indicates that both int1p and other adhesins mediate binding of *C. albicans* to epithelial cells. Moreover, int1p is needed for filamentous growth of *C. albicans* -- a phenotype linked to virulence, and particularly to the ability to penetrate keratinized epithelium. *INT1*-deficient *C. albicans* exhibits markedly reduced virulence in a mouse model of infection.

For several fungal pathogens that initiate infections after inhalation of infectious material, the inoculum is ingested by alveolar macrophages, in which the cells transform to pathogenic phenotypes. Like *C. albicans*, *Blastomyces dermatitidis* binds to CD11b/CD18 integrins as well as to CD14 on macrophages. *B. dermatitidis* produces a 120-kDa surface protein, designated WI-1, that mediates this adherence. The binding domain of WI-1 is homologous to the invasin protein of *Yersinia* that binds to the same type of host cell receptor. An unidentified factor on *Histoplasma capsulatum* also mediates binding of this fungal pathogen to the integrin surface proteins.

HOST RECEPTORS

Host receptors are found both on target cells (such as epithelial cells lining mucosal surfaces) and within the mucus layer covering these cells. Microbial pathogens bind to a wide range of host receptors to establish infection (Table 120-1). Selective loss of host receptors for a pathogen may confer natural resistance to an otherwise susceptible population. For example, *Plasmodium vivax*, one of four *Plasmodium* species causing malaria, binds to the Duffy blood group antigen, Fy, on erythrocytes. In West Africa, 70% of individuals lack Fy antigens and are resistant to *P. vivax* infection. *Salmonella typhi*, the etiologic agent of typhoid fever, usesCFTR to enter the gastrointestinal submucosa after being ingested. As homozygous mutations in *CFTR* are the cause of the life-shortening disease cystic fibrosis, heterozygote carriers (e.g., 4 to 5% of individuals of European ancestry) may have had a selective advantage due to decreased susceptibility to *S. typhi* infection.

Numerous virus-target cell interactions have been described, and it is now clear that different viruses can use similar host cell receptors for entry. The list of certain and likely host receptors for viral pathogens is long. Among the host membrane components that can serve as receptors for viruses are sialic acids, gangliosides, glycosaminoglycans, integrins and other members of the immunoglobulin superfamily, histocompatibility antigens, and regulators and receptors for complement components.

MICROBIAL GROWTH AFTER ENTRY

Once established on a mucosal or skin site, pathogenic microbes must replicate before causing full-blown infection and disease. Within cells, viral particles release their nucleic acids, which may be directly translated into viral proteins (positive-strand RNA viruses), transcribed from a negative strand of RNA into a complementary mRNA (negative-strand RNA viruses), or transcribed into a complementary strand of DNA (retroviruses); for DNA viruses, mRNA may be transcribed directly from viral DNA, either in the cell nucleus or in the cytoplasm. To grow, bacteria must acquire specific nutrients

or synthesize them from precursors in host tissues. For example, since aromatic amino acids are not available as nutrients in host tissues, pathogenic bacteria must synthesize them from precursors. Many infectious processes are usually confined to specific epithelial surfaces -- influenza to the respiratory mucosa, gonorrhea to the urogenital epithelium, shigellosis to the gastrointestinal epithelium. While there are multiple reasons for this specificity, one important consideration is probably the ability of these pathogens to obtain from these specific environments the nutrients needed for growth and survival.

Temperature restrictions also play a role in limiting certain pathogens to specific tissues. Rhinoviruses, a cause of the common cold, grow best at 33°C and replicate in cooler nasal tissues but not in the lung. Leprosy lesions due to *Mycobacterium leprae* are found in and on relatively cool body sites. Fungal pathogens that infect the skin, hair follicles, and nails (dermatophyte infections) remain confined to the cooler, exterior, keratinous layer of the epithelium.

A topic of major interest is the ability of many bacterial, fungal, and protozoal species to grow in multicellular masses referred to as *biofilms*. These masses are biochemically and morphologically quite distinct from the free-living individual cells referred to as *planktonic cells*. Growth in biofilms leads to altered microbial metabolism, production of extracellular virulence factors, and decreased susceptibility to biocides, antimicrobial agents, and host defense molecules and cells. Regulation of biofilm morphogenesis is controlled by bacterial quorum-sensing systems. Quorum sensing for some organisms involves the production of homoserine lactone molecules such as *N*-(3-oxododecanoyl)homoserine lactone and *N*-butyrylhomoserine lactone, which combine with transcriptional activators to control gene expression. *P. aeruginosa* growing on the bronchial mucosa during chronic infection, staphylococci and other pathogens growing on implanted medical devices, and dental pathogens growing on tooth surfaces to form plaques represent several examples of microbial biofilm growth associated with human disease. Many other pathogens can form biofilms during in vitro growth, including *Helicobacter pylori*, the cause of stomach ulcers; *E. coli* O157, one cause of the hemolytic-uremic syndrome; and *Gardnerella vaginalis*, an organism associated with bacterial vaginosis.

AVOIDANCE OF INNATE HOST DEFENSES

As microbes have probably interacted with mucosal/epithelial surfaces since the emergence of multicellular organisms, it is not surprising that multicellular hosts have a variety of innate surface defense mechanisms that can sense when pathogens are present and contribute to their elimination. The skin, a formidable physical barrier to microbial entry, is both acidic and bathed with fatty acids toxic to many microbes. Successful skin pathogens such as staphylococci must tolerate these adverse conditions. Mucosal surfaces themselves present a barrier composed of a thick mucus layer that entraps microbes and facilitates their transport out of the body by such processes as mucociliary clearance, coughing, and urination. Mucous secretions, saliva, and tears contain antibacterial factors such as lysozyme and antiviral factors such as interferons. Gastric acidity is inimical to the survival of many ingested pathogens, and many mucosal surfaces -- particularly the nasopharynx, the vaginal tract, and the gastrointestinal tract -- contain a resident flora of commensal microbes that interfere

with the ability of pathogens to colonize and infect a host.

Pathogens that survive these factors must still contend with host endocytic, phagocytic, and inflammatory responses as well as with host genetic factors that determine the degree to which a pathogen can survive and grow. The growth of viral pathogens entering skin or mucosal epithelial cells can be limited by a variety of host genetic factors, including production of interferons, modulation of receptors for viral entry, and age- and hormone-related susceptibility factors; by nutritional status; and even by personal habits such as smoking and exercise.

ENCOUNTERS WITH EPITHELIAL CELLS

Over the past decade, many bacterial pathogens have been shown to enter epithelial cells (Fig. 120-1), often using specialized surface structures that bind to receptors for internalization. However, the exact role and the importance of this process in infection and disease are not well defined for most of these pathogens. Bacterial entry into host epithelial cells is seen as a means for dissemination to adjacent or deeper tissues or as a route to sanctuary to avoid ingestion and killing by professional phagocytes. Epithelial cell entry appears, for instance, to be a critical aspect of dysentery induction by *Shigella*.

Curiously, the less virulent strains of many bacterial pathogens are more adept at entering epithelial cells than are more virulent strains; examples include pathogens that lack the surface polysaccharide capsule needed to cause serious disease. Thus, for *Haemophilus influenzae*, *Streptococcus pneumoniae*, *S. agalactiae* (group B *Streptococcus*), and *S. pyogenes*, isogenic mutants or variants lacking capsules enter epithelial cells better than the wild-type, encapsulated parental forms that cause disseminated disease. These observations have led to the proposal that epithelial cell entry may be a manifestation of host defense, resulting in bacterial clearance by both shedding of epithelial cells containing internalized bacteria and initiation of a subclinical inflammatory response. However, a consequence of this process would be the opening of a hole in the epithelium, potentially allowing uningested organisms to enter the submucosa. This scenario has been documented in murine *Salmonella typhimurium* infections and in experimental bladder infections with uropathogenic *E. coli*. In the latter system, bacterial pili mediate cell attachment to integral membrane glycoproteins called uroplakins that coat the host cells, resulting in exfoliation of the cells with attached bacteria. Subsequently, infection is produced by residual bacterial cells that invade the denuded epithelium. Perhaps at low bacterial inocula epithelial cell ingestion and subclinical inflammation are efficient means to eliminate pathogens, while at higher inocula a proportion of surviving bacterial cells enter the host tissue through the damaged mucosal surface and multiply, producing disease. Alternatively, failure of the appropriate epithelial cell response to a pathogen may allow the organism to survive on a mucosal surface where, if it avoids other host defenses, it can grow and cause a local infection. Along these lines, as noted above, *P. aeruginosa* is taken into epithelial cells byCFTR, a protein missing or nonfunctional in most severe cases of cystic fibrosis. The major clinical consequence of this disease is chronic airway-surface infection with *P. aeruginosa* in 80 to 90% of patients with cystic fibrosis. The failure of airway epithelial cells to ingest and promote the removal of *P. aeruginosa* has been proposed as a key component of the hypersusceptibility of these patients to chronic airway infection.

ENCOUNTERS WITH PHAGOCYTES

Phagocytosis of microbes is a major innate host defense that limits the growth and spread of pathogens. Phagocytes appear rapidly at sites of infection in conjunction with the initiation of inflammation. Ingestion of microbes by both tissue-fixed macrophages and migrating phagocytes probably accounts for the limited ability of most microbial agents to cause disease. A family of related molecules called *collectins*, *soluble defense collagens*, or *pattern recognition molecules* are found in blood (mannose-binding lectin), in lung (surfactant proteins A and D), and most likely in other tissues as well and bind to carbohydrates on microbial surfaces to promote phagocyte clearance. Bacterial pathogens seem to be ingested principally by polymorphonuclear neutrophils (PMNs), while eosinophils are frequently found at sites of infection by protozoan or multicellular parasites. Successful pathogens, by definition, must avoid being cleared by professional phagocytes. One of several antiphagocytic strategies employed by bacteria and by the fungal pathogen *Cryptococcus neoformans* is to elaborate large-molecular-weight surface polysaccharide antigens, often in the form of a capsule that coats the cell surface. Most pathogenic bacteria produce such antiphagocytic capsules.

As activation of local phagocytes in tissues is a key step in initiating inflammation and migration of additional phagocytes into infected sites, much attention has been paid to microbial factors that initiate inflammation. Encounters with phagocytes are governed largely by the structure of the microbial constituents that elicit inflammation, and detailed knowledge of these structures for bacterial pathogens has contributed greatly to our understanding of molecular mechanisms of microbial pathogenesis (Fig. 120-2). The best-studied system involves the interaction ofLPS from gram-negative bacteria and the glycosylphosphatidylinositol (GPI)-anchored membrane protein CD14 found on the surface of professional phagocytes, including migrating and tissue-fixed macrophages andPMNs. A soluble form of CD14 is also found in plasma and on mucosal surfaces. A plasma protein, LPS-binding protein (LBP), transfers LPS to membrane-bound CD14 on myeloid cells and promotes binding of LPS to soluble CD14. Soluble CD14/LPS/LBP complexes bind to many cell types and may be internalized to initiate cellular responses to microbial pathogens. It has been shown that peptidoglycan and lipoteichoic acid from gram-positive bacteria and cell-surface products of mycobacteria and spirochetes can interact with CD14 (Fig. 120-2).

GPI-anchored receptors do not have intracellular signaling domains, and mammalian Toll-like receptors (TLRs) transduce signals for cellular activation due toLPSbinding. TLRs initiate cellular activation through a series of signal-transducing molecules (Fig. 120-2) that lead to nuclear translocation of the transcription factor NF-kB, a master-switch for production of important inflammatory cytokines such as tumor necrosis factora (TNF-a) and interleukin (IL) 1.

The initiation of inflammation can occur not only with LPS and peptidoglycan but also with viral particles and other microbial products such as polysaccharides, enzymes, and toxins.

Bacterial Cell Wall Structure Gram-positive bacteria have a rigid cell wall that gives the organisms their characteristic shape, differentiates them from eukaryotic cells, and allows them to survive in osmotically unfavorable environments. The cell wall is

composed mainly of peptidoglycan (Fig. 120-3, panel *C*; a polymer of *N*-acetylglucosamine and its lactyl ether, *N*-acetylmuramic acid), with peptide side chains covalently bound to the lactyl group (Fig. 120-3, panel *A*). The peptide chains consist of alternating D and L amino acids and are usually linked to each other by a pentaglycine bridge binding a terminal D-alanine on one peptide substituent to the penultimate L-lysine on a neighboring peptide. Variations in this basic structure have been described for a number of bacterial genera. In addition, the cell walls of gram-positive bacteria contain teichoic acids (Fig. 120-3, panel *D*), phosphate-linked polymers of ribitol or glycerol that can have additional compounds linked to available side groups. Lipid tails anchor these acids to the cytoplasmic membrane, giving rise to lipoteichoic acids.

Gram-negative bacteria possess a cytoplasmic membrane and a peptidoglycan layer similar to but reduced from that found in gram-positive organisms, but these organisms also produce an outer membrane that is covalently linked to the tetrapeptides of the peptidoglycan layer by a lipoprotein (Fig. 120-3, panel *B*). Embedded in the outer membrane are special proteins with important functions, including maintaining the outer membrane's integrity, acting as a selective barrier for diffusion of molecules into the cell, serving as receptors for bacteriophages, and binding siderophores that scavenge iron for transport into the bacterial cell. The exterior layer of the outer membrane contains the major surface glycolipid, which can be either a classical bacterialLPS or a lipooligosaccharide (LOS); pathogens such as *Neisseria* and *Haemophilus* spp. express LOS, which contains smaller polysaccharide constituents. Although LPS/LOS was thought to be essential to the viability of gram-negative bacteria, a viable strain of *N. meningitidis* lacking LOS has now been made.

Exterior to theLPS for many, but not all, gram-negative pathogens is a capsular polysaccharide, which (along with LPS for some pathogenic species) confers resistance to phagocytosis by preventing innate host opsonins, such as the complement proteins C3 and C4, from coating the organisms -- a process that promotes their uptake by phagocytes. Capsular polysaccharides are also important extracellular components of gram-positive bacteria, serving as critical factors in bacterial resistance to opsonophagocytosis and phagocytic killing. Variation in the expression of the capsule in *S. pneumoniae* accounts for the different morphologies of colonies of this pathogen on agar plates (smooth and rough phenotypes); this property was exploited in studies proving that DNA carries genetic information in a cell.

Lipopolysaccharide Most of the important biologic properties associated withLPS(endotoxin) are due to the lipid A portion (Fig. 120-3, panel *E*), a relatively conserved, highly acylated di-*N*-acetylglucosamine backbone linkedb 1®6 and containing phosphate groups on the reducing 1 and nonreducing 4¢ carbons. Attached to carbon 6¢ is the inner polysaccharide core, which is usually, but not always, composed of a di- or trisaccharide of 2-keto-3-deoxyoctonate (KDO). Additional sugar substituents are linked to the inner core, forming a complete core. Attached to the complete core are either short polysaccharide side chains (formingLOS) or longer O polysaccharide side chains (forming complete LPS) composed of a variety of monosaccharides, substituted with a variety of components, such as formyl, acetyl, and hydroxy-butyryl side chains; amino acids or peptides; and phosphate groups. Further biologic functions of LOS/LPS that are important to the survival of microbes after entry

into a host include resistance to the bacteriolytic effects of complement and protection against antimicrobial factors such as defensins and bactericidal permeability-increasing protein, a molecule closely related toLBP in structure and function. Defensins are found in high concentrations in granules of myeloid cells, including platelets, and are usually highly cationic peptides capable of insertion into bacterial cells and killing of these cells.

Additional Interactions of Microbial Pathogens and Phagocytes Other ways that microbial pathogens avoid destruction by phagocytes include production of factors that are toxic to the phagocytes or that interfere with the chemotactic and ingestion function of phagocytes. Hemolysins, leukocidins, and the like are microbial proteins that can kill phagocytes that are attempting to ingest organisms elaborating these substances. For example, staphylococcal hemolysins inhibit macrophage chemotaxis and kill these phagocytes. Streptolysin O made by *S. pyogenes* binds to cholesterol in phagocyte membranes and initiates a process of internal degranulation, with the release of normally granule-sequestered toxic components into the phagocyte's cytoplasm. *Entamoeba histolytica*, an intestinal protozoan that causes amebic dysentery, can disrupt phagocyte membranes after direct contact via the release of protozoal phospholipase A and pore-forming peptides.

Microbial Survival Inside Phagocytes Many important microbial pathogens use a variety of strategies to survive inside phagocytes (particularly macrophages) after ingestion. Inhibition of fusion of the phagocytic vacuole (the phagosome) containing the ingested microbe with the lysosomal granules containing antimicrobial substances (the lysosome) allows *M. tuberculosis*, *S. typhi*, and *Toxoplasma gondii* to survive inside macrophages. Some organisms, such as *Listeria monocytogenes*, escape into the phagocyte's cytoplasm to grow and eventually spread to other cells. Resistance to killing within the macrophage and subsequent growth are critical to successful infection by herpes-type viruses, measles virus, poxviruses, *Salmonella*, *Yersinia*, *Legionella*, *Mycobacterium*, *Trypanosoma*, *Nocardia*, *Histoplasma*, *Toxoplasma*, and *Rickettsia*. *Salmonella* spp. use a master regulatory system, in which the *PhoP/PhoQ* genes control other genes, to enter and survive within cells, with intracellular survival entailing structural changes in the cell envelopeLPS.

TISSUE INVASION AND TISSUE TROPISM

TISSUE INVASION

Most viral pathogens cause disease by growth at skin or mucosal entry sites, but some pathogens spread from the initial site to deeper tissues. Virus can spread via the nerves (rabies virus) or plasma (picornaviruses) or within migratory blood cells (poliovirus, Epstein-Barr virus, and many others). Specific viral genes determine where and how individual viral strains can spread.

Bacteria may invade deeper layers of mucosal tissue via intracellular uptake by epithelial cells, traversal of epithelial cell junctions, or penetration through denuded epithelial surfaces. Among virulent *Shigella* strains and invasive *E. coli*, outer-membrane proteins are critical to epithelial cell invasion and bacterial multiplication. *Neisseria* and *Haemophilus* spp. penetrate mucosal cells by poorly understood mechanisms before dissemination into the bloodstream. Staphylococci and

streptococci elaborate a variety of extracellular enzymes, such as hyaluronidase, lipases, nucleases, and hemolysins, that are probably important in breaking down cellular and matrix structures and allowing the bacteria access to deeper tissues and blood. Organisms that colonize the gastrointestinal tract can often translocate through the mucosa into the blood and, under circumstances in which host defenses are inadequate, cause bacteremia. *Yersinia enterocolitica* can invade the mucosa through the activity of the invasin protein. Some bacteria (e.g., *Brucella*) can be carried from a mucosal site to a distant site by phagocytic cells (e.g.,PMNs) that ingest but fail to kill the bacteria.

Fungal pathogens almost always take advantage of host immunocompromise to spread hematogenously to deeper tissues. The AIDS epidemic has resoundingly illustrated this principle: the immunodeficiency of many HIV-infected patients permits the development of life-threatening fungal infections of the lung, blood, and brain. Other than the capsule of *C. neoformans*, specific fungal antigens involved in tissue invasion are not well characterized. Both fungal pathogens and protozoal pathogens (e.g., *Plasmodium* spp. and *E. histolytica*) undergo morphologic changes to spread within a host. Malarial parasites grow in liver cells as merozoites and are released into the blood to invade erythrocytes and become trophozoites. *E. histolytica* is found as both a cyst and a trophozoite in the intestinal lumen, through which this pathogen enters the host, but only the trophozoite form can spread systemically to cause amebic liver abscesses. Other protozoal pathogens, such as *T. gondii*, *Giardia lamblia*, and *Cryptosporidium*, also undergo extensive morphologic changes after initial infection to spread to other tissues.

TISSUE TROPISM

The propensity of certain microbes to cause disease by infecting specific tissues has been known since the early days of bacteriology, yet the molecular basis for this propensity is understood somewhat better for viral pathogens than for other agents of infectious disease. Specific receptor-ligand interactions clearly underlie the ability of certain viruses to enter cells within tissues and disrupt normal tissue function, but the mere presence of a receptor for a virus on a target tissue is not sufficient for tissue tropism. Factors in the cell, route of viral entry, viral capacity to penetrate into cells, viral genetic elements that regulate gene expression, and pathways of viral spread in a tissue all affect tissue tropism. Some viral genes are best transcribed in specific target cells, such as hepatitis B genes in liver cells and Epstein-Barr virus genes in B lymphocytes. The route of inoculation of poliovirus determines its neurotropism, although the molecular basis for this circumstance is not understood.

The lesser understanding of the tissue tropism of bacterial and parasitic infections is exemplified by *Neisseria* spp. There is no well-accepted explanation of why *N. gonorrhoeae* colonizes and infects the human genital tract while the closely related species *N. meningitidis* principally colonizes the human oropharynx. *N. meningitidis* expresses a capsular polysaccharide, while *N. gonorrhoeae* does not; however, there is no indication that this property plays a role in the different tissue tropisms displayed by these two bacterial species. *N. gonorrhoeae* can use cytidine monophosphate *N*-acetylneuraminic acid from host tissues to add *N*-acetylneuraminic acid (sialic acid) to itsLOS O side chain, and this alteration appears to make the organism resistant to host defenses. Lactate, present at high levels on genital mucosal surfaces, stimulates

sialylation of gonococcal LOS. Bacteria with sialic acid sugars in their capsules, such as *N. meningitidis*, *E. coli* K-1, and group B streptococci, have a propensity to cause meningitis, but this generalization has many exceptions. For example, all recognized serotypes of group B streptococci contain sialic acid in their capsules, but only one serotype (III) is responsible for most cases of group B streptococcal meningitis. Moreover, both *H. influenzae* and *S. pneumoniae* can readily cause meningitis, but these organisms do not have sialic acid in their capsules.

TISSUE DAMAGE AND DISEASE

Disease is a complex phenomenon resulting from tissue invasion and destruction, toxin elaboration, and host response. Viruses cause much of their damage by exerting a cytopathic effect on host cells and inhibiting host defenses. The growth of bacterial, fungal, and protozoal parasites in tissue, which may or may not be accompanied by toxin elaboration, can also compromise tissue function and lead to disease. For some bacterial and possibly some fungal pathogens, toxin production is one of the best-characterized molecular mechanisms of pathogenesis, while host factors such as IL-1,TNF-a, kinins, inflammatory proteins, products of complement activation, and mediators derived from arachidonic acid metabolites (leukotrienes) and cellular degranulation (histamines) readily contribute to the severity of disease.

VIRAL DISEASE

Viral pathogens are well known to inhibit host immune responses by a variety of mechanisms. Immune responses can be affected by down-regulating production of most major histocompatibility complex (MHC) molecules (adenovirus E3 protein), by diminishing cytotoxic T cell recognition of virus-infected cells (Epstein-Barr virus EBNA1 antigen and cytomegalovirus IE protein), by producing virus-encoded complement receptor proteins (herpesvirus and vaccinia virus) that protect infected cells from complement-mediated lysis, by making proteins that interfere with the action of interferon (influenza virus and poxvirus), and by elaborating superantigen-like proteins (mouse mammary tumor virus and related retroviruses, rabies nucleocapsid, and possibly the Nef protein of HIV). Superantigens activate large populations of T cells that express particular subsets of the T cell receptorb protein, causing massive cytokine release and subsequent host reactions. Another molecular mechanism of viral virulence involves the production of peptide growth factors for host cells, which disrupt normal cellular growth, proliferation, and differentiation. In addition, viral factors can bind to and interfere with the function of host receptors for signaling molecules. Modulation of cytokine production during viral infection can stimulate viral growth inside cells with receptors for the cytokine, and virus-encoded cytokine homologues (e.g., the Epstein-Barr virus BCRF1 protein, which is highly homologous to the immunoinhibitoryIL-10 molecule) can potentially prevent immune-mediated clearance of viral particles. Viruses can cause disease in neural cells by interfering with levels of neurotransmitters without necessarily destroying the cells, or they may induce either programmed cell death (apoptosis) to destroy tissues or inhibitors of apoptosis to allow for prolonged viral infection of cells. Overall, any disruption of normal cellular and tissue function due to viral infection can underlie the resultant clinical disease.

BACTERIAL TOXINS

Among the first infectious diseases to be understood were those due to toxin-elaborating bacteria. Diphtheria, botulism, and tetanus toxins are responsible for the diseases associated with local infections due to *Corynebacterium diphtheriae*, *Clostridium botulinum*, and *Clostridium tetani*, respectively. Enterotoxins produced by *E. coli*, *Salmonella*, *Shigella*, *Staphylococcus*, and *V. cholerae* contribute to diarrheal disease caused by these organisms. Staphylococci, streptococci, *P. aeruginosa*, and *Bordetella* elaborate various toxins that cause or contribute to disease, including toxic shock syndrome toxin 1 (TSST-1); erythrogenic toxin; exotoxins A, S, and U; and pertussis toxin. A number of these toxins (e.g., cholera toxin, diphtheria toxin, pertussis toxin, *E. coli* heat-labile toxin, and *P. aeruginosa* exotoxin) have adenosine diphosphate (ADP)-ribosyltransferase activity; i.e., the toxins enzymatically catalyze the transfer of the ADP-ribosyl portion of nicotinamide adenine diphosphate to target proteins and inactivate them. The staphylococcal enterotoxins, TSST-1, and the streptococcal pyogenic exotoxins behave as superantigens, stimulating certain T cells to proliferate without processing of the protein toxin by antigen-presenting cells. Part of this process involves stimulation of the antigen-presenting cells to produceIL-1 andTNF-a, which have been implicated in many of the clinical features of diseases like toxic shock syndrome and scarlet fever. A number of gram-negative pathogens (*Salmonella*, *Yersinia*, and *P. aeruginosa*) possess the ability to inject toxins directly into host target cells by means of a complex set of proteins referred to as the type III secretion system.

ENDOTOXIN

The lipid A portion of gram-negativeLPS has potent biologic activities that cause many of the clinical manifestations of gram-negative bacterial sepsis, including fever, muscle proteolysis, uncontrolled intravascular coagulation, and shock. The effects of lipid A appear to be mediated by the production of potent cytokines due to LPS binding to CD14 and signal transduction viaTLRs, particularly TLR4. Cytokines exhibit potent hypothermic activity through effects on the hypothalamus; they also increase vascular permeability, alter the activity of endothelial cells, and induce endothelial-cell procoagulant activity. Numerous therapeutic strategies aimed at neutralizing the effects of endotoxin are under investigation, but so far the results have been disappointing.

INVASION

Many diseases are caused primarily by pathogens growing in tissue sites that are normally sterile. Pneumococcal pneumonia is mostly attributable to the growth of *S. pneumoniae* in the lung and the attendant host inflammatory response, although specific factors that enhance this process (e.g., pneumolysin) may be responsible for some of the pathogenic potential of the pneumococcus. Disease that follows bacteremia and invasion of the meninges by meningitis-producing bacteria such as *N. meningitidis*, *H. influenzae*, *E. coli* K1, and group B streptococci appears to be due solely to the ability of these organisms to gain access to these tissues, multiply in them, and provoke cytokine production leading to tissue-damaging host inflammation.

Specific molecular mechanisms accounting for tissue invasion by fungal and protozoal pathogens are less well described. Except for studies pointing to factors like capsule and melanin production by *C. neoformans* and possibly levels of cell wall glucans in

some pathogenic fungi, the molecular basis for fungal invasiveness is not well defined. Melanism has been shown to protect the fungal cell against death caused by phagocyte factors such as nitric oxide, superoxide, and hypochlorite. Morphogenic variation and production of proteases (e.g., the *Candida* aspartyl proteinase) have been implicated in fungal invasion of host tissues.

If pathogens are effectively to invade host tissues (particularly the blood), they must avoid the major host defenses represented by complement and phagocytic cells. Bacteria most often avoid these defenses through their cell surface polysaccharides -- either capsular polysaccharides or long O-side-chain antigens characteristic of the smoothLPS of gram-negative bacteria. These molecules can prevent the activation and/or deposition of complement opsonins or limit the access of phagocytic cells with receptors for complement opsonins to these molecules when they are deposited on the bacterial surface below the capsular layer. Another potential mechanism of microbial virulence is the ability of some organisms to present the capsule as an apparent self antigen through molecular mimicry. For example, the polysialic acid capsule of group B *N. meningitidis* is chemically identical to an oligosaccharide found on human brain cells.

Immunochemical studies of capsular polysaccharides have led to an appreciation of the tremendous chemical diversity that can result from the linking of a few monosaccharides. For example, three hexoses can link up in more than 300 different, potentially serologically distinct ways, while three amino acids have only six possible peptide combinations. Capsular polysaccharides have been used as effective vaccines against meningococcal meningitis as well as against pneumococcal and *H. influenzae* infections and may prove to be of value as vaccines against any organisms that express a nontoxic, immunogenic capsular polysaccharide. In addition, most encapsulated pathogens become virtually avirulent when capsule production is interrupted by genetic manipulation; this observation emphasizes the importance of this structure in pathogenesis.

HOST RESPONSE

The inflammatory response of the host is critical for interruption and resolution of the infectious process but also is often responsible for the signs and symptoms of disease. Infection promotes a complex series of host responses involving the complement, kinin, and coagulation pathways. The production of cytokines such asIL-1,TNF-a, and other factors regulated in part by the NF-kB transcription factor leads to fever, muscle proteolysis, and other effects, as noted above. An inability to kill or contain the microbe usually results in further damage due to the progression of inflammation and infection. For example, in many chronic infections, degranulation of host inflammatory cells can lead to release of host proteases, elastases, histamines, and other toxic substances that can degrade host tissues. Chronic inflammation in any tissue can lead to the destruction of that tissue and to clinical disease associated with loss of organ function, such as sterility from pelvic inflammatory disease caused by chronic infection with *N. gonorrhoeae*.

The nature of the host response elicited by the pathogen often determines the pathology of a particular infection. Local inflammation produces local tissue damage, while systemic inflammation, such as that seen during sepsis, can result in the signs and

symptoms of septic shock. The severity of septic shock is associated with the degree of production of host effectors. Disease due to intracellular parasitism results from the formation of granulomas, wherein the host attempts to wall off the parasite inside a fibrotic lesion surrounded by fused epithelial cells that make up so-called multinucleated giant cells. A number of pathogens, particularly anaerobic bacteria, staphylococci, and streptococci, provoke the formation of an abscess, probably because of the presence of zwitterionic surface polysaccharides such as the capsular polysaccharide of *Bacteroides fragilis*. The outcome of an infection depends on the balance between an effective host response that eliminates a pathogen and an excessive inflammatory response that is associated with an inability to eliminate a pathogen and with the resultant tissue damage that leads to disease.

TRANSMISSION TO NEW HOSTS

As part of the pathogenic process, most microbes are shed from the host, often in a form infectious for susceptible individuals. However, the rate of transmissibility may not necessarily be high, even if the disease is severe in the infected individual, as these traits are not linked. Most pathogens exit via the same route by which they entered: respiratory pathogens by aerosols from sneezing or coughing or through salivary spread, gastrointestinal pathogens by fecal-oral spread, sexually transmitted diseases by venereal spread, and vector-borne organisms by either direct contact with the vector through a blood meal or indirect contact with organisms shed into environmental sources such as water. Microbial factors that specifically promote transmission are not well characterized. Respiratory shedding is facilitated by overproduction of mucous secretions, with consequently enhanced sneezing and coughing. Diarrheal toxins such as cholera toxin, *E. coli* heat-labile toxins, and *Shigella* toxins probably facilitate fecal-oral spread of microbial cells in the high volumes of diarrheal fluid produced during infection. The ability to produce phenotypic variants that resist hostile environmental factors (e.g., the highly resistant cysts of *E. histolytica* shed in feces) represents another mechanism of pathogenesis relevant to transmission. Blood parasites such as *Plasmodium* spp. change phenotype after ingestion by a mosquito -- a prerequisite for the continued transmission of this pathogen. Venereally transmitted pathogens may undergo phenotypic variation due to the production of specific factors to facilitate transmission, but shedding of these pathogens into the environment does not result in the formation of infectious foci.

In summary, the molecular mechanisms used by pathogens to colonize, invade, infect, and disrupt the host are numerous and diverse. Each phase of the infectious process involves a variety of microbial and host factors interacting in a manner that can result in disease. Recognition of the coordinated genetic regulation of virulence factor elaboration when organisms move from their natural environment into the mammalian host emphasizes the complex nature of the host-parasite interaction. Fortunately, the need for diverse factors in successful infection and disease implies that a variety of therapeutic strategies may be developed to interrupt this process and thereby prevent and treat microbial infections.

121. LABORATORY DIAGNOSIS OF INFECTIOUS DISEASES - *Andrew B. Onderdonk*

The laboratory diagnosis of infection requires the demonstration, either direct or indirect, of viral, bacterial, fungal, or parasitic agents in tissues, fluids, or excreta of the host. Clinical microbiology laboratories are responsible for processing these specimens and also for determining the antibiotic susceptibility of bacterial pathogens. Traditionally, detection of pathogenic agents has relied largely on either the microscopic visualization of pathogens in clinical material or the growth of microorganisms in the laboratory. Identification is generally based on phenotypic characteristics, such as fermentation profiles for bacteria, cytopathic effects in tissue culture for viral agents, and microscopic morphology for fungi and parasites. These techniques are reliable but are often time-consuming. Increasingly, the use of nucleic acid probes is becoming a standard detection and/or identification method in the clinical microbiology laboratory, gradually replacing phenotypic characterization and microscopic visualization methods.

DETECTION METHODS

Reappraisal of the methods employed in the clinical microbiology laboratory has led to the development of strategies for detection of pathogenic agents through nonvisual biologic signal detection systems. Much of this methodology is based on either computerization of detection systems with relatively inexpensive but sophisticated computers or the use of nucleic acid probes directed at specific DNA or RNA targets. This chapter discusses both the methods that are currently available and those that are being developed.

BIOLOGIC SIGNALS

A *biologic signal* is a material that can be reproducibly differentiated from other substances present in the same physical environment. Key issues in the use of a biologic (or electronic) signal are distinguishing it from background noise and translating it into meaningful information. Examples of biologic signals applicable to clinical microbiology include structural components of bacteria, fungi, and viruses; specific antigens; metabolic end products; unique DNA or RNA base sequences; enzymes; toxins or other proteins; and surface polysaccharides.

DETECTION SYSTEMS

A detector is used to sense a signal and to discriminate between the signal and background noise. Detection systems range from the trained eyes of a technologist assessing morphologic variations to sensitive electronic instruments, such as gas-liquid chromatographs coupled to computer systems for signal analysis. The sensitivity with which signals can be detected varies widely. It is essential to use a detection system that discerns small amounts of signal even when biologic background noise is present -- i.e., that is both sensitive and specific. Common detection systems include immunofluorescence; chemiluminescence for DNA/RNA probes; flame ionization detection of short- or long-chain fatty acids; and detection of substrate utilization or end-product formation as color changes, of enzyme activity as a change in light absorbance, of turbidity changes, of cytopathic effects in cell lines, and of particle

agglutination.

AMPLIFICATION

Amplification enhances the sensitivity with which weak signals can be detected. The most common microbiologic amplification technique is growth of a single bacterium into a discrete colony on an agar plate or into a suspension containing many identical organisms. The advantage of growth as an amplification method is that it requires only an appropriate growth medium; the disadvantage is the amount of time required for amplification. More rapid specific amplification of biologic signals can be achieved with techniques such as polymerase (ligase) chain reactions (PCRs, for DNA/RNA), enzyme immunoassays (EIAs, for antigens and antibodies), electronic amplification (for gas-liquid chromatography assays), antibody capture methods (for concentration and/or separation), and selective filtration or centrifugation. Although a variety of methods are available for the amplification and detection of biologic signals in research, thorough testing is required before they are validated as diagnostic assays.

DIRECT DETECTION

MICROSCOPY

The field of microbiology has been defined largely by the development and use of the microscope. The examination of specimens by microscopic methods rapidly provides useful diagnostic information. Staining techniques permit organisms to be seen more clearly.

The simplest method for microscopic evaluation is the wet mount, which is used, for example, to examine cerebrospinal fluid (CSF) for the presence of *Cryptococcus neoformans*, with India ink as a background against which to visualize large-capsuled yeast cells. Wet mounts with dark-field illumination are also used to detect spirochetes from genital lesions and to reveal *Borrelia* or *Leptospira* in blood. Skin scrapings and hair samples can be examined with use of either 10% KOH wet-mount preparations or the calcofluor white method and ultraviolet illumination to detect fungal elements as fluorescing structures. Staining of wet mounts -- for example, with lactophenol cotton blue stain for fungal elements -- is often used for morphologic identification. These techniques enhance signal detection and decrease the background, making it easier to identify specific fungal structures.

STAINING

Gram's Stain Without staining, bacteria are difficult to see at the magnifications (400 to 1000´) used for their detection. Although simple one-step stains can be used, differential stains are more common. Gram's stain differentiates between organisms with thick peptidoglycan cell walls (gram-positive) and those with outer membranes that can be dissolved with alcohol or acetone (gram-negative).

Gram's stain is particularly useful for examining sputum for polymorphonuclear leukocytes (PMNs) and bacteria. Sputum specimens with 25 or more PMNs and fewer than 10 epithelial cells per low-power field often provide clinically useful information.

However, the presence in "sputum" samples of more than 10 epithelial cells per low-power field and of multiple bacterial types suggests contamination with oral microflora. Despite the difficulty of discriminating between normal microflora and pathogens, Gram's stain may prove useful for specimens from areas with a large resident microflora if a useful biologic marker (signal) is available. Gram's staining of vaginal swab specimens can be used to detect epithelial cells covered with gram-positive bacteria in the absence of lactobacilli and the presence of gram-negative rods -- a scenario regarded as a sign of bacterial vaginosis. Similarly, examination of stained stool specimens for leukocytes is useful as a screening procedure before testing for *Clostridium difficile* toxin or other enteric pathogens.

The examination ofCSF and joint, pleural, or peritoneal fluid with Gram's stain is useful for determining whether bacteria and/orPMNs are present. The sensitivity is such that>10_4bacteria per milliliter should be detected. Centrifugation is often performed before staining to concentrate specimens thought to contain low numbers of organisms. The pellet is examined after staining. This simple method is particularly useful for examination of CSF for bacteria and white blood cells or of sputum for acid-fast bacilli (AFB).

Acid-Fast Stain The acid-fast stain identifies organisms that retain carbol fuchsin dye after acid/organic solvent disruption (e.g., *Mycobacterium* spp.). Modifications of this procedure allow the differentiation of *Actinomyces* from *Nocardia* or other weakly acid-fast organisms. The acid-fast stain is applied to sputum, other fluids, and tissue samples whenAFB(e.g., *Mycobacterium* spp.) are suspected. The identification of the pink/red AFB against the blue background of the counterstain requires a trained eye, since few AFB may be detected in an entire smear, even when the specimen has been concentrated by centrifugation. An alternative method is the auramine-rhodamine combination fluorescent dye technique.

Fluorochrome Stains Fluorochrome stains, such as acridine orange, are used to identify white blood cells, yeasts, and bacteria in body fluids. Other specialized stains, such as Dappe's stain, may be used for the detection of *Mycoplasma* in cell cultures. Capsular, flagellar, and spore stains are used for identification or demonstration of characteristic structures.

Immunofluorescent Stains The direct immunofluorescent antibody technique uses antibody coupled to a fluorescing compound, such as fluorescein, and directed at a specific antigenic target to visualize organisms or subcellular structures. When samples are examined under appropriate conditions, the fluorescing compound absorbs ultraviolet light and reemits light at a higher (visible) wavelength detectable by the human eye. In the indirect immunofluorescent antibody technique, an unlabeled (target) antibody binds a specific antigen. The specimen is then stained with fluorescein-labeled polyclonal antibody directed at the target antibody. Because each unlabeled target antibody attached to the appropriate antigen has multiple sites for attachment of the second antibody, the visual signal can be intensified (i.e., amplified). This form of staining is called *indirect* because a two-antibody system is used to generate the signal for detection of the antigen. Both direct and indirect methods detect viral inclusions (e.g., cytomegalovirus and herpes simplex virus) within cultured cells as well as many difficult-to-grow bacterial agents (e.g., *Legionella pneumophila*) directly in clinical

specimens.

MACROSCOPIC ANTIGEN DETECTION

Latex agglutination assays andEIAs are rapid and inexpensive methods for identifying organisms, extracellular toxins, and viral agents by means of protein and polysaccharide antigens. Such assays may be performed directly on clinical samples or after growth of organisms on agar plates or in viral cell cultures. The biologic signal in each case is the antigen to be detected. Monoclonal or polyclonal antibodies coupled to a reporter (such as latex particles or an enzyme) are used for detection of antibody-antigen binding reactions.

Techniques such as direct agglutination of bacterial cells with specific antibody are simple but relatively insensitive, while latex agglutination andEIAs are more sensitive. Some cell-associated antigens, such as capsular polysaccharides and lipopolysaccharides, can be detected by agglutination of a suspension of bacterial cells when antibody is added; this method is useful for typing of the somatic antigens of *Shigella* and *Salmonella*. In systems such as EIAs, which employ antibodies coupled to an enzyme, an antigen-antibody reaction results in the conversion of a colorless substrate to a colored product. Because the coupling of an enzyme to the antibody can amplify a weak biologic signal, the sensitivity of such assays is often high. In each instance, the basis for antigen detection is antigen-antibody binding, with the detection system changed to accommodate the biologic signal. Most such assays provide information as to whether antigen is present but do not quantify the antigen. EIAs are also useful for detecting bacterial toxins -- e.g., *C. difficile* toxins A and B in stool.

DETECTION OF PATHOGENIC AGENTS BY CULTURE

SPECIMEN COLLECTION AND TRANSPORT

To culture bacterial, mycotic, or viral pathogens, an appropriate sample must be placed into the proper medium for growth (amplification). The success of efforts to identify a specific pathogen often depends on the collection and transport process coupled to a laboratory-processing algorithm suitable for the specific sample/agent. In some instances, it is better for specimens to be plated at the time of collection rather than first being transported to the laboratory (e.g., urethral swabs being cultured for *Neisseria gonorrhoeae* or sputum specimens for pneumococci). In general, the more rapidly a specimen is plated onto appropriate media, the better the chance for isolating bacterial pathogens. Appendix B lists procedures for collection and transport of common specimens. Because there are many pathogen-specific paradigms for these procedures, it is important to seek advice from the microbiology laboratory when in doubt about a particular situation.

ISOLATION OF BACTERIAL PATHOGENS

Isolation of suspect pathogen(s) from clinical material relies on the use of artificial media that support bacterial growth in vitro. Such media are composed of agar, which is not metabolized by bacteria; nutrients to support the growth of the species of interest; and sometimes substances to inhibit the growth of other bacteria. Broth is employed for

growth (amplification) of organisms from specimens with few bacteria, such as peritoneal dialysis fluid,CSF, or samples in which anaerobes or other fastidious organisms may be present. The general use of liquid medium for all specimens is not worthwhile.

Two basic strategies are used to isolate pathogenic bacteria. The first is to employ enriched media that support the growth of any bacteria that may be present in a sample such as blood orCSF, which contain no bacteria under normal conditions. Broths that allow the growth of small numbers of organisms may be subcultured to solid media when growth is detected. The second strategy is to isolate (amplify) specific bacterial species from stool, genital tract secretions, or sputum -- sites that contain many bacteria under normal conditions. Antimicrobial agents or other inhibitory substances are incorporated into the agar medium to inhibit growth of all but the bacteria of interest. After incubation, organisms that grow on such media are further characterized to determine whether they are pathogens. Selection for organisms that may be pathogens from the normal microflora shortens the time required for diagnosis (Fig. 121-1).

ISOLATION OF VIRAL AGENTS (See also Chap. 180)

Pathogenic viral agents often are cultured when the presence of serum antibody is not a criterion for active infection or when an increase in serum antibody may not be detected during infection. The biologic signal -- virus -- is amplified to a detectable level. Although a number of techniques are available, an essential element is a monolayer of cultured mammalian cells sensitive to infection with the suspected virus. These cells serve as the amplification system by allowing the proliferation of viral particles. Virus may be detected by direct observation of the cultured cells for cytopathic effects or by immunofluorescent detection of viral antigens following incubation. Culture methods are particularly useful for detection of rapidly propagated agents, such as cytomegalovirus or herpes simplex virus.

AUTOMATION OF MICROBIAL DETECTION IN BLOOD

The detection of microbial pathogens in blood is difficult because the number of organisms present in the sample is often low and the organisms' integrity and ability to replicate may be damaged by humoral defense mechanisms or antimicrobial agents. Over the years, systems that rely on the detection of CO_2produced by bacteria and yeasts in blood culture medium have allowed the automation of the detection procedure. The most common systems involve either the insertion of a sampling device into each culture bottle at periodic intervals, with drawing off of the head-space gas for analysis by an infrared monitor, or the use of reflectance optics, with a light-emitting diode and photodiode employed to detect a color change in a CO_2-sensitive indicator built into the bottom of the culture bottle. These systems measure CO_2concentration as indicative of microbial growth. Sophisticated algorithms are used to evaluate the rate at which CO_2 is being produced and then to determine whether the rate of change is consistent with microbial growth. Such methods are no more sensitive than the human eye in detecting a positive culture; however, because the bottles in an automated system are monitored more frequently, a positive culture is often detected more rapidly than by manual techniques, and important information, including the result of Gram's stain and preliminary susceptibility assays, can be obtained sooner. One advantage of reflectance

optic systems is that the bottles are scanned continuously in a noninvasive monitoring procedure, and thus the likelihood of laboratory contamination is decreased.

Automated systems also have been applied to the detection of microbial growth from specimens other than blood, such as peritoneal and other normally sterile fluids. *Mycobacterium* spp. can be detected in certain automated systems if appropriate liquid media are used for culture.

DETECTION OF PATHOGENIC AGENTS BY SEROLOGIC METHODS

Measurement of serum antibody provides an indirect marker for past or current infection with a specific viral agent or other pathogens, including *Brucella*, *Legionella*, *Rickettsia*, and *Helicobacter pylori*. The biologic signal is usually either IgM or IgG antibody directed at surface-expressed antigen(s). The detection systems include those used for bacterial antigens (agglutination reactions, immunofluorescence, andEIA) and unique systems such as hemolysis inhibition and complement fixation. Serologic methods generally fall into two categories: those that determine protective antibody levels and those that measure changing antibody titers during infection. Determination of an antibody response as a measure of current immunity is important in the case of viral agents for which there are vaccines, such as rubella virus or varicella-zoster virus; assays for this purpose normally use one or two dilutions of serum for a qualitative determination of protective antibody levels. Quantitative serologic assays to detect increases in antibody titers most often employ paired serum samples obtained 10 to 14 days apart (i.e., acute- and convalescent-phase samples). Since the incubation period before symptoms are noted may be long enough for an antibody response to occur, the demonstration of acute-phase antibody alone is often insufficient to establish the diagnosis of active infection as opposed to past exposure. In such circumstances, IgM may be useful as a measure of an early, acute-phase antibody response. A fourfold increase in total antibody titer or in EIA activity between the acute- and convalescent-phase samples is also regarded as evidence for active infection.

For certain viral agents, such as Epstein-Barr virus, the antibodies produced may be directed at different antigens during different phases of the infection. For this reason, most laboratories test for antibody directed at both viral capsid antigens and antigens associated with recently infected host cells to determine the stage of infection.

IDENTIFICATION METHODS

Once bacteria are isolated, traditional methods of phenotypic characterization are often used to identify specific isolates. An organism's phenotypic characteristics include traits that are readily detectable after growth on agar media (colony size, color, hemolytic reactions, odor), use of specific substrates and carbon sources (such as carbohydrates), formation of specific end products during growth, and microscopic appearance. Broth tubes containing specific substrates are commonly employed for phenotypic characterization. While such methods have been used since the time of Pasteur, their simplicity and low cost continue to make them appealing today.

CLASSIC PHENOTYPING

Automated systems allow rapid phenotypic identification of bacterial pathogens. Most such systems are based on biotyping techniques, in which isolates are grown on multiple substrates and the reaction pattern is compared with known patterns for various bacterial species. This procedure is relatively fast, and commercially available systems include miniaturized fermentation, coding to simplify recording of results, and probability calculations for the most likely pathogens. If the biotyping approach is automated and the reading process is coupled to computer-based data analysis, rapidly growing organisms, such as Enterobacteriaceae, can be identified within hours of detection on agar plates.

Several systems use preformed enzymes for even speedier identification (within 2 to 3 h). Such systems do not rely on bacterial growth per se to determine whether a substrate has been used or not. They employ a heavy inoculum in which specific bacterial enzymes are present in sufficient quantity to convert substrate to product rapidly. In addition, some systems use fluorogenic substrate/end-product detection methods to increase sensitivity (through signal amplification).

GAS-LIQUID CHROMATOGRAPHY

Gas-liquid chromatography is often used to detect metabolic end products of bacterial fermentations. One common application is identification of short-chain fatty acids produced by obligate anaerobes during glucose fermentation. Because the types and relative concentrations of volatile acids differ among the various genera and species that make up this group of organisms, such information serves as a metabolic "fingerprint" for a particular isolate.

Gas-liquid chromatography can be coupled to a sophisticated signal-analysis software system for identification and quantitation of long-chain fatty acids (LCFAs) in the outer membranes and cell walls of bacteria and fungi. For any given species, the types and relative concentrations of LCFAs are distinctive enough to allow identification of even closely related species. An organism may be identified definitively within a few hours after detection of growth on appropriate media. LCFA analysis is one of the most advanced procedures currently available for phenotypic characterization.

NUCLEIC ACID PROBES

Techniques for the detection and quantitation of specific DNA and RNA base sequences in clinical specimens have become powerful tools for the diagnosis of bacterial, viral, parasitic, and fungal infections. The basic strategy is to detect a relatively short sequence of bases specific for a particular pathogen on single-stranded DNA or RNA by hybridization of a complementary sequence of bases (probe) coupled to a "reporter" system that serves as the signal for detection. Detection of an organism by nucleic acid probes offers a decided advantage over culture methods for difficult-to-grow organisms. Current technology encompasses a wide array of methods for amplification and signal detection, some of which have been approved by the U.S. Food and Drug Administration (FDA) for clinical diagnosis.

Use of nucleic acid probes generally involves lysis of intact cells and denaturation of the DNA or RNA to render it single-stranded. The probe may be hybridized to the target

sequence in a solution or on a solid support, depending on the system employed. In situ hybridization of a probe to a target is also possible and allows the use of probes with agents present in tissue specimens. Once the probe has been hybridized to the target (biologic signal), a variety of strategies may be employed to amplify and/or quantify the target-probe complex (Fig. 121-2).

Probes for Direct Detection of Pathogens in Clinical Specimens Nucleic acid probes are available commercially for direct detection of various bacterial and parasitic pathogens, including *L. pneumophila*, *Chlamydia trachomatis*, *N. gonorrhoeae*, group A *Streptococcus*, *Gardnerella vaginalis*, *Mycoplasma hominis*, and *Giardia lamblia*. In addition, probes for direct detection of human papillomavirus, *Candida* spp., and *Trichomonas vaginalis* have been approved. An assortment of probes for confirming the identity of cultured pathogens, such as *Mycobacterium* and *Salmonella* spp., are also available. Probes for the direct detection of bacterial pathogens are often aimed at highly conserved 16S ribosomal RNA sequences, of which there are many more copies than there are of any single genomic DNA sequence in a bacterial cell. The sensitivity and specificity of probe assays for direct detection are comparable to those of more traditional assays, includingEIA and culture. Many laboratories have developed their own probes for pathogens; however, unless a method-validation protocol for diagnostic testing has been performed, the use of such probes is restricted to research by federal law in the United States.

Nucleic Acid Probe Target-Amplification Strategies In theory, a single target nucleic acid sequence can be amplified to detectable levels. There are several strategies for target and/or probe amplification, includingPCR, ligase chain reaction, strand displacement amplification, and self-sustaining sequence replication. In each case, a target sequence or hybridized probe is amplified exponentially to obtain sufficient signal for detection, usually by the attachment of chemiluminescent reporter groups to the amplified product. The PCR strategy requires repeated heating of the DNA or RNA to separate the two complementary strands of the double helix, hybridization of a primer sequence to the appropriate target sequence, target amplification using the PCR for complementary strand extension, and signal detection via a labeled probe. The sensitivity of such assays is far greater than that of traditional assay methods such as culture. However, the care with which the assays are performed is important, because cross-contamination of clinical material with DNA or RNA from other sources (even at low levels) can cause false-positive results. An alternative method employs transcription-mediated amplification, in which an RNA target sequence is converted to DNA, which is then exponentially transcribed into RNA target. The advantage of this method is that only a single heating/annealing step is required for amplification. At present, amplification assays for *Mycobacterium tuberculosis*, *N. gonorrhoeae*, *C. trachomatis*, and *M. hominis* are on the market. Again, many laboratories have used commercially available *taq* polymerase, probe sequences, and reagents to develop "in-house" assays for diagnostic use. Issues related to quality control, interpretation of results, sample processing, and regulatory requirements have slowed the commercial development of diagnostic assay kits.

Signal Amplification Strategies Alternative systems for signal amplification have great appeal, particularly for quantitative determination of the amount of target present in a given specimen. With the advent of newer therapeutic regimens for HIV-associated

disease, cytomegalovirus infection, and hepatitis C virus infection, the response to therapy has been monitored by determining both genotype and "viral load" at various times after treatment initiation. Target amplification (PCR, transcription-mediated amplification) is difficult to control in a manner that allows accurate determination of the original target (genome) concentration. In other systems, probes attached to complementary target sequences are amplified by the attachment of a second probe and an amplification multimer to the original probe. In one such system, branched-chain DNA (bDNA)-based amplification, bDNA is attached to a site different from the target-binding sequence of the original probe. Chemiluminescent-labeled oligonucleotides can then bind to multiple repeating sequences on the bDNA. The amplified bDNA signal is detected by chemiluminescence. Alternatively, a DNA probe may be attached to an RNA target and the resulting DNA/RNA hybrid captured on a solid support by antibody specific for DNA/RNA hybrids (concentration/amplification) and detected by chemiluminescent-labeled antibody specific for DNA/RNA hybrids. Both methods can be used to determine the approximate number of target copies (virus) in the starting material. The advantage of these systems over PCR is that only a single heating/annealing step is required to hybridize the target-binding probe to the target sequence for amplification.

Application of Nucleic Acid Probe Technology Nucleic acid probe technology is being used to identify difficult-to-grow or noncultivable bacterial pathogens, such as *Mycobacterium*, *Legionella*, *Ehrlichia*, *Rickettsia*, *Babesia*, *Borrelia*, and *Tropheryma whippelii*. Amplification methods are also being used to detect chronic viral infections, such as herpes simplex encephalitis, cytomegalovirus infection, and hepatitis C. The monitoring of therapy with quantitative viral-load testing is a significant new application of nucleic acid technology. Further applications will likely include the replacement of culture for identification of many pathogens with solid-state DNA/RNA chip technology, in which thousands of unique nucleic acid sequences can be detected on a single computer chip. Probe technology also has the potential to detect viral pathogens faster than is possible with current culture techniques. However, if laboratories are to take full advantage of probe technology, the cost of reagents and assay automation must be competitive with the cost of existing methodology. At present, the detection of agents such as *C. trachomatis* or *N. gonorrhoeae* by probe technology is more expensive for most laboratories than detection by traditional culture orEIA. Moreover, because automated processing equipment is just beginning to find its way into the laboratory for these assays, nucleic acid amplification methods are both more labor-intensive and more expensive than other detection systems. In the absence of clear documentation of clinical utility, many laboratories continue to wait forFDAapproval of commercially available DNA/RNA probe assays rather than validating in-house assays.

SUSCEPTIBILITY TESTING

A principal responsibility of the clinical microbiology laboratory is to determine which antimicrobial agents inhibit a specific bacterial isolate. Such testing is used to screen for infection control problems, such as methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus faecium*, or extended-spectrum b-lactamase-producing organisms. Two approaches are useful. The first is a qualitative assessment of susceptibility, with responses categorized as susceptible, resistant, or intermediate. This approach can involve either the placement of paper disks containing

antibiotics on an agar surface inoculated with the bacterial strain to be tested (Kirby-Bauer or disk/agar diffusion method), with measurement of the zones of growth inhibition following incubation, or the use of broth tubes containing a set concentration of antibiotic (breakpoint method). These methods have been carefully calibrated against quantitative methods and clinical experience with each antibiotic, and zones of inhibition and breakpoints have been calculated on a species-by-species basis.

The second approach is to inoculate the test strain of bacteria into a series of broth tubes (or agar plates) with increasing concentrations of antibiotic. The lowest concentration of antibiotic that inhibits microbial growth in this test system is known as the *minimum inhibitory concentration* (MIC). If tubes in which no growth occurs are subcultured, the minimum concentration of antibiotic required to kill the starting inoculum can also be determined (*minimum bactericidal concentration*, or MBC). Quantitative susceptibility testing by the microbroth dilution technique, a miniaturized version of the broth dilution technique using microwell plates, lends itself to automation and is commonly used in larger clinical laboratories.

A novel version of the disk/agar diffusion method employs a quantitative diffusion gradient, or epsilometer (E-test), and uses an absorbent strip with a known gradient of antibiotic concentrations along its length. When the strip is placed on the surface of an agar plate seeded with a bacterial strain to be tested, antibiotic diffuses into the medium, and bacterial growth is inhibited. TheMIC is estimated as the lowest concentration that inhibits growth.

For some organisms, such as obligate anaerobes, routine susceptibility testing generally is not performed because of the difficulty of growing the organisms and the predictable sensitivity of most isolates to specific antibiotics.

122. IMMUNIZATION PRINCIPLES AND VACCINE USE - *Gerald T. Keusch*, *Kenneth J. Bart*

Most humans live their lives ignoring the certainty of their own mortality. Perhaps this fact explains why the adage "an ounce of prevention is worth a pound of cure" has so little effect on their everyday behavior. Even when it comes to acting to protect their young, parents are capable of ignoring the potential for mortality among their children (in the developed world) and of accepting the certainty of childhood deaths (in the developing world). In both settings, parents all too often fail to seek out and demand the best preventive measures available. Unless mandated by the law in the former setting or provided by benevolent organizations or governments in the latter, universal immunization has invariably remained an unattained goal. Compulsion and benevolence, it seems, are two essential components of immunization.

However, the integration of immunization practices (a major component of primary disease prevention) into routine health care services has provided caregivers with control over a substantial proportion of the disease and mortality that plagued the United States during the first half of the twentieth century (Table 122-1). For society today, immunization represents one of the most cost-effective means of preventing infectious disease. For every dollar spent, diphtheria/tetanus/pertussis (DTP) vaccine saves $29, measles/mumps/rubella (MMR) vaccine saves $21, trivalent oral poliovirus vaccine (OPV) saves $6, varicella vaccine saves $5, and *Haemophilus influenzae* type b vaccine saves $2. At present, >50 biologic products are licensed in the United States, and 6 vaccines (12 antigens) are used for routine immunization in the young, including diphtheria/tetanus/acellular pertussis vaccine (DTaP), inactivated poliovirus vaccine (IPV), MMR, *H. influenzae* type b (Hib) vaccine, hepatitis B virus (HBV) vaccine, and varicella vaccine. Five vaccines are designed for routine use in adults: tetanus/diphtheria (Td) toxoids, adsorbed, for adult use; HBV vaccine; influenza virus vaccine; polyvalent pneumococcal polysaccharide vaccine; and varicella vaccine. Some preparations are designated as special-use vaccines (e.g., hepatitis A vaccine for travelers). Unfortunately, vaccines for eukaryotic pathogens (protozoa and helminths), which affect a large proportion of the world's population, have been difficult to develop and remain only a hope for the future.

IMPACT OF IMMUNIZATION

The epidemiologically appropriate use of vaccines has resulted in the global eradication of smallpox and in the potential eradication of poliomyelitis in the next few years and of measles by 2020. Already achieved are the virtual elimination of congenital rubella syndrome, tetanus, and diphtheria as well as a dramatic reduction in pertussis, rubella, measles, and mumps in the United States. The introduction ofHibconjugate vaccines for immunization of infants has all but eliminated invasive *Haemophilus* infections (including meningitis and pneumonia), presumably because these vaccines also reduce nasopharyngeal carriage of Hib and induce protection before the period of greatest vulnerability in infancy. The recently licensed polyvalent pneumococcal polysaccharide conjugate vaccine promises to have the same impact on invasive pneumococcal disease, including otitis media.

DEFINITIONS

Vaccination and *immunization* are often used as interchangeable terms. However, the former denotes only the administration of a vaccine or toxoid, whereas the latter describes the process of inducing or providing immunity by any means, whether active or passive. Thus, vaccination does not guarantee immunization. *Active immunization* refers to the induction of immune defenses by the administration of antigens in appropriate forms, whereas *passive immunization* involves the provision of temporary protection by the administration of exogenously produced immune substances. Immunizing agents thus include vaccines, toxoids, and antibody-containing immunoglobulin preparations from human or animal donors (Table 122-2).

PRINCIPLES OF IMMUNIZATION

Artificial induction of immunity closely follows two well-tested principles of nature. The first, active immunization, can be traced at least as far back as Thucydides, who noted that people surviving epidemics of plague in Athens were spared during later outbreaks of the same disease. The second, passive immunization, is a natural process as well and is exemplified by the transplacental transmission of maternal antibodies to the fetus to provide protection against several diseases during the first months of life. Use of the two measures together may produce a complementary effect (as withHBVvaccine plus hepatitis B immune globulin) or may actually interfere with the development of immunity (as when measles vaccine is administered within 6 weeks of immunoglobulin). Depending on whether there are multiple species or serotypes of an organism and -- if so -- whether there are common, cross-reactive, protective antigens, a specific vaccine may induce protection against all representative forms of an infectious agent or against the immunizing strain only. One of the intrinsic virtues of whole-organism vaccines is that they potentially contain all protective antigens of the organism. However, this virtue is counterbalanced by an inherent problem with such vaccines: the possibility of adverse responses to reactive but nonprotective antigens present in the mix. Because the immune response to specific antigens is controlled genetically, all individuals cannot be expected to respond identically to the same vaccine.

APPROACHES TO ACTIVE IMMUNIZATION

The two standard approaches to active immunization are (1) the use of live, generally attenuated, infectious agents (e.g., measles virus); and (2) the use of inactivated agents or their constituents or products obtained by genetic recombination (e.g., acellular pertussis vaccines). For many diseases (e.g., poliomyelitis, influenza), both approaches have been employed. Live attenuated vaccines are believed to induce an immunologic response more nearly like that resulting from natural infection than the response induced by killed vaccines. Currently available inactivated or killed vaccines consist of inactivated whole organisms (e.g., plague vaccine); detoxified protein exotoxins (e.g., tetanus toxoid); recombinant protein antigens (e.g.,HBVvaccine); or carbohydrate antigens, either present as soluble purified capsular material (e.g., *Streptococcus pneumoniae* polysaccharides) or conjugated to a protein carrier (e.g.,Hibpolysaccharide conjugated to diphtheria or tetanus toxoids).

APPROACHES TO PASSIVE IMMUNIZATION

Passive immunization is generally used to provide temporary immunity in an unimmunized subject exposed to an infectious disease when active immunization either is unavailable (e.g., for cytomegalovirus infection) or has not been implemented before exposure (e.g., for rabies). Passive immunization is used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively].

Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., gamma globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody for specific agents (e.g.,HBV or varicella-zoster immune globulin); and (3) animal sera and antitoxins.

ROUTE OF ADMINISTRATION

The route of administration in part determines the rapidity and nature of the immune responses to vaccines. Vaccines can be administered orally, intranasally, intradermally, subcutaneously, or intramuscularly. Parenterally administered vaccine may not induce mucosal secretory IgA, and mucosal immunization may not induce good systemic responses. Vaccines must be administered by the licensed route to ensure immunogenicity and safety. For example, administration ofHBVvaccine into the gluteal rather than the deltoid muscle often fails to induce an adequate immune response, while subcutaneous rather than intramuscular administration ofDTPincreases the risk of reactions.

AGE

Because age influences the response to vaccines, schedules for immunization are based on age-dependent responses determined empirically from clinical trials. The presence of high levels of maternal antibody and/or the immaturity of the immune system in the early months of life impairs the initial immune response to some vaccines (e.g., measles orHibpolysaccharide but notHBV). In the elderly, vaccine responses may be diminished because of natural waning of the immune system. Hence, larger amounts of an antigen may be required to produce the desired response (e.g., in vaccination against influenza).

ADJUVANT POTENTIATION

The immune response to some antigens is potentiated by the addition of adjuvants such as aluminum salts or, in the case of polysaccharides (e.g., the polyribose phosphate oligosaccharide of Hib), by conjugation to a carrier protein. Adjuvants, nonspecific boosters of immune responses, are used with inactivated products such as diphtheria and tetanus toxoids, acellular pertussis (aP) vaccine, andHBVvaccine. The mechanism for adjuvant enhancement of immunogenicity is not well defined but relates in part to the rendering of soluble antigens into a particulate form, the mobilization of phagocytes to the site of antigen deposition, and the slowing down of the release of antigens, which prolongs stimulation of the immune response.

THE IMMUNE RESPONSE

While many constituents of infectious microorganisms and their products, such as exotoxins, are or can be made to be immunogenic, only a limited number stimulate a protective immune response. The immune system is complex, and antigen composition and presentation are critical for stimulation of the desired immune responses.

The Primary Response In the primary response to a vaccine antigen, an apparent latent period of several days precedes the detection of humoral and cell-mediated immunity. Although the immune response is turned on by contact with the antigen and the immune system, measurable circulating antibodies do not appear for 7 to 10 days. The immunoglobulin class of the response also changes over time. Early-appearing IgM antibodies generally exhibit only low affinity for the antigen, whereas later-appearing IgG antibodies display high affinity. For "thymus-dependent" antigens, CD4+ T helper lymphocytes control the switch from IgM to IgG. Some individuals do not respond, even when presented repeatedly with a vaccine antigen, often because they lack the major histocompatibility complex determinants required to recognize the antigen. This situation is known as *primary vaccine failure*.

The Secondary Response Heightened humoral or cell-mediated responses are elicited by a second exposure to the same antigen. These secondary responses occur rapidly, usually within 4 or 5 days, and result, for example, in increased titers of IgG antibody. The secondary response depends on immunologic memory after the first exposure and is characterized by a marked proliferation of antibody-producing B lymphocytes and/or effector T cells. Polysaccharide vaccines, such as that for *S. pneumoniae*, evoke immune responses that are independent of T cells and are not enhanced by repeated administration. Covalent linking of polysaccharides to proteins converts the former to T cell-dependent antigens that induce immunologic memory and secondary responses to revaccination. Although levels of vaccine-induced antibodies may decline over time (*secondary vaccine failure*), revaccination or exposure to the organism may elicit a rapid protective secondary response consisting of IgG antibodies with little or no detectable IgM. This *anamnestic response* indicates that immunity has persisted. The lack of measurable antibody does not necessarily mean that the individual is unprotected. Furthermore, the mere presence of detectable antibodies after the administration of some vaccines and toxoids does not ensure clinical protection. A minimal circulating level of antibody is known to be required for protection from some diseases (e.g., 0.01 IU/mL for tetanus antitoxin).

Hypersensitivity Reactions Independent of antibody production, the stimulation of the immune system by vaccination may elicit unanticipated responses, especially hypersensitivity reactions. In the past, killed measles vaccine induced incomplete humoral immunity and cell-mediated hypersensitivity, resulting in the development of a syndrome of atypical measles in some children after subsequent exposure; thus this type of vaccine is no longer in use.

Mucosal Immunity Some pathogens are confined to and replicate only at mucosal surfaces (e.g., *Vibrio cholerae*), while others are able to penetrate the mucosa and replicate (e.g., poliovirus, rubella virus, and influenza virus). At the mucosal site, these organisms induce secretory IgA. The induction of secretory IgA by vaccines may be an

efficient way to block the essential first steps in pathogenesis, whether the organism is restricted to mucosal surfaces or systemically invades the host across mucosal surfaces.

Measurement of the Immune Response Immune responses to vaccines are often gauged by the concentration of specific antibody in serum. While seroconversion serves as a dependable indicator of an immune response, it measures only one immunologic parameter and does not necessarily indicate protection. The development of circulating antibodies after immunization often correlates directly with clinical protection (e.g., against measles or rubella). Some responses may not in themselves confer immunity but may be sufficiently associated with protection that they remain useful proxy measures of protective immunity (e.g., vibriocidal serum antibodies in cholera).

HERD IMMUNITY

It is not necessary to immunize every person in order to stop transmission of an infectious agent through a population. For those organisms dependent on person-to-person transmission, there may be a definable prevalence of immunity in the population above which it becomes difficult for the organism to circulate and reach new susceptibles. This prevalence is called *herd immunity*. When herd immunity is operative, the goals of immunization are converted from the immunization of every person in the community to the immunization of a specified minimum percentage of persons at risk. Herd immunity may wane if immunization capacity fails (as in diphtheria in the new independent states of the former Soviet Union) or if a sufficient percentage of individuals refuse to be immunized (as in pertussis in the United Kingdom and Japan in the 1970s because concern about infrequent -- albeit severe -- vaccine reactions came to exceed the fear of the disease itself). In both situations, loss of herd immunity led to renewed circulation of the organism and increased susceptibility to infection, with subsequent large outbreaks.

TARGET POPULATIONS AND TIMING OF IMMUNIZATION

For common and highly communicable childhood diseases like measles, the target population is the universe of susceptible individuals, and the time to immunize is as early in life as is feasible. Epidemiologic differences in measles in different settings, however, dictate different strategies of immunization. In the industrialized world, immunization with live-virus vaccine at 12 to 15 months of age has been the norm because the vaccine protects>95% of those immunized at this age and there is little measles morbidity/mortality among very young infants. In contrast, in the developing world, measles accounts for a significant proportion of deaths of young infants. Thus it is desirable to immunize children during the first few months of life in order to narrow the window of vulnerability between the rapid decline of maternal antibody after 4 to 6 months and the development of vaccine-induced active immunity.

Hibcauses meningitis, epiglottitis, and pneumonia in early childhood, with rates rising sharply after the disappearance of maternally derived antibody. The first Hib vaccines often failed when administered during infancy; this failure was due mainly to an age-related inability to respond to polysaccharide antigens. To overcome this problem, the protective polysaccharide was coupled to protein and converted to a T

cell-dependent antigen to which young infants could respond.

In contrast to measles andHibinfection, rubella is primarily a threat to the fetus; young infants and children are not at risk of serious illness. Given the susceptibility of the fetus, immunization of all women of reproductive age before pregnancy would be an ideal strategy. However, it is difficult to systematically vaccinate adolescent and young-adult females. Thus, to assure the protection of as many women as possible, the rubella component is included in a combination vaccine with mumps and measles (MMR) that is administered during infancy.

Some vaccines are now used primarily for adults. For example, influenza virus and polyvalent pneumococcal polysaccharide vaccines are used to prevent pneumonia deaths in the elderly. Unfortunately, these vaccines are underutilized, in part because physicians and otherwise healthy individuals in the target group ignore the indications and in part because there is still a tendency to think about disease prevention with vaccines as a strategy for children. Pneumococcal polysaccharide vaccine is also recommended for children>2 years old who are at risk of severe or even life-threatening pneumococcal infection, such as those with sickle cell disease, asplenia (whether functional or anatomic), renal failure with nephrotic syndrome, cerebrospinal fluid leak, and HIV infection or other immunosuppressive disease states.

THE DEVELOPMENT OF VACCINES

BIOLOGIC IMPEDIMENTS

There are often major technical problems to overcome in vaccine development. Although just one major antigenic type of influenza virus is typically in circulation at any one time, the virus is characterized biologically by its antigenic drift. Thus, a new antigenic version capable of causing a global pandemic emerges periodically, and a new vaccine must be rapidly devised, produced, and distributed. In contrast, many prevalent pneumococcal polysaccharide serotypes circulate at all times. Because immunity to the pneumococcus is serotype specific, an individual is susceptible to all serotypes against which he or she lacks antibody. Serotype-specific protection has made it more difficult to develop an effective pneumococcal vaccine than it was to develop a vaccine against *H. influenzae*, of which one capsular serotype (type b) is associated with nearly all cases of severe disease. To overcome this problem, pneumococcal vaccine currently includes 23 polysaccharides that represent ~80% of the virulent serotypes commonly encountered in the United States. Unfortunately, some serotypes are poorly immunogenic, and immunized individuals remain susceptible to the serotypes not included in the vaccine.

STRATEGY FOR VACCINE DEVELOPMENT

Vaccine development depends on the systematic application of a four-phase strategy: (1) studies in animals to identify protective antigen, (2) determination of how to present this antigen effectively to the immune system, (3) assessment of the safety and immunogenicity of the preparation in small and then in large human populations at various ages, and (4) evaluation of safety and efficacy in the target population. Each of these steps is simple in concept but difficult in execution, not least because of the

clinical trials necessary to assess safety and efficacy; failure at any level stops the process. Thus, in 1995,>190 candidate vaccines were under investigation, but just 5 new products were licensed in the United States. Progress in immunology has taught us much about the organization and function of the immune system (Chap. 305); it has also taught us that the immune system is complicated and that details of antigen composition and presentation are critical for stimulating desired immune responses.

Ultimately, vaccines for humans must be tested in humans. After initial animal studies and small phase 1 and 2 human studies to assess immune responses, optimal dosage, and safety, clinical trials of vaccine efficacy are performed, sometimes with informed volunteers who are challenged with a virulent strain. Larger clinical effectiveness trials in the community, typically involving 1000 to 10,000 vaccinees, may lead to application for licensure. Because of their limited size, however, these trials cannot be expected to detect rare adverse effects. Thus, licensing does not guarantee that a new vaccine is completely safe, and postlicensing monitoring is needed to ensure effectiveness and to document the occurrence of adverse events of low frequency. In 1999, the recently licensed rhesus rotavirus vaccine was withdrawn because postmarketing surveillance uncovered an association with a rare event in infants, intussusception of the bowel.

The development of vaccines goes beyond technology and proof of principle to issues such as development costs, manufacturers' liability and indemnity, perceived public health needs, and the likelihood that a product will be used or sold. Given the complex science required, the costs of vaccine development are high and success is uncertain, adding risk to the development decision. It is unfortunate that the one sure implication of uncertainty in vaccine development is increased cost. In addition, a rational assignment of costs for development between the public and private sectors in the United States has never been achieved.

VACCINE FORMULATIONS

Studies of clinical immunology have shown that living and dead antigens do not necessarily induce the same immune responses and that the requirements for the development of protective immunity differ with the organism. These insights, together with the refinement of epidemiologic concepts surrounding immunization, have changed the strategy of vaccine development. The goal is not only to select the correct antigens but also to ensure that the vaccines will result in the type of immune response needed for protection, whether the T cell-mediated activation of macrophages or the generation of cytotoxic T cells, B cell-mediated secretory IgA, or a particular IgG subtype response to a specific polysaccharide epitope.

Live vaccines consist of selected or genetically altered organisms that are avirulent or dramatically attenuated yet remain immunogenic. These agents are expected to cause a subclinical illness that mimics natural infection except for the lack of clinically significant disease. They offer the advantage of replication in vivo, which increases the antigenic load presented to the host's immune system; they may confer lifelong protection with one dose; they present all expressed antigens, thus overcoming immunogenetic restrictions in some hosts; they may reach the local sites most relevant to the induction of protective immunity; and they may produce important protective antigens in vivo that are not efficiently expressed in vitro.

Nonviable vaccines may fail to elicit mucosal IgA-mediated immunity, as they lack a delivery system that will effectively transport them to local antigen-processing cells. Moreover, except for pure polysaccharide antigens, these preparations must almost always be given in multiple doses to induce effective responses. However, killed vaccines can be extremely effective. For example, the nonviable hepatitis A vaccine formulation appears to be close to 100% effective in inducing protective immunity. Methods are under development to incorporate vaccine antigens into degradable polymers that may release antigen at predictable times after a single inoculation and simulate multiple injections over time of the same vaccine.

In spite of their advantages, live vaccines are not always to be preferred. For example, liveOPV is contraindicated for use in children with immune-deficiency diseases and in their adult contacts. In addition, even though killed poliovirus vaccine does not completely immunize the gut and can neither reduce the circulation of wild-type poliovirus nor immunize contacts of vaccine recipients, the United States has now switched to a four-dose schedule of this vaccine because of the risk of vaccine-associated polio posed by live OPV.

To create a deliverable vaccine, constituents other than the antigens are required (Table 122-3). These constituents can affect the immunogenicity, efficacy, and safety of a vaccine and can render one formulation superior to another.

NEW VACCINE APPROACHES

The first generation of vaccines included whole killed -- or, more recently, live -- attenuated microorganisms or partially purified microbial products, such as tetanus toxoid, that induced protective antibodies. The second generation of vaccines has taken advantage of molecular genetics and protein chemistry to isolate and manipulate purified proteins or components or subunits of organisms or to generate genetically engineered and attenuated live native organisms or cloned antigens expressed by harmless vector organisms. One conceptual leap is the production of transgenic plants expressing protective vaccine antigens (cloned, for example, in potatoes or bananas) that, when ingested orally, induce mucosal and systemic immune responses to homologous infectious challenges. While the practical use of this technique awaits further refinement, the concept that protective immunity can be induced in this manner has been proven in both animals and humans. Ease of production, stability, ease of administration without equipment, and low cost are the obvious advantages.

Another conceptual leap has led to a third generation of vaccines, in which nucleic acids (either DNA or RNA) are used to induce immunity. Development of DNA vaccines is at a more advanced stage. The principle is simple. First, a DNA plasmid containing the gene sequence for the immunogenic protein or fragment of interest is assembled, and the gene is placed under the control of a strong promoter and an appropriate transcription termination sequence. A single immunization with the plasmid (via intramuscular or intradermal injection, helium-accelerated gene gun injection of DNA-coated gold particles, compressed-air pneumatic jet injection of soluble DNA, direct skin application after suitable preparation, or even insertion of biodegradable stents loaded with the DNA of interest) results in DNA uptake into cells where the gene is expressed and

processed normally; thus the product stimulates an immune response. Alteration of the DNA construct or of the mode of administration or the coadministration of cytokine genes can determine whether the immune response is humoral or cellular or whether it involves primarily Th1, Th2, or cytotoxic T cells. Such decisions can be used to optimize the protective immunity induced.

This form of immunization offers real advantages and only theoretical and remote disadvantages (Table 122-4). Moreover, DNA vaccines may be useful in inducing tumor immunity, treating allergy (by suppressing IgE production), or even administering genes for gene therapy. RNA vaccines would avoid some of the potential concerns raised by DNA vaccines because RNA is less stable and does not persist or integrate into the chromosome or cause insertional mutagenesis. However, this lack of stability and the likely need for multiple doses, along with the increased cost of producing, storing, and transporting RNA, are significant disadvantages that remain to be overcome. The concept of nucleic acid vaccines -- whether based on DNA or RNA -- has been validated experimentally, and early human trials have begun. There is great optimism for the future but much to be learned if we are to apply this powerful new immunization technique successfully.

PRODUCTION OF VACCINES

As products to be given to healthy individuals to prevent disease, vaccines must not only be efficacious but also cause no harm. In the United States, quality assurance is the responsibility of vaccine manufacturers. Standards of manufacture of biologics [known as good manufacturing practices (GMPs)] are regulated and supervised by the U.S. Food and Drug Administration (FDA). Proof of the safety, efficacy, sterility, and purity of products is required before licensure, and sterility and purity are continually monitored for all lots of vaccine after licensure. Postmarketing studies of safety (phase IV studies) are part of routine regulatory control. On rare occasions, either GMP or quality assurance is inadequate; for example, the release of incompletely killed Salk polio vaccine in 1955 caused an outbreak of poliomyelitis in nearly 200 vaccine recipients and their contacts. Unregulated and uncontrolled manufacture of vaccines in developing countries has sometimes led to immunization with inactive products that fail to provide the expected protective immunity.

Another problem in the production of vaccines has unexpectedly cropped up in the past decade. For various reasons, including the high costs of vaccine development and the prospect of much higher profitability from investments in other products, the number of vaccine manufacturers in the United States has declined and the cost of some basic childhood vaccines has increased. Concern therefore exists about the future availability of these essential biologics for national use. Furthermore, pricing decisions made within the private-sector pharmaceutical industry can have a major impact on vaccine use. This situation has stimulated an initiative toward increased public involvement in supplying vaccine to individuals for whom price is an issue as well as in oversight of the vaccine supply and of price negotiations with the industry.

ADMINISTRATION OF VACCINES

Health care workers administering vaccines must take the precautions necessary to

minimize the risk of spreading disease -- for example, hand washing between immunizations. They should be immunized against hepatitis B, measles, rubella, influenza, and varicella. Different vaccines should not be mixed in the same syringe unless such a practice is specifically endorsed by licensure. Disposable needles and syringes should be discarded in labeled, puncture-proof containers to prevent inadvertent needlestick injury or reuse.

The addition of new, individually injectable vaccines to the immunization schedule has heightened parental concerns about the administration of up to four injections at a single clinic visit. The development and use of combinations of vaccines are intended to mitigate these concerns. Even when multiple injections are required, providers must make every effort to administer all indicated vaccines at each visit.

Wherever effective primary health care systems ensure access to medical services for the majority and the population is educated about the need for and efficacy of vaccines, coverage rates for basic immunization are usually high, regardless of the route of vaccine administration or the number of doses necessary. However, without systematic attention to the completion of multiple-dose vaccine schedules, coverage rates for second, third, and booster doses may drop off significantly.

USE OF VACCINES

Recommendations for vaccine use in the United States are developed by several different groups. These recommendations are the result of a collaborative process among the recommending groups, the pharmaceutical industry, and theFDA.

Vaccines recommended in 1999 for routine administration to infants, children, and adults are shown in Table 122-5; vaccines recommended for special use are shown in Table 122-6; and schedules for immunization of children and adults are shown in Fig. 122-1 andTable 122-7, respectively. The recommendations on route, site, and dosages for vaccination are derived from theoretical considerations, experimental trials, and clinical experience; deviation from these recommendations can result in inadequate protection. The administration of doses at intervals longer than those recommended does not diminish the ultimate protective response but merely delays it. It is not necessary to restart an interrupted series from the beginning or to add an extra dose. In contrast, giving vaccines at shorter-than-recommended intervals may result in poor responses.

RECORDING AND REPORTING REQUIREMENTS

Certain aspects of vaccine use are regulated by the National Childhood Vaccine Injury Act (NCVIA) of 1986 (modified in 1995). The act requires that all mandated childhood vaccinations be recorded by health care providers in the child's permanent medical record, including date of administration, manufacturer and lot number, and name of the provider administering the vaccine. State-based immunization information systems and registries are being developed to help public and private providers manage their immunization activities and particularly to address the problem of assessing immunization coverage when an individual's records are divided among multiple medical facilities.

Parents must be informed about the benefits and risks of immunization and should maintain an up-to-date immunization record on their children. Educational materials providing the required information (Vaccine Information Statements, VISs) are available from the American Academy of Pediatrics (AAP) or the Centers for Disease Control and Prevention (CDC).

VACCINES FOR ROUTINE USE

Infants and Children Recommended routine-use vaccines and schedules for their administration to infants and children are shown in Table 122-5 and Fig. 122-1, respectively. It is current practice for all children in the United States to receive DTaP, poliovirus, MMR, Hib, HBV, and varicella vaccines unless there are specific contraindications. Hepatitis A vaccine is currently recommended when there is a special risk of exposure to infection due to residence in communities with elevated rates of hepatitis A or travel to highly endemic countries.

Adults (See Table 122-7) All adults should be immune to diphtheria and tetanus. If not previously immunized, adults require a primary immunizing course of Td. Many individuals remain immune to tetanus into adulthood because they have received tetanus toxoid rather than Td after injuries, but they are commonly at risk of diphtheria because of the decline in titer of diphtheria antitoxin and the lack of boosting against diphtheria. The development of acellular pertussis vaccines that appear to be safe in adults may lead to a recommendation for booster immunization of adults if clinical trials confirm safety and efficacy. Routine immunization against polio is not recommended for adults unless they are at particular risk of exposure (e.g., through travel to endemic regions, as discussed below) or are the parents or guardians of a child with an immunodeficiency disorder. Adults should be protected from measles, mumps, and rubella; they should be vaccinated unless they are known to have received vaccine on or after their first birthday or to have had physician-diagnosed disease. Rubella vaccine should be given to all women of childbearing age unless they have documentary proof of immunization after their first birthday or laboratory evidence of immunity. An unsupported history of rubella disease is unreliable and should not be accepted. Adults without a clear history of chickenpox should receive varicella vaccine. College students, particularly freshmen living in a dormitory, are at increased risk of meningococcal meningitis. They should be made aware of the polysaccharide vaccine for serogroups A, C, Y, and W-135 and should be offered the option of immunization.

Current recommendations also include influenza vaccine for routine annual administration to adults³55 years of age and to individuals with chronic illness at any age. Polyvalent pneumococcal polysaccharide vaccine is similarly recommended for the elderly or chronically ill. HBV vaccine is recommended for individuals at high risk of exposure, including health care workers exposed to potentially infected blood or blood products, homosexuals, injection drug users, individuals living and working in institutions for the mentally retarded, and household contacts of known carriers of hepatitis B surface antigen (HBsAg). A new recombinant outer-surface protein A (rOspA) is licensed for persons 15 to 70 years of age for Lyme disease (LYMErix, SmithKline Beecham Pharmaceuticals), with use based on individual risk (geography and risk of exposure to ticks).

Adverse Events Modern vaccines, while safe and effective, are associated with adverse effects that range from infrequent and very mild to rare and life-threatening. The decision to use a vaccine involves an assessment of the risks of disease, the benefits of vaccination, and the risks associated with vaccination. Because these factors may change over time, continued assessment is essential.Table 122-8 lists valid and invalid contraindications to immunization and describes appropriate precautions in the use of specific vaccines. Antivaccine advocacy groups actively encourage avoidance of immunization because of their unproven belief that vaccines may cause certain disorders (for example, autism). This situation presents a challenge to the physician in educating parents about vaccine benefits and risks.

Vaccine components, including protective antigens, animal proteins introduced during vaccine production, and antibiotics or other preservatives or stabilizers, can cause allergic reactions in some recipients. These reactions may be local or systemic and may include urticaria and serious anaphylaxis. The most common extraneous allergen is egg protein introduced when vaccines such as those for measles, mumps, influenza, and yellow fever are prepared in embryonated eggs. Local or systemic reactions can result from too-frequent administration of vaccines such asTd, diphtheria/tetanus (DT), or rabies; these reactions are probably due to antigen-antibody complexes. In addition, live-virus vaccines can interfere with tuberculin test responses. When a tuberculin skin test is indicated, it should be done either on the day of immunization or 6 weeks later. When influenza vaccine is given to children <13 years old, only "split-virus" preparations should be used since whole-virus vaccines are associated with higher rates of adverse reactions in young children. Cumulative exposure to mercury in thimerosal-preserved vaccines is a concern, and plans are under way to replace current vaccines with thimerosal-free products. In the interim, infants born to HBsAg-negative mothers should not receive the initial dose of HBV vaccine at birth.

All detected adverse events temporally related to vaccination are expected to be reported to both the local health department and the vaccine manufacturer. TheNCVIArequires health care providers to report certain suspected adverse events following the receipt of a mandated vaccine to theFDA's Vaccine Adverse Events Reporting System (Table 122-9). Although a temporal relationship does not establish cause and effect, this surveillance system remains the only mechanism for collecting the data needed to form conclusions and make decisions.

USE OF VACCINES IN SPECIAL CIRCUMSTANCES

Pregnancy Because of theoretical risk to the fetus and real risk of litigation to the practitioner, routine immunization of pregnant women is best avoided. However, wherever hygienic conditions during delivery cannot be guaranteed, it is essential to ensure that pregnant women are immune to tetanus: the transfer of maternal antitoxin is an important means of preventing neonatal tetanus, and pregnant women can safely receive tetanus as well as diphtheria toxoids. Although live-virus vaccines in general should be withheld during pregnancy, polio and yellow fever vaccines are exceptions and may be administered if the risk of exposure to disease is great. If indicated, some inactivated vaccines (e.g.,HBV, influenza, and pneumococcal vaccines) are safe for pregnant women. Known pregnancy is considered a contraindication to the receipt of

rubella, measles, mumps, and varicella vaccines. Although of theoretical concern, no cases of congenital rubella syndrome or abnormalities attributable to rubella vaccine virus have been observed in infants born to susceptible mothers who received rubella vaccine during pregnancy.

Breast Feeding Neither killed nor live vaccine affects the safety of breast feeding for either mother or infant. Breast-fed infants can be immunized on a normal schedule.

Occupational Exposure Immunization recommendations for most occupational groups remain to be developed. Specific practices are now mandated by the Occupational Safety and Health Administration for the immunization of health care workers against hepatitis B in the United States. Rubella is transmitted to and from health care workers in medical facilities, particularly in pediatric practice. Health care workers who might transmit rubella to pregnant patients should be immune to rubella; it is prudent to screen these employees for antibodies to rubella virus and to immunize susceptible individuals. Persons providing health care are also at greater risk from measles and varicella than the general public, and those who are likely to come into contact with measles- and varicella-infected patients should be immune. Persons employed in caring for patients with chronic diseases can transmit influenza; such workers should be vaccinated annually. Unfortunately, these recommendations often are not fully implemented, even in academic institutions.

HIV Infection and Other Immunocompromised States Limited studies in HIV-infected individuals have found no increase in the risk of adverse events from live or inactivated vaccines. However, immune responses may not be as vigorous in immunocompromised individuals as in those with a normal immune system. Persons known to be infected with HIV should be immunized with recommended vaccines in the same manner as individuals with a normal immune system and as early in the course of their disease as possible, before immune function becomes significantly impaired. Live attenuatedMMRvaccine can be administered to this group, butOPVcannot (Table 122-10).IPVshould be used when vaccination against polio is indicated. Household contacts of immunocompromised individuals should be immune to polio; when vaccinated, they should receive IPV. In practice, it is not necessary to test for HIV before making decisions about the immunization of asymptomatic individuals from known HIV risk groups.

Live attenuated vaccines are normally contraindicated in immunocompromised patients, including those with congenital immunodeficiency syndromes and those receiving immunosuppressive therapy. Passive immunization with immunoglobulin preparations or antitoxins can be considered in individual cases, either as postexposure prophylaxis or as part of the treatment of established infection.

Postexposure Immunization For certain infections, active or passive immunization soon after exposure prevents or attenuates disease expression. Recommended postexposure immunization regimens are compiled in Table 122-11. Measles immune globulin given within 6 days of exposure may prevent or modify infection, and measles vaccine given within the first few days after exposure may prevent symptomatic infection. Although clinical manifestations of rubella in pregnant women are minimized by postexposure passive immunization, this approach may not prevent maternal

viremia, fetal infection, and congenital rubella syndrome. Therefore, the administration of immune globulin is recommended only for women developing rubella during pregnancy who will not consider abortion under any circumstances. Tetanus immune globulin can be used in patients with tetanus. Survivors with no history of tetanus immunization should receive a primary series of toxoid injections since disease does not result in the development of protective levels of antitoxin. Administration of rabies immune globulin plus rabies vaccine in the immediate postexposure period is highly effective in preventing disease. Similarly, for persons who have not been actively immunized, the use of immune globulin within 2 weeks of exposure to hepatitis A is likely to prevent clinical illness. Good data indicate the efficacy of human hepatitis B immune globulin in preventing disease after exposure. While no high-titer preparation is available for postexposure protection against non-A, non-B hepatitis, standard human immune serum globulin is efficacious.

Simultaneous Administration of Multiple Vaccines The simultaneous administration of the most widely used live and inactivated vaccines has not resulted in impaired antibody responses or in increased rates of adverse reactions. Simultaneous administration of vaccines is advantageous in that it increases the probability that a child will ultimately be fully immunized; it is also useful in any age group when the potential exists for exposure to multiple infectious diseases during travel to endemic countries. However, combinationDTaP/Hibvaccines should not be used for primary immunization of infants because the response to Hib is blunted and suboptimal. Live-virus vaccines not given together on the same day should generally be administered at least 30 days apart.

High doses of immune globulin may inhibit the efficacy of measles and rubella vaccines, and an interval of at least 3 months is recommended between the administration of immune globulin and that ofMMRvaccine or its components. Postpartum vaccination of rubella-susceptible women should not be delayed because of the administration of anti-Rho(D) immune globulin or any other blood product during the last trimester or at delivery. Should administration of an immune globulin preparation become necessary after vaccination, it should be postponed, if possible, for at least 14 days to allow time for vaccine-virus replication and development of immunity. In general, there is little interaction of immune globulin with inactivated vaccines, and postexposure passive prophylaxis can be given together withHBVvaccine or tetanus toxoid, resulting in both immediate and long-lasting protection.

Travel The International Sanitary Regulations allow countries to impose requirements for yellow fever and killed cholera vaccines as a condition for admission, even though the latter is not an effective public health tool. Travelers should know whether these vaccines are required for entry into the countries on their itinerary to avoid being turned back or immunized on the spot. Infants, children, and adults should have all routine immunizations updated before traveling, with particular attention to polio, measles, andDTP/DTaPor Tdvaccines. The use of hepatitis A vaccine may be advisable for travelers to some locales. Special-use vaccines (Table 122-6), including rabies, meningococcal polysaccharide, typhoid (oral live or Vi polysaccharide), Japanese encephalitis, and plague vaccines, should be considered for those individuals who expect to go beyond the usual tourist routes or to spend extended periods in rural areas in disease-endemic regions. Most U.S. cities have at least one travel clinic that

maintains up-to-date epidemiologic information and can provide the appropriate vaccines.

DELIVERY OF VACCINES

Over the past 25 years, considerable progress has been made to ensure that every child in the United States is fully immunized by the time of school entry. All 50 states now require immunization for school entry, and most have laws addressing attendance at preschools and day-care centers. The impact of immunization and of other improvements in the health care provided to the American population on the incidence of vaccine-preventable illness is shown inTable 122-1. Nonetheless, many children are not fully immunized, especially in poor and underserved communities. The failure to vaccinate preschool children was largely responsible for the resurgence of measles between 1989 and 1991, with >55,000 cases and >130 measles-related deaths. Outbreaks of pertussis, mumps, and congenital rubella syndrome have occurred for the same reason: low immunization rates among preschool children.

ACCESS TO IMMUNIZATION

Four major barriers to infant and childhood immunization have been identified within the health care system: (1) low public awareness and lack of public demand for immunization, (2) inadequate access to immunization services, (3) missed opportunities to administer vaccines, and (4) inadequate resources for public health and preventive programs. These problems are sources of public concern, and their solution is a priority for national health policy in the United States. In response, the Children's Immunization Initiative was begun in 1990. At the national level, this program includes outreach and educational campaigns to promote parental awareness of the value of vaccination and to encourage health care providers to use every opportunity to vaccinate the children in their care. At the state and local levels, community and business groups, religious and service groups, schools, and the media have joined together in community-based networks. A National Immunization Week each April has been established to focus attention on the vaccination needs of infants and children. To improve the quality and quantity of vaccination services, expanded immunization-clinic hours and computerization of immunization records are being implemented as well.

There has been only modest progress towards the goals for adult immunization in the United States. Adult-immunization goals are important: As many as 60,000 adults die each year of vaccine-preventable diseases for which effective vaccines are not being optimally used. Most persons ³65 years of age do not receive influenza vaccine each year, and even fewer have ever received pneumococcal vaccine. Health care providers more often miss vaccination opportunities with adults than with infants and children. From 60 to 90% of adults hospitalized for or dying of influenza-associated respiratory disease have received medical care during the previous year and could have been immunized at that time. Medicare reimbursement for excess hospitalization during influenza epidemics ranges from $750 million to $1 billion. Additional efforts are required to ensure that adults receive pneumococcal,Td, andHBVvaccines as well.

A special setting for adult immunization is the administration of certain vaccines to pregnant women to enhance passive immunity in their offspring (e.g., tetanus toxoid). In

most cases the mother herself derives important benefits as well. Immunization of the mother should be undertaken at least 6 weeks before delivery to allow for efficient transplacental transfer of antibody to the fetus.

STANDARDS FOR IMMUNIZATION PRACTICES

National standards of immunization for adult and pediatric practice have been established to define common policies and practices for public health clinics and in physicians' private offices (Table 122-12). These guidelines highlight the need to distinguish between valid contraindications and conditions that are often considered but are not in fact contraindications (Table 122-8). Among the valid contraindications applicable to all vaccines are a history of anaphylaxis or other serious allergic reactions to a vaccine or vaccine component and the presence of a moderate or severe illness, with or without fever. Infants who develop encephalopathy within 72 h of a dose ofDTP orDTaPshould not receive further doses; those who develop a "precaution" (Table 122-8) should not normally receive further doses. Because of theoretical risks to the fetus, pregnant women should not receiveMMR or varicella vaccine. Diarrhea, minor respiratory illness with or without fever, mild to moderate local reactions to a previous dose of vaccine, the concurrent or recent use of antimicrobial agents, mild to moderate malnutrition, or the convalescent phase of an acute illness are not valid contraindications to routine immunization. Failure to vaccinate children because of these conditions is increasingly viewed as a missed opportunity for immunization.

BIOTERRORISM

The end of the twentieth century witnessed a rise in the risk of bioterrorism. While smallpox has been eradicated, known stocks of smallpox virus still exist in the United States and Russia, and unknown stocks probably exist in other countries considered likely to engage in terrorism. Global supplies of smallpox vaccine for use in case of deliberate release of smallpox virus are inadequate, and millions of people are likely to become infected and die in the event of such a release. Steps are only now being taken to ensure sufficient stockpiles of vaccine for this eventuality, and it will be several more years before these reach a critical size.

THE NATIONAL VACCINE INJURY COMPENSATION PROGRAM

The use of mandated vaccines benefits society as a whole by reducing morbidity and the cost of care for preventable diseases and by reducing childhood mortality. Thus, in the United States, society has assumed the obligation to care for those injured by the administration of mandated vaccines. TheNCVIA of 1986 (modified in 1995) is the instrument in use to ensure fairness to injured persons as well as protection for federal, state, and local immunization programs; private immunization providers; and vaccine manufacturers. The act was designed to implement two vital public policies: (1) to provide prompt and fair compensation to the families of children who have died or have been injured as a result of routine mandated immunization; and (2) to reduce the adverse impact of the tort system on vaccine supply, cost, and innovation/development. The success of immunization programs in the United States depends upon the continued viability of the National Vaccine Injury Compensation Program.

CONTROL OF VACCINE-PREVENTABLE DISEASE

A continuing task of public health practice is to maintain individual and herd immunity. The job is not over once a population is fully vaccinated; rather, it is imperative to immunize each subsequent generation as long as the threat of the disease persists. Ongoing surveillance and prompt reporting of disease to local or state health departments are essential to this goal, ensuring a continuing awareness of the possibility of vaccine-preventable illness. Nearly all vaccine-preventable diseases are now notifiable, and individual case data are routinely forwarded to theCDC. These data are used to detect outbreaks or other unusual events that require investigation and to evaluate prevention and control policies, practices, and strategies.

As a direct consequence of successes in immunization, vaccine-preventable diseases have become less visible; ironically, this situation may foster complacency among parents and health care providers about routine immunization of children. Even among the affluent and educated, immunization levels may be low, reflecting a misunderstanding of the continuing threat of disease with which parents and health care providers have limited experience or perhaps an unjustifiably greater fear of adverse reactions to vaccination than of the potential for illness and death due to vaccine-preventable diseases. Health care workers play an essential role in influencing the attitudes of patients regarding appropriate immunization; therefore, it is essential that these professionals continually update their own knowledge about vaccines and about the epidemiology of vaccine-preventable illnesses.

RESEARCH ON VACCINES AND IMMUNIZATION

The potential to eradicate selected diseases and to build sustainable immunization programs that reach every child is not being fulfilled with existing vaccines and delivery technology. New vaccines or new formulations that will not only improve protective responses but also simplify the immunization schedule are needed. The ideal would be vaccines that can be administered orally early in life, that provide lifelong protection against multiple infections, that can be given as one or only a few doses, and that are less reactive and more heat stable than current vaccines. To attain these ambitious goals may take decades, but progress is already being made in the development of new combinations of current vaccines to facilitate complete immunization. The results will be applicable to immunization programs in both developed and developing countries.

REEMERGENCE OF CONTROLLED DISEASE AND EMERGENCE OF NEW DISEASE

The emergence of new pathogens is fostered by the genetic potential of microbes to evolve as well as by rapid changes in human demographics and behavior and in a global ecology that creates new or more favorable hosts. Proof of the need for continuing vaccine research is found in the emergence of new infectious diseases such as HIV infection, Lyme borreliosis, hantavirus pulmonary syndrome, and hepatitis C; the appearance of a new epidemic cholera strain (serotype O139 Bengal) that exhibits no cross-immunity with the traditional O1 serotype; and the increase in global incidence and in drug resistance of familiar diseases that were once considered under control, such as tuberculosis and malaria. In addition, some common illnesses without a

previously known etiology, such as peptic ulcer disease and cervical and nasopharyngeal cancer, have now been epidemiologically linked to specific infectious agents and have thus become potentially vaccine-preventable conditions.

DEVELOPMENT OF NEW VACCINES

For many serious or even life-threatening infectious diseases, no effective vaccines are available. Although many new vaccines are undergoing human trials, the task of developing vaccines is proving very complex. Priorities for the United States currently include research on the following vaccines: HIV, pneumococcus (conjugate), group B *Streptococcus*, respiratory syncytial virus, rotavirus, *Mycobacterium tuberculosis*, herpes simplex virus, influenza A and B viruses, and hepatitis C virus. Also of high priority are vaccines for two virus-associated tumors: cervical cancer (human papillomavirus) and nasopharyngeal cancer (Epstein-Barr virus).

INTERNATIONAL CONSIDERATIONS

Since the establishment of the World Health Organization's Expanded Programme on Immunization in 1981, levels of coverage for the recommended basic children's vaccines (bacille Calmette-Guerin, polio,DTP/DTaP, measles, andHBV) have risen from 5% to ~80% worldwide. Each year, at least 2.7 million deaths from measles, neonatal tetanus, and pertussis and 200,000 cases of paralysis due to polio are prevented by immunization. Despite the successes of this program, many vaccine-preventable diseases remain prevalent in the developing world. Measles, for example, continues to kill an estimated 1.5 million children each year, and cases of diphtheria, whooping cough, polio, and neonatal tetanus still occur at unacceptably high rates. It is estimated that between 20 and 35% of all deaths of children under the age of 5 years are still associated with vaccine-preventable diseases.

In addition to the antigens included in the Expanded Programme for routine use in the developing world, others (Hib, Japanese B encephalitis, yellow fever, group A meningococcus, mumps, and rubella) are used regionally, depending on disease epidemiology and resources. Polio has been targeted for eradication; this disease has already been eliminated in the Americas and Europe and is close to elimination in the Western Pacific.

Because infectious diseases know no geographic or political boundaries, uncontrolled disease anywhere in the world poses a threat to the United States. Vaccines offer the opportunity to control and even eradicate some diseases, and eradication means that vaccines are no longer needed. Vaccines represent the best hope for stopping the pandemic of HIV infection throughout the world. The experience with smallpox has shown that the eradication of disease is a remarkably good economic investment. The entire sum that the United States spent for the global smallpox eradication campaign has been recouped, in 1968 dollars, every 2.5 months since 1971. The global eradication of polio will save the United States over $300 million a year in vaccine and associated delivery costs and will save over $1.5 billion a year worldwide.

Issues of cost, liability, risk, and profitability limit the interest of the pharmaceutical industry in the development of vaccines (e.g., for malaria) that will be used primarily in

poor developing countries. Efforts have been made to create partnerships in public research and privately funded development. Activities of established international organizations (such as the World Health Organization) and some new organizations (such as the Global Alliance for Vaccines and Immunization, the International AIDS Vaccine Initiative, and the Bill and Melinda Gates Foundation) have helped to move the process forward with strategy development and implementation or new funding. New international schemes are being considered by wealthy industrial nations; for example, advance-purchase schemes are being proposed in which the purchase of effective vaccines is guaranteed, ensuring the profitability that the marketplace has provided for industry in the wealthy countries. The effectiveness of such approaches remains to be seen, but they offer much-needed hope for at-risk populations around the world.

123. HEALTH ADVICE FOR INTERNATIONAL TRAVEL - *J.S. Keystone*, *P.E. Kozarsky*

In 1991, the World Health Organization estimated that more than 30 million persons traveled from industrialized countries to the developing world. Studies show that between 50 and 75% of short-term travelers to the tropics or subtropics report some health impairment. Most of these health problems are minor, with only 5% requiring medical attention and fewer than 1% requiring hospitalization.

Although infectious agents contribute substantially to morbidity in travelers, these pathogens account for only about 1% of deaths among this population. Cardiovascular disease and injuries are the most frequent causes of death among travelers from the United States, accounting for 49 and 22% of deaths, respectively. Age-specific rates of mortality due to cardiovascular disease are similar to those among nontravelers. In contrast, rates of death due to injury -- the majority from motor vehicle, drowning, or aircraft accidents -- are several times higher among travelers. Figure 123-1 summarizes the monthly incidence of health problems during travel in developing countries.

GENERAL ADVICE

Staying healthy during travel requires familiarity with the health risks that may be encountered at a given destination. However, health maintenance recommendations are based not only on the traveler's destination but also on risk assessment, which is determined by health status, specific itinerary, and lifestyle during travel. Detailed information regarding country-specific risks and recommendations may be obtained from many sources, including those listed under "Sources of Information on Travel Medicine."

IMMUNIZATIONS FOR TRAVEL

Immunizations for travel are generally divided into three categories: routine (childhood/adult boosters that are necessary regardless of travel), required (immunizations that are mandated by international regulations for entry into certain areas or for border crossings), and recommended (immunizations that are desirable because they confer protection against a variety of illnesses for which travel increases the risk). Vaccines commonly given to travelers are listed inTable 123-1.

Routine Immunizations

Diphtheria, Tetanus, and Polio Diphtheria continues to be a problem worldwide, with large outbreaks in the independent states formerly encompassed by the Soviet Union. Serosurveys show that tetanus antitoxin is lacking in many North Americans, especially those over the age of 50. Although the risk of polio to the international traveler is extremely low and although polio has been eradicated from the western hemisphere, studies in the United States have found varying levels of immunity in the general population; data indicate that 12% of adult American travelers are unprotected against at least one poliovirus serogroup. Foreign travel offers an ideal opportunity to have these immunizations updated.

Measles Measles (rubeola) continues to be a major cause of morbidity and mortality in the developing world (Chap. 194). Several outbreaks of measles in the United States have been linked to imported cases. The group at highest risk consists of persons born after 1956 and vaccinated before 1980, in many of whom primary vaccination failed. Travelers in this group should be reimmunized.

Influenza Influenza occurs year-round in the tropics and during the summer months in the southern hemisphere (which coincide with the winter months in the northern hemisphere). Vaccination should be considered for all travelers to these regions, particularly those who are elderly or chronically ill. The largest outbreak of travel-related influenza occurred in the summer of 1998 in Alaska and the Northwest Territories of Canada among cruise ship passengers and staff (Chap. 190).

Pneumococcal Infection Pneumococcal vaccine should be administered routinely to persons at high risk of serious pneumococcal infection, such as individuals with chronic heart, lung, or renal disease and those who have been splenectomized or have sickle cell disease.

Required Immunizations

Yellow Fever Documentation of yellow fever vaccination may be required for entry into countries of sub-Saharan Africa and equatorial South America, where the disease is endemic or epidemic, or into countries that are at risk of having the infection introduced. This vaccine is given only by state-authorized yellow fever centers, and its administration must be documented on an official International Certificate of Vaccination. The incidence of yellow fever among travelers is extremely low, probably because the vaccine is highly efficacious.

Cholera According to the World Health Organization, cholera vaccine should no longer be required for entry into any country. (However, see *recommended* use below.)

Meningococcal Meningitis Meningococcal vaccination is required for entry into Saudi Arabia during the Hajj. (For information on *recommended* use, see below.)

Recommended Immunizations

Hepatitis A and B Hepatitis A is the most frequent vaccine-preventable infection of travelers; the incidence of symptomatic infection during a 1-month stay in a developing country ranges from 3 to 6 cases per 1000. The risk is six times greater for those who stray from the usual tourist routes. The mortality rate for hepatitis A increases with age, reaching almost 3% among symptomatic individuals over age 50. Several vaccines are available in North America, each of which has an efficacy rate of >95%. The monthly incidence of hepatitis B infection, both symptomatic and asymptomatic, is 80 to 240 cases per 100,000. For reasons that are not entirely clear, long-stay overseas workers are at considerable risk for hepatitis B infection. In the near future, a combined hepatitis A and B vaccine should become available in the United States.

Typhoid Fever The attack rate for typhoid fever is 1 case per 30,000 per month of travel to the developing world (Chap. 156). However, the rates in India, Senegal, and North

Africa are tenfold higher, and, within these areas, rates are especially high among travelers to relatively remote destinations and among persons who are returning to their homelands to stay with relatives or friends. Each of the three available vaccines -- one oral and two injectable -- has an efficacy rate of approximately 70%.

Meningococcal Meningitis Although the risk of meningococcal disease among travelers has not been quantified, it is likely to be higher among those who live with poor indigenous populations in overcrowded conditions. The vaccine is recommended for persons traveling to sub-Saharan Africa during the dry season or to areas of the world where there are epidemics. Meningococcal vaccine, which protects against serogroups A/C/Y/W-135, has an efficacy rate of>90%.

Japanese Encephalitis The risk of Japanese encephalitis, an infection transmitted by mosquitoes in rural Asia and Southeast Asia, is approximately 1 case per 5000 per month of stay in an endemic area. Most symptomatic infections in U.S. residents have involved military personnel or their families. The vaccine efficacy rate is >80%. Serious allergic reactions sometimes occur; these reactions may be delayed in onset, developing up to 10 days after immunization. The vaccine is recommended for persons staying>1 month in endemic areas.

Cholera The risk of cholera is extremely low, with approximately 1 case per 500,000 journeys to endemic areas. Cholera vaccine is rarely recommended but should be considered for aid workers in refugee camps or in disaster/war-torn areas. The injectable vaccine available in the United States is only 30 to 50% effective, and its protective effect persists for only a short period. A more effective oral cholera vaccine is available in other countries.

Rabies Many cases of rabies have been reported in travelers, but there are no data on the risk of infection. Domestic animals are the major transmitters of rabies in developing countries (Chap. 197). Countries where canine rabies is highly endemic include Mexico, the Philippines, Sri Lanka, India, Thailand, and Vietnam. Each of the three vaccines available in the United States provides>90% protection. Rabies vaccine is recommended for long-stay travelers, particularly children, and persons who may be occupationally exposed in endemic areas.

PREVENTION OF MALARIA AND OTHER INSECT-BORNE DISEASES

It is estimated that more than 30,000 American and European travelers develop malaria each year (Chap. 214). Nevertheless, several studies indicate that fewer than 50% of U.S. travelers to malaria-endemic regions adhere to basic recommendations for malaria prevention.

The risk of malaria is highest in sub-Saharan Africa and Oceania (1:50 to 1:1000) and during the past decade has increased by more than fivefold for travelers to Kenya. The risk is intermediate (1:1000 to 1:12,000) for travelers to Haiti and the Indian subcontinent and is low (<1:50,000) for travelers to Asia and to Central and South America. Of the 1000 cases of malaria reported annually in the United States, 90% of those due to *Plasmodium falciparum* occur in travelers returning or immigrating from Africa and Oceania. With the worldwide increase in chloroquine- and multidrug-resistant

falciparum malaria, decisions about chemoprophylaxis have become more difficult. Moreover, the spread of malaria due to primaquine- and chloroquine-resistant strains of *P. vivax* has added to the complexity of treatment. The case-fatality rate of falciparum malaria in the United States is 4%; however, in only one-third of patients who die is the diagnosis of malaria considered before death.

Compliance with chemoprophylaxis regimens and use of personal protection measures are keys to the prevention of malaria. Personal protection measures are aimed at preventing mosquito bites, especially between dusk and dawn, and include the use of DEET-containing insect repellents, permethrin-impregnated bed nets and clothing, screened sleeping accommodations, and protective clothing. These practices also help prevent other insect-transmitted illnesses, such as dengue fever. Over the past decade, the incidence of dengue has increased, particularly in the Caribbean region, Latin America, and Southeast Asia. Since dengue fever is transmitted by a day-biting, urban-dwelling mosquito, attention to personal protection measures is required around the clock in most tropical areas.

The decision about whether or not to use malaria prophylaxis is based on the traveler's destination; the particular medication prescribed is determined not only by destination but also by the traveler's preference and medical history.Table 123-2 lists the currently recommended drugs of choice for prophylaxis of malaria by destination. Alternative medications for prophylaxis that are in use by some physicians include primaquine, atovaquone/proguanil, and chloroquine/proguanil.

PREVENTION OF GASTROINTESTINAL ILLNESS

Diarrhea is the leading cause of illness in travelers (Chap. 131) and is usually a short-lived, self-limited condition; however, 40% of affected individuals must alter their scheduled activities, and another 20% are confined to bed. The most important determinant of risk is the traveler's destination. Incidence rates per 2-week stay have been reported to be as low as 8% in industrialized countries and as high as 55% in parts of Africa, Central and South America, and Southeast Asia. Infants and young adults are at particularly high risk. The incidence of diarrhea is proportional to the number of dietary indiscretions. Studies of U.S. students in Mexico showed that eating meals in restaurants and cafeterias or consuming food from street vendors was associated with increased risk.

The most frequently identified pathogen causing traveler's diarrhea is toxigenic *Escherichia coli*, although in some parts of the world (notably northern Africa and Southeast Asia) *Campylobacter* infections appear to predominate. Other common causative organisms include *Salmonella*, *Shigella*, rotavirus, and the Norwalk agent. Except for giardiasis, parasitic infections are uncommon causes of traveler's diarrhea. A growing problem for travelers is the development of antibiotic resistance in many bacterial pathogens, including strains of *Campylobacter* and *Salmonella* resistant to quinolones and strains of *E. coli*, *Shigella*, and *Salmonella* resistant to trimethoprim-sulfamethoxazole.

Although the mainstay of prevention of traveler's diarrhea involves food and water precautions, the literature has repeatedly documented dietary indiscretions in 98% of

travelers within the first 48 h after arrival at their destination. The old maxim "Boil it, cook it, peel it, or forget it!" is easy to remember but appears to be difficult to adhere to. General food and water precautions include eating foods piping hot; avoiding foods that are raw, poorly cooked, or sold by street vendors; and drinking boiled or commercially bottled beverages, particularly those that are carbonated. Heating kills diarrhea-causing organisms, whereas freezing does not; therefore, ice cubes made from unpurified water should be avoided.

As traveler's diarrhea can occur despite rigorous food and water precautions, travelers should carry medications for self-treatment. For mild to moderate diarrhea, loperamide and fluid replacement may be sufficient. An antibiotic is useful in reducing the frequency of bowel movements and duration of illness in moderate to severe diarrhea. The standard regimen is a 3-day course of a quinolone taken twice daily or (in the case of some of the newer agents) once daily. However, studies have shown that a single large dose of a quinolone may be as effective as the 3-day regimen, particularly if infection with a multidrug-resistant organism is not suspected. For diarrhea acquired in areas such as Thailand, where>70% of *Campylobacter* infections are quinolone resistant, azithromycin may be a better choice.

Prophylaxis of traveler's diarrhea with bismuth subsalicylate is widely used but only about 60% effective. For certain individuals (e.g., athletes who must be in peak physical condition to perform, persons with a repeated history of traveler's diarrhea, and some persons with chronic diseases), a single daily dose of a quinolone antibiotic during travel of <1 month's duration is highly effective.

PREVENTION OF OTHER TRAVEL-RELATED PROBLEMS

Travelers are at high risk for *sexually transmitted diseases*. Surveys have shown that large numbers engage in casual sex, and there is a reluctance to use condoms consistently. An increasing number of travelers are being diagnosed with *schistosomiasis*. Travelers should be cautioned to avoid bathing, swimming, or wading in freshwater lakes, streams, or rivers in the parts of tropical South America, the Caribbean, Africa, and Southeast Asia where this infection can be acquired. Travelers are cautioned to avoid walking barefoot because of the risk of *hookworm* and *strongyloidiasis* and, at night, *snakebites*. Prevention of *travel-associated injury* depends mostly on common-sense precautions. Riding on motorcycles and overcrowded public vehicles is not recommended; in particular, individuals should not travel by road after dark in rural areas. In addition to its association with motor vehicle accidents, excessive alcohol use has been a significant factor in drownings, assaults, and injuries.

THE TRAVELER'S MEDICAL KIT

A traveler's medical kit is strongly advisable, particularly for long-stay travelers. The contents may vary widely, depending on the itinerary, duration of stay, style of travel, and local medical facilities. While many medications are available abroad, often over the counter, directions for their use may be nonexistent or in a foreign language, and, more important, a product may be outdated or counterfeit. Therefore, if possible, a complete supply of medications should accompany the traveler. In the kit, the short-term traveler should consider carrying an analgesic, an antidiarrheal agent, antihistamines, a laxative,

oral rehydration salts, sunscreen with a skin protection factor of at least 30, insect repellents (DEET) for the skin, an insecticide for clothing (permethrin), and (if necessary) an antimalarial. To these medications the long-stay traveler might add a broad-spectrum general-purpose antibiotic, an antibacterial eye and skin ointment, and a topical antifungal cream. Regardless of the duration of travel, a first-aid kit containing items such as scissors, tweezers, and bandages should be considered.

TRAVEL AND SPECIAL HOSTS

PREGNANCY AND TRAVEL

A woman's medical history and itinerary, the quality of medical care at her destinations, and her degree of flexibility determine whether travel is wise during pregnancy. According to the American College of Obstetrics and Gynecology, the safest part of pregnancy in which to travel is the second trimester (between 18 and 24 weeks), when there is the least danger of spontaneous abortion or premature labor. Some obstetricians prefer that women stay within a few hundred miles of home after the 28th week of pregnancy in case problems arise; in general, however, healthy women may be advised that it is acceptable to travel.

Despite this general recommendation, there are some relative contraindications to international travel during pregnancy, including certain obstetric risk factors: a history of miscarriage, premature labor, incompetent cervix, or toxemia. General medical problems such as diabetes, heart failure, severe anemia, or a history of thromboembolic disease should also prompt the pregnant woman to postpone her travels. Finally, regions in which the pregnant woman and her fetus may be at excessive risk (e.g., those at high altitudes and those where live-virus vaccines are required or where multidrug-resistant malaria is endemic) are not ideal destinations during any trimester.

Malaria Malaria during pregnancy carries a significant risk of morbidity and death. Levels of parasitemia are highest and failure to clear the parasites after chloroquine treatment are most frequent among primigravidae. Severe disease, with complications such as cerebral malaria, massive hemolysis, and renal failure, is especially likely in pregnancy. Fetal sequelae include spontaneous abortion, stillbirth, preterm delivery, and congenital infection.

Traveler's Diarrhea Because dehydration due to traveler's diarrhea can lead to inadequate placental blood flow, pregnant travelers must be extremely cautious regarding their food and beverage intake. The exclusive consumption of bottled (carbonated) or boiled drinks without ice, the eating of well-cooked meats and pasteurized dairy products, and the avoidance of pre-prepared salad items should help protect against traveler's diarrhea due to the usual causes as well as against infections such as toxoplasmosis, hepatitis E, and listeriosis, which can have serious sequelae in pregnancy.

The mainstay of therapy for traveler's diarrhea is rehydration. Kaolin-pectin combinations and loperamide may be used if necessary, but many of the usual antibiotics (e.g., quinolones) are contraindicated during pregnancy. Ampicillin alone or with clavulanic acid may be used, but many strains of *E. coli* and other organisms

implicated in traveler's diarrhea are resistant. Azithromycin or an oral third-generation cephalosporin may be the best option.

Because of the major problems encountered when infants are given local foods and beverages, women are strongly encouraged to breast-feed when traveling with a neonate. A nursing mother with traveler's diarrhea should not stop breast-feeding but should increase her fluid intake.

Air Travel and High-Altitude Destinations Commercial air travel is not a risk to the healthy pregnant woman or to the fetus. Fetal oxygenation is not adversely affected by the decreased cabin pressures because of the fetal hemoglobin dissociation curve; the higher radiation levels reported at altitudes>10,500 m (35,000 ft) should pose no problem to the healthy pregnant traveler. Since each airline has a policy regarding pregnancy and flying, it is best to check with the specific carrier when booking reservations. Domestic air travel is usually permitted until the 36th week, whereas international air travel is generally curtailed after the 32nd week.

There are no known risks for pregnant women who travel to high-altitude destinations and stay for short periods. However, there are likewise no data on the safety of pregnant women at altitudes>4500 m (15,000 ft). Because of the harsh conditions usually associated with such trips, they are generally contraindicated for other reasons.

THE HIV-INFECTED TRAVELER

The traveler infected with HIV is at special risk of serious infections due to a number of pathogens that may be more prevalent at travel destinations than at home. However, the degree of risk depends primarily on the state of the immune system at the time of travel. For persons whose CD4+ cell counts are normal or>500/uL, no data suggest a greater risk during travel than for persons without HIV infection. Individuals with AIDS (CD4+ counts <200/uL) and others who are symptomatic need special counseling and should visit a travel medicine practitioner before departure, especially when traveling to the developing world.

Several countries now routinely deny entry to HIV-positive individuals, even though no data show that these restrictions decrease rates of transmission of the virus. In general, HIV testing is required of those individuals who wish to stay abroad longer than 3 months or who intend to work or study abroad. Some countries will accept an HIV serologic test done within 6 months of departure, whereas others will not accept a blood test done at any time in the traveler's home country. In addition, border officials often have the authority to make inquiries of individuals entering a country and to check the medications they are carrying. If a drug such as zidovudine (AZT) is identified, the person may be barred from entering the country. Information on testing requirements for specific countries is available from consular offices but is subject to frequent change.

Health insurance policies should be checked to make sure they are valid for care in other countries. The HIV-positive traveler should strongly consider obtaining trip cancellation insurance and evacuation insurance in case of illness. It is ideal to have the name of a physician at the travel destination who is familiar with the treatment of patients with AIDS, as the clinical findings associated with infection may be atypical in a

patient with AIDS, and several infections may exist simultaneously. The traveler should be encouraged to visit the physician promptly if problems arise.

Immunizations All of the HIV-infected traveler's routine immunizations should be up to date (Chap. 122). The response to immunization may be impaired at CD4+ cell counts of <200/uL (and in some cases at even higher counts). However, when the risk of illness is high or the sequelae of illness are serious, immunization is recommended. In certain circumstances, it may be prudent to check the adequacy of the serum antibody response before departure (e.g., yellow fever neutralization inhibition if exposure is unavoidable).

Because of the increased risk of infections due to *Streptococcus pneumoniae* and other bacterial pathogens that cause pneumonia following influenza, pneumococcal polysaccharide and influenza vaccines should be administered. The estimated rates of response to influenza vaccine are >80% among persons with asymptomatic HIV infection and<50% among those with AIDS.

In general, live attenuated vaccines are contraindicated for persons with immune dysfunction. Live oral polio vaccine should not be given to HIV-infected patients or to members of their households. Instead, inactivated polio vaccine (eIPV) should be used; most HIV-infected individuals without AIDS will develop protective antibody levels in response to this vaccine.

Because measles (rubeola) can be a severe and lethal infection in HIV-positive patients, the measles vaccine (or the combination measles-mumps-rubella vaccine) should be given to these individuals. Although this is a live vaccine, there have been no reports of serious complications in this population. Between 18 and 58% of symptomatic HIV-infected vaccinees develop adequate antibody titers, and between 50 and 100% of those who are infected but asymptomatic seroconvert.

The decision of whether or not to administer any of the special vaccines to an HIV-infected traveler should be based on the individual's risk. Inactivated vaccines can be administered without concern for safety but with concern about adequate protection. For example, data suggest that HIV-infected persons do not have as strong an antibody response to the meningococcal meningitis vaccine as do uninfected persons. Moreover, few data are available on the efficacy of many of the other vaccines (e.g., those for hepatitis A, typhoid, and cholera).

It is recommended that the live yellow fever vaccine not be given to HIV-infected travelers. Nevertheless, when inadvertently administered to HIV-positive military personnel, this vaccine elicited no adverse reactions. Therefore, if the traveler's CD4+ count is >200/uL and travel in an endemic area is absolutely necessary, the vaccine can probably be administered safely. HIV-infected persons whose CD4+ count is<200/uL should be discouraged from traveling to endemic regions. If the traveler is passing through or traveling to an area where the vaccine is required but the disease risk is low, a physician's waiver should be issued. Bacille Calmette-Guerin vaccine should not be given because of reports of disseminated infection in HIV-infected persons.

A transient (days to weeks) burst of viremia has been demonstrated in HIV-infected

individuals following immunization with vaccines for such diseases as influenza, pneumococcal infection, and tetanus (Chap. 309). However, at this point, there is no evidence that this transient increase in viremia is detrimental over time. Furthermore, it is likely that immune activation associated with infection with the live organisms in question would result in increases in viremia of greater magnitude and duration than those associated with vaccination. Therefore, the vaccination recommendations discussed above need not be modified at this time.

Gastrointestinal Illness Decreased levels of gastric acid, abnormal gastrointestinal mucosal immunity, other complications of HIV infection, and medications taken by HIV-infected patients make traveler's diarrhea especially problematic in these individuals. Traveler's diarrhea is likely to occur more frequently, be more severe, and be more difficult to treat in association with HIV infection. *Salmonella*, *Shigella*, and *Campylobacter* infections are also more protracted and more often accompanied by bacteremia in HIV-infected persons.

Cryptosporidium (Chap. 218), a common cause of diarrhea in tropical countries, produces severe chronic diarrhea and cholecystitis with increased mortality among patients with AIDS. *Isospora belli* causes infections at high rates among AIDS patients in the developing world; this infection is associated with malabsorption, weight loss, and relapses after treatment. Persistent diarrhea due to microsporidiosis has been reported.

Because of these potential problems, the HIV-infected traveler must be careful to consume only appropriately prepared foods and beverages. In addition, this group of individuals may benefit from prophylaxis for traveler's diarrhea, using bismuth subsalicylate or a daily antibiotic (ideally a quinolone derivative) for short-term travel to the developing world. If the traveler is already taking a sulfonamide preparation for prophylaxis of *Pneumocystis* pneumonia, a regimen of self-treatment with a quinolone would be appropriate.

Other Travel-Related Infections Data are lacking on the severity of vector-borne diseases in HIV-infected individuals. Malaria is especially severe in asplenic and certain immunocompromised hosts, although increased severity has not been demonstrated in AIDS. *Babesia* infection is known to cause serious illness and to recur in HIV-infected patients; this tick-transmitted illness occurs in parts of the United States but is not known to be a widespread problem.

Visceral leishmaniasis (Chap. 215) has been reported in numerous HIV-infected travelers. Because the usual signs -- splenomegaly and hyperglobulinemia -- are nonspecific and may even be lacking, the diagnosis is difficult to make. In addition, serologic results are often negative. This infection is difficult to treat, and its associated mortality is high. Even short-term travelers to southern Europe have developed the illness; thus, the avoidance of sandfly bites is critical.

Certain respiratory illnesses, such as histoplasmosis and coccidioidomycosis, cause greater morbidity and mortality among patients with AIDS than in the general population. Though tuberculosis is common among HIV-infected persons (especially in developing countries), the acquisition of this infection by the short-term traveler is not a major concern. The possibility of acquiring *Legionella* infections from spas should be

considered, although no data confirm an increase in the severity of such infections in AIDS.

Finally, the HIV-infected traveler should always be cautioned about safe sexual practices, which may help prevent both the transmission of HIV to others and the acquisition by the traveler of other sexually transmitted diseases that may be drug resistant or may result in serious sequelae (e.g., syphilis).

Medications Adverse events due to medications and drug interactions are common and raise complex issues for HIV-infected persons. In addition, rates of cutaneous reaction are unusually high among patients with AIDS. Physicians advising these travelers need to consider the problems that may arise from the use of agents such as antimalarial drugs, medications for altitude acclimatization, or antidiarrheal compounds; one example is increased cutaneous sensitivity to sulfonamides. Since zidovudine is metabolized by hepatic glucuronidation, inhibitors of this process may elevate serum levels of the drug. Though quinine does not affect levels of zidovudine, there are no relevant data on chloroquine, primaquine, or mefloquine. Furthermore, it is not known whether the antagonistic effect of zidovudine on pyrimethamine has clinical relevance in the treatment or prevention of plasmodial infections.

CHRONIC ILLNESS, DISABILITY, AND TRAVEL

Evaluating fitness for travel is a growing issue in view of the increased number of elderly and chronically ill individuals journeying to exotic destinations. Conditions encountered during flight are of particular concern in these cases. Since most commercial aircraft are pressurized to 2500 m (8000 ft) above sea level, corresponding to a Pa_{O_2} of about 55 mmHg, individuals with serious cardiopulmonary problems should be evaluated before travel. In addition, those who have recently had surgery, a myocardial infarction, a cerebrovascular accident, or another medical crisis may be at high risk for adverse events in flight. A summary of current recommendations regarding fitness to fly has been published by the Aerospace Medical Association Air Transport Medical Committee. Chronic health problems should not prevent travel, but special measures can make the journey safer and more comfortable.

Heart Disease Cardiovascular events are the main cause of deaths among travelers and of in-flight emergencies on commercial aircraft. Persons with underlying heart disease should review their itineraries with a physician prior to departure; travel in harsh environments or to remote destinations is not wise. Extra supplies of all medications should be kept in carry-on luggage, along with a recent copy of an electrocardiogram and the name and telephone number of the traveler's physician at home. Pacemakers are not affected by airport security devices, but electronic telephone checks of pacemaker function cannot be transmitted by international satellites. The traveler may benefit from supplemental oxygen, which should be ordered by a physician (since oxygen delivery systems are not standard) 48 to 72 h before flight time. Personal oxygen tanks are not permitted on aircraft. Travelers should request aisle seating and should walk, perform stretching and flexing exercises, and remain hydrated during the flight to prevent venous thrombosis and pulmonary embolism.

Chronic Lung Disease Chronic obstructive pulmonary disease (COPD) is one of the

most common diagnoses in patients who require emergency-room evaluation for symptoms occurring during airline flights. Patients with COPD experience dyspnea, edema, wheezing, cyanosis, and chest pain. The best predictor of the development of these symptoms is the sea level Pa_{O2}. A Pa_{O2} of at least 72 mmHg corresponds to an in-flight Pa_{O2} of 55 mmHg when the cabin is pressurized to 2500 m (8000 ft). Therefore, if the traveler's baseline Pa_{O2} is<72 mmHg, the provision of supplemental oxygen during the flight should be considered. Pulmonary function is also maximized by continuing bronchodilator treatment and the use of glucocorticoids as prescribed. Contraindications to flight include active bronchospasm, lower respiratory infection, phlebitis, pulmonary hypertension, and recent thoracic surgery (within the preceding 3 weeks) or pneumothorax. Consideration should be given to decreasing the amount of outdoor activity at the destination if there is excessive air pollution.

Diabetes Mellitus Alterations in glucose control and changes in insulin requirements are common problems when diabetic patients travel. Changes in time zone, in the amount and timing of food intake, and in physical activity demand more vigilant assessment of metabolic control. The diabetic traveler should pack medication (including a bottle of regular insulin for emergencies), insulin syringes and needles, equipment and supplies for glucose monitoring, and snacks in carry-on luggage. Insulin is stable for about 3 months at room temperature but should be kept as cool as possible. The name and telephone number of the home physician and a card and necklace listing the medical problems and the type and dose of insulin used should accompany the traveler. When six or more time zones are crossed, insulin requirements may be temporarily altered, depending on food intake and physical activity. In traveling eastward (e.g., from the United States to Europe), the morning insulin dose on arrival may need to be decreased. The blood glucose can then be checked during the day to determine whether additional insulin is required. For flights westward, with lengthening of the day, an additional dose of regular insulin may be required. Comfortable footwear is essential for the diabetic traveler.

Other Special Groups Other groups for whom special travel measures are now being encouraged include patients undergoing dialysis, those with transplants, and those with other disabilities. Up to 13% of travelers have some disability, but few advocacy groups and tour companies dedicate themselves to this growing population. The key to safe travel in each case is adequate research ahead of time. Patients undergoing chronic ambulatory peritoneal dialysis may ship their dialysis solutions to their destinations before traveling. They should carry essential medical records as well as antibiotics for self-treatment of presumed peritonitis. Hemodialysis patients need to reserve appointments at dialysis centers prior to their departure from home. Travel by transplant recipients to distant destinations should ideally be scheduled at least 1 year after surgery, as most rejection episodes occur early. Medication interactions are a source of serious concern for these travelers, and appropriate medical information should be carried, along with the home physician's name and telephone number. Some travelers taking glucocorticoids carry stress doses in case they become ill. Immunization of these immunocompromised travelers may result in less than adequate protection against certain diseases. Thus, the traveler and physician must carefully consider which destinations are appropriate.

PROBLEMS AFTER RETURN

The most frequent medical problems encountered by travelers after their return home are diarrhea, fever, respiratory illnesses, and skin diseases. Frequently ignored problems are fatigue and emotional stress, especially in long-stay travelers. The approach to diagnosis requires some knowledge of geographic medicine, in particular the epidemiology and clinical presentation of infectious disorders. A geographic history should focus on the traveler's exact itinerary, including dates of arrival and departure; exposure history (food indiscretions, drinking-water sources, freshwater contact, sexual activity, animal contact, insect bites); location and style of travel (urban vs. rural, first-class hotel accommodation vs. camping); immunization history; and use of antimalarial chemosuppression.

DIARRHEA

Although extremely common, acute traveler's diarrhea is usually self-limited or amenable to antibiotic therapy. Bowel symptoms that persist after the traveler's return home have a less well-defined etiology and may require medical attention from a specialist. Infectious agents appear to be responsible for only a small proportion of cases with persistent bowel symptoms. Of the pathogens detected in these instances, *Giardia lamblia* (Chap. 218) is by far the most common; *Cyclospora cayetanensis*, *Cryptosporidium* spp., and *Entamoeba histolytica* are rare isolates. The most frequent causes of persistent diarrhea after travel are postinfectious sequelae, such as lactose intolerance or an irritable bowel syndrome. When no infectious etiology can be identified, a trial of metronidazole therapy for presumed giardiasis, a strict lactose-free diet for 1 week, or a several-week trial of high-dose hydrophilic mucilloid relieves the symptoms of many patients.

FEVER

Fever in a traveler who has returned from a malarious area should be considered a medical emergency because death from *P. falciparum* malaria can follow an illness of only several days' duration. Although "fever from the tropics" does not always have a tropical cause, malaria should be the first diagnosis considered. The risk of *P. falciparum* malaria is highest among travelers returning from Africa or Oceania and among those who become symptomatic within the first 2 months after return. Other important causes of fever after travel include viral hepatitis (hepatitis A and E), typhoid fever, bacterial enteritis, arbovirus infections (e.g., dengue fever), rickettsial infections (including tick and scrub typhus or Q fever) and -- in rare instances -- leptospirosis, acute HIV infection, and amebic liver abscess. In at least 25% of cases, no etiology can be found, and the illness resolves spontaneously. Clinicians should keep in mind that no present-day antimalarial agent guarantees protection from malaria and that some immunizations -- notably, those against typhoid and cholera -- are only partially protective.

As noted above, the approach to the febrile returned traveler begins with a detailed medical and geographic history. Knowing exact dates of arrival and departure from tropical areas enables the physician to ascertain the shortest and longest possible incubation periods for illnesses in the differential diagnosis. For example, a traveler who develops fever <1 week after arrival in a malarious area cannot have malaria because

the incubation period is too short, whereas a fever whose onset comes >2 weeks after departure from an endemic area cannot be dengue fever because the incubation period is too long. In the physical examination, particular attention should be given to the skin so as not to miss a subtle rash or eschar.

When no specific diagnosis is forthcoming, the following investigations may be helpful: complete blood count, liver function tests, thick/thin blood films for malaria (repeated twice if necessary), urinalysis, blood cultures (repeated once if necessary), and collection of an acute-phase serum sample to be held for later examination along with a paired convalescent-phase serum sample.

SKIN DISEASES

Pyodermas, sunburn, insect bites, skin ulcers, and cutaneous larva migrans are the most common skin conditions encountered in travelers after their return home. In those with persistent skin ulcers, the diagnoses of cutaneous leishmaniasis, mycobacterial infection, or fungal infection should be considered. Careful, complete inspection of the skin is important in detecting the rickettsial eschar in a febrile patient or the central breathing hole in a "boil" due to myiasis.

EMERGING INFECTIOUS DISEASES

In recent years, travel and commerce have fostered the worldwide spread of HIV infection, led to the reemergence of cholera as a global health threat, and created considerable fear about the possible spread of Ebola virus infection and plague. For travelers, there are more realistic concerns. One of the largest outbreaks of dengue fever ever documented is now raging in Latin America; schistosomiasis is being described in previously unaffected lakes in Africa; and antibiotic-resistant strains of sexually transmitted and enteric pathogens are emerging at an alarming rate in the developing world. As Nobel Laureate Dr. Joshua Lederberg pointed out, "The microbe that felled one child in a distant continent yesterday can reach yours today and seed a global pandemic tomorrow." The vigilant clinician understands that the importance of a thorough travel history cannot be overemphasized.

SECTION 2 -CLINICAL SYNDROMES: COMMUNITY-ACQUIRED INFECTIONS

124. SEPSIS AND SEPTIC SHOCK - *Robert S. Munford*

DEFINITIONS (See Table 124-1)

The host's reaction to invading microbes involves a rapidly amplifying polyphony of signals and responses that may spread beyond the invaded tissue. Fever or hypothermia, tachypnea, and tachycardia often herald the onset of *sepsis*, the systemic response to microbial invasion. When counterregulatory control mechanisms are overwhelmed, homeostasis may fail, and dysfunction of major organs may supervene (*severe sepsis*). Further regulatory imbalance leads to *septic shock*, which is characterized by hypotension as well as organ dysfunction. As sepsis progresses to septic shock, the risk of dying increases substantially. Sepsis is usually reversible, whereas patients with septic shock often succumb despite aggressive therapy.

The *systemic inflammatory response syndrome* (SIRS), as defined in the early 1990s by critical care specialists, may have an infectious or a noninfectious etiology. If infection is suspected or proven, a patient with SIRS is said to have sepsis.

ETIOLOGY

Sepsis can be a response to any class of microorganism. Microbial invasion of the bloodstream is not essential for the development of sepsis, since local or systemic spread of microbial signal molecules or toxins can also elicit the response. Blood cultures yield bacteria or fungi in ~20 to 40% of cases of severe sepsis and 40 to 70% of cases of septic shock. Individual gram-negative or gram-positive bacteria account for ~70% of these isolates; the remainder are fungi or a mixture of microorganisms (Table 124-2). In patients whose blood cultures are negative, the etiologic agent is often established by culture or microscopic examination of infected material from a local site. In some case series, a majority of patients with a clinical picture of severe sepsis or septic shock have had negative microbiologic data.

Factors that predispose to gram-negative bacillary bacteremia include diabetes mellitus, lymphoproliferative diseases, cirrhosis of the liver, burns, invasive procedures or devices, and treatment with drugs that cause neutropenia. Major risk factors for gram-positive bacteremia include vascular catheterization, the presence of indwelling mechanical devices, burns, and intravenous drug use. Fungemia occurs most often in immunosuppressed patients with neutropenia, often after broad-spectrum antimicrobial therapy. In patients who experience bacteremia, factors that increase the risk of developing severe sepsis include age (>50 years) and a primary pulmonary, abdominal, or neuromeningeal site of infection. Bacteremia that arises from an intravascular catheter or the urinary tract is less likely to induce severe sepsis.

EPIDEMIOLOGY

The septic response is now a contributing factor in>100,000 deaths per year in the United States. The incidence of severe sepsis and septic shock has increased over the last 15 years and is now probably between 300,000 and 500,000 cases per year.

Approximately two-thirds of cases occur in patients hospitalized for other illnesses. The increasing incidence of severe sepsis in the United States is attributable to the aging of the population, the increasing longevity of patients with chronic diseases, and the relatively high frequency with which sepsis develops in patients with AIDS. The widespread use of antimicrobial agents, glucocorticoids, indwelling catheters and mechanical devices, and mechanical ventilation also plays a role.

PATHOPHYSIOLOGY

The septic response is often triggered when microorganisms spread from the gastrointestinal tract or skin into contiguous tissues. Localized tissue infection may then lead to bacteremia or fungemia. Alternatively, microorganisms may be introduced directly into the bloodstream (for example, via intravenous catheters). In general, the septic response occurs when immune defenses fail to contain an invading microbe. Since most cases are triggered by microbes that do not ordinarily cause systemic disease in normal hosts (Table 124-2), deficiencies in nonadaptive host factors may be most important. The septic response may also be induced by microbial exotoxins that act as superantigens (e.g., toxic shock syndrome toxin 1;Chap. 139).

Microbial Signals Animals recognize certain microbial molecules as signals that microorganisms have invaded. Lipopolysaccharide (LPS, also called *endotoxin*) is the most potent and best-studied gram-negative bacterial signal molecule. A plasma protein (LPS-binding protein, or LBP) transfers LPS to CD14 on the surfaces of monocytes, macrophages, and neutrophils. This interaction rapidly triggers the production and release of mediators, such as tumor necrosis factor (TNF) a (see below), that amplify the LPS signal and transmit it to other cells and tissues. Soluble CD14 may also bind LPS in plasma and transfer it to cells that lack cell-surface CD14. The peptidoglycan and lipoteichoic acids of gram-positive bacteria, certain polysaccharides, extracellular enzymes, and toxins elicit responses in animals that are similar to those induced by LPS; some of these molecules may also bind CD14. CD14 thus attracts numerous non-self molecules to the surfaces of myeloid cells, greatly increasing the sensitivity with which these molecules can be recognized by the host. Evidence suggests that signal specificity occurs in or on the plasma membrane and is conferred, at least in part, by members of the toll-like receptor family of transmembrane proteins. Other innate immune mechanisms for recognizing microbial molecules include complement (principally the alternative pathway), mannose-binding protein, and C-reactive protein.

Host Responses The septic response involves complex interactions among microbial signal molecules, leukocytes, humoral mediators, and the vascular endothelium.

Cytokines Inflammatory cytokines amplify and diversify the response. These proteins can exert endocrine, paracrine, and autocrine effects (Chap. 305).TNF-astimulates leukocytes and vascular endothelial cells to release other cytokines (as well as additional TNF-a), to express cell-surface adhesion molecules, and to increase arachidonic acid turnover. Blood levels of TNF-a are high in most patients with severe sepsis or septic shock. Moreover, intravenous infusion of TNF-acan elicit many of the characteristic abnormalities of sepsis, including fever, tachycardia, tachypnea, leukocytosis, myalgias, and somnolence. In animals, larger doses of TNF-a induce shock, disseminated intravascular coagulation (DIC), and death. Specific TNF-a

antagonists can abrogate the septic response and prevent the deaths of experimental animals challenged with endotoxin.

AlthoughTNF-ais a central mediator, it is only one of many cytokines that contribute to the septic process. Interleukin (IL) 1b, for example, which exhibits many of the same activities as TNF-a, seems to play an increasingly significant role as sepsis intensifies. TNF-a, IL-1b, interferon-g, IL-8, and other cytokines probably interact synergistically with each other and with additional mediators. Moreover, some mediators (such as IL-1b and TNF-a) may enhance their own rates of synthesis by positive feedback. As sepsis progresses, the mixture of cytokines and other molecules becomes very complex: elevated blood levels of>50 molecules have been found in patients with septic shock. In animal models, the septic response can be interrupted by early interventions that neutralize one or another of its many components; this observation testifies to the importance of mediator interactions for the overall outcome. It has been much more difficult to rescue animals from severe sepsis and septic shock.

Phospholipid-Derived Mediators Arachidonic acid, released from membrane phospholipids by phospholipase A_2, is converted by the cyclooxygenase pathway into prostaglandins and thromboxanes. Prostaglandin E_2 and prostacyclin cause peripheral vasodilatation, whereas thromboxane is a vasoconstrictor and promotes platelet aggregation. Administration of the cyclooxygenase inhibitor ibuprofen for 48 h to patients with severe sepsis suppressed production of these metabolites and decreased body temperature, heart rate, and metabolic acidosis without reducing mortality. Leukotrienes are also potent mediators of ischemia and shock; the fact that the reaction to endotoxin challenge is normal in mice that lack the 5-lipoxygenase gene, however, casts doubt on the role of leukotrienes in the septic response.

Another important phospholipid-derived mediator is platelet-activating factor (PAF; 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphorylcholine). PAF potently stimulates neutrophil aggregation and degranulation, promotes platelet aggregation, and may contribute to tissue injury.

Coagulation Factors Intravascular fibrin deposition, thrombosis, andDIC are important features of the septic response.IL-6 and other mediators promote intravascular coagulation initially by inducing blood monocytes to express tissue factor (Chap. 62). When tissue factor is expressed on monocytes, it binds to factor VIIa to form an active complex that can convert factors X and IX to enzymatically active forms. The result is activation of both extrinsic and intrinsic clotting pathways, culminating in the generation of fibrin. Clotting is also favored by impaired function of the protein C-protein S inhibitory pathway and depletion of antithrombin, while fibrinolysis is prevented by increased plasma levels of plasminogen activator inhibitor 1. Thus, there may be a striking propensity to intravascular fibrin deposition, thrombosis, and bleeding (Chap. 146). Contact-system activation occurs during sepsis but contributes more to the development of hypotension than to DIC.

Complement C5a and other products of complement activation may promote neutrophil reactions such as chemotaxis, aggregation, degranulation, and oxygen-radical production. When administered to animals, C5a induces hypotension, pulmonary vasoconstriction, neutropenia, and vascular leakiness due in part to endothelial

damage.

Activation of the Vascular Endothelium Many tissues may be damaged by the septic response. The probable underlying mechanism is widespread vascular endothelial injury, with fluid extravasation and microthrombosis that decrease oxygen and substrate utilization by the affected tissues. Leukocyte-derived mediators and platelet-leukocyte-fibrin thrombi contribute to this injury, but the vascular endothelium itself seems to play an active role. Stimuli such asTNF-ainduce vascular endothelial cells to produce and release cytokines, procoagulant molecules,PAF, endothelium-derived relaxing factor (nitric oxide), and other mediators. In addition, regulated cell-adhesion molecules promote the adherence of neutrophils to endothelial cells. While these responses may attract phagocytes to infected sites and activate their antimicrobial arsenals, endothelial cell activation can also promote increased vascular permeability, microvascular thrombosis,DIC, and hypotension. Moreover, vascular integrity may be damaged by neutrophil enzymes (such as elastase) and toxic oxygen metabolites so that local hemorrhage ensues. Blocking the adhesion of leukocytes to endothelial cell surfaces, as with monoclonal antibodies to intercellular adhesion molecule 1, can prevent tissue necrosis in response to endotoxin administration in animals.

Septic Shock Much evidence now implicates nitric oxide, produced by inducible nitric oxide synthase (iNOS), as a mediator of septic shock in experimental animals and probably in humans. Mice that lack the *iNOS* gene may not be resistant to endotoxic shock, however. Other prominent hypotensive molecules are b-endorphin, bradykinin,PAF, and prostacyclin. Agents that inhibit the synthesis or action of each of these mediators can prevent or reverse endotoxic shock in animals. However, in clinical trials, neither a PAF receptor antagonist nor a bradykinin antagonist improved the survival rate of patients with septic shock, and a NOS inhibitor, L-N_G-methylarginine HCl, actually increased the mortality rate.

Control Mechanisms Elaborate host mechanisms regulate both microbial signals and the inflammatory response. While plasma LBP promotes the inflammatory response by facilitating the interaction ofLPS with monocyte cell-surface CD14, LBP and other plasma proteins (such as phospholipid transfer protein) also can prevent LPS signaling by transferring LPS molecules into plasma lipoprotein particles. The relative plasma concentrations of LPS, LBP, CD14, and lipoproteins may therefore govern the intensity with which LPS -- and probably other microbial molecules -- can trigger host responses. The mechanisms that control the inflammatory response are also complex, overlapping, and poorly understood. Glucocorticoids inhibit cytokine synthesis by monocytes in vitro and, when administered with or shortly after an inflammatory stimulus, may protect animals from septic shock. The increase in blood cortisol levels early in the septic response presumably plays a similar inhibitory role. In addition, certain cytokine antagonists may contribute. Blood levels ofIL-1 receptor antagonist (IL-1Ra) often greatly exceed those of circulating IL-1b, and this excess may result in inhibition of the binding of IL-1b to its receptors. Transforming growth factor b (TGF-b) and IL-10 can also inhibit LPS-induced responses by human monocytes in vitro and prevent endotoxic death in animals. Blood and tissue levels of prostaglandin E_2, TGF-b,a-melanocyte-stimulating hormone, cortisol, IL-1Ra, soluble TNF receptors, and IL-10 increase during the septic response, and these molecules probably act in concert

to diminish its intensity. In fact, very high concentrations of many anti-inflammatory molecules are found in the blood of patients with severe sepsis or septic shock, so that the net mediator balance in the blood of these extremely sick patients may actually be anti-inflammatory. In addition, blood leukocytes from patients with severe sepsis are often hyporesponsive to agonists such as LPS. In patients with severe sepsis, persistence of leukocyte hyporesponsiveness has been associated with an increased risk of dying. Research is needed to clarify the role of the anti-inflammatory response in the septic process.

CLINICAL MANIFESTATIONS

The manifestations of the septic response are usually superimposed on the symptoms and signs of the patient's underlying illness and primary infection. The systemic response to infection often intensifies over time from mild (sepsis) to extremely severe (septic shock). The rate at which the response increases may differ from patient to patient, and there are striking individual variations in its manifestations. For example, some patients with sepsis are normo- or hypothermic; the absence of fever is most common in neonates, in elderly patients, and in persons with uremia or alcoholism.

Hyperventilation is often an early sign. Disorientation, confusion, and other manifestations of encephalopathy may also develop early in the septic response, particularly in the elderly and in individuals with preexisting neurologic impairment. Focal neurologic signs are uncommon, although preexisting focal deficits may become more prominent.

Hypotension andDICpredispose to acrocyanosis and ischemic necrosis of peripheral tissues, most commonly the digits (Fig. 124-CD1). Cellulitis, pustules, bullae, or hemorrhagic lesions may develop when hematogenous bacteria or fungi seed the skin or underlying soft tissue (Fig. 124-CD2). Bacterial toxins may also be distributed hematogenously to elicit diffuse cutaneous reactions. On occasion, skin lesions may suggest specific pathogens. When sepsis is accompanied by cutaneous petechiae or purpura, infection with *Neisseria meningitidis* (or, less commonly, *Haemophilus influenzae*) should be suspected (Plate IID-44); in a patient who has been bitten by a tick while in an endemic area, petechial lesions also suggest Rocky Mountain spotted fever (Plate IID-45). A cutaneous lesion seen almost exclusively in neutropenic patients is ecthyma gangrenosum (Fig. 19-CD1), usually caused by *Pseudomonas aeruginosa*. It is a bullous lesion, surrounded by edema, that undergoes central hemorrhage and necrosis (Plate IID-57C). Histopathologic examination shows bacteria in and around the wall of a small vessel, with little or no neutrophilic response. Hemorrhagic or bullous lesions in a septic patient who has recently eaten raw oysters suggest *Vibrio vulnificus* bacteremia, while such lesions in a patient who has recently suffered a dog bite may indicate bloodstream infection due to *Capnocytophaga canimorsus* or *C. cynodegmi*. Generalized erythroderma in a septic patient suggests the toxic shock syndrome due to *Staphylococcus aureus* or *Streptococcus pyogenes*.

Gastrointestinal manifestations such as nausea, vomiting, diarrhea, and ileus may suggest acute gastroenteritis. Stress ulceration can lead to upper gastrointestinal bleeding. Cholestatic jaundice, with elevated levels of serum bilirubin (mostly conjugated) and alkaline phosphatase, may precede other signs of sepsis.

Hepatocellular or canalicular dysfunction appears to underlie most cases, and the results of hepatic function tests return to normal with resolution of the infection. Prolonged or severe hypotension may induce acute hepatic injury or ischemic bowel necrosis.

Many tissues may be unable to extract oxygen normally from the blood, so that anaerobic metabolism occurs despite near-normal mixed venous oxygen saturation. Blood lactate levels rise early, in part because of increased glycolysis with impaired clearance of the resulting lactate and pyruvate by the liver and kidneys. As hypoperfusion develops, tissue hypoxia generates more lactic acid, contributing to metabolic acidosis. The blood glucose concentration often increases, particularly in patients with diabetes, although impaired gluconeogenesis and excessive insulin release on occasion produce hypoglycemia. The cytokine-driven acute-phase response inhibits the synthesis of albumin and transthyretin while enhancing the production of C-reactive protein,LBP, fibrinogen, and complement components. Protein catabolism is often markedly accelerated.

MAJOR COMPLICATIONS

Cardiopulmonary Complications Ventilation-perfusion mismatching produces a fall in arterial P_{O_2}early in the course. Increasing alveolar capillary permeability results in an increased pulmonary water content, which decreases pulmonary compliance and interferes with oxygen exchange. Progressive diffuse pulmonary infiltrates and arterial hypoxemia (Pa_{O_2}/FI_{O_2},<200 mmHg) indicate the development of the acute respiratory distress syndrome (ARDS). ARDS develops in ~50% of patients with severe sepsis or septic shock. The failure of the respiratory muscles can exacerbate hypoxemia and hypercapnia. An elevated pulmonary capillary wedge pressure (>18 mmHg) suggests fluid volume overload or cardiac failure rather than ARDS. Pneumonia caused by viruses or by *Pneumocystis carinii* may be clinically indistinguishable from ARDS.

Sepsis-induced hypotension usually results from a generalized maldistribution of blood flow and blood volume and from hypovolemia that is due, at least in part, to diffuse capillary leakage of intravascular fluid. Other factors that may decrease effective intravascular volume include dehydration from antecedent disease or insensible fluid losses, vomiting or diarrhea, and polyuria. During early septic shock, systemic vascular resistance is usually elevated and cardiac output may be low. After fluid repletion, in contrast, cardiac output typically increases and systemic vascular resistance falls. Indeed, normal or increased cardiac output and decreased systemic vascular resistance distinguish septic shock from cardiogenic, extracardiac obstructive, and hypovolemic shock; other processes that can produce this combination include anaphylaxis, beriberi, cirrhosis, and overdoses of nitroprusside or narcotics (Chap. 38).

Depression of myocardial function, manifested as increased end-diastolic and systolic ventricular volumes with a decreased ejection fraction, develops within 24 h in most patients with severe sepsis. Cardiac output is maintained despite the low ejection fraction because ventricular dilatation permits a normal stroke volume. In survivors, myocardial function returns to normal over several days. Although myocardial dysfunction may contribute to hypotension, refractory hypotension is usually due to a low systemic vascular resistance, and death results from refractory shock or the failure

of multiple organs rather than from cardiac dysfunction per se.

Renal Complications Oliguria, azotemia, proteinuria, and nonspecific urinary casts are frequently found. Many patients are inappropriately polyuric; hyperglycemia may exacerbate this tendency. Most renal failure is due to acute tubular necrosis induced by hypotension or capillary injury, although some patients also have glomerulonephritis, renal cortical necrosis, or interstitial nephritis. Drug-induced renal damage may complicate therapy, particularly when hypotensive patients are given aminoglycoside antibiotics.

Coagulation Although thrombocytopenia occurs in 10 to 30% of patients, the underlying mechanism(s) are not understood. Platelet counts are usually very low (<50,000/uL) in patients withDIC; these low counts typically reflect diffuse endothelial injury or microvascular thrombosis.

Neurologic Complications When the septic illness lasts for weeks to months, "critical-illness" polyneuropathy may prevent weaning from ventilatory support and produce distal motor weakness. Electrophysiologic studies are diagnostic. Guillain-Barre syndrome, metabolic disturbances, and toxin activity must be ruled out.

LABORATORY FINDINGS

Abnormalities that occur early in the septic response may include leukocytosis with a left shift, thrombocytopenia, hyperbilirubinemia, and proteinuria. Leukopenia may develop. The neutrophils may contain toxic granulations (Fig. 124-CD3), Dohle bodies, or cytoplasmic vacuoles. As the septic response becomes more severe, thrombocytopenia worsens (often with prolongation of the thrombin time, decreased fibrinogen, and the presence of D-dimers, suggestingDIC), azotemia and hyperbilirubinemia become more prominent, and levels of aminotransferases rise. Active hemolysis suggests clostridial bacteremia, malaria, a drug reaction, or DIC; in the case of DIC, microangiopathic changes may be seen on a blood smear.

During early sepsis, hyperventilation induces respiratory alkalosis. With respiratory muscle fatigue and the accumulation of lactate, metabolic acidosis (with increased anion gap) typically supervenes. Evaluation of arterial blood gases reveals hypoxemia, which is initially correctable with supplemental oxygen but whose later refractoriness to 100% oxygen inhalation indicates right-to-left shunting. The chest radiograph may be normal or may show evidence of underlying pneumonia, volume overload, or the diffuse infiltrates ofARDS. The electrocardiogram may show only sinus tachycardia or nonspecific ST-T wave abnormalities.

Most diabetic patients with sepsis develop hyperglycemia. Severe infection may precipitate diabetic ketoacidosis, which may exacerbate hypotension (Chap. 333). Hypoglycemia occurs rarely. The serum albumin level, initially within the normal range, declines as sepsis continues. Serum lipid concentrations are often elevated. Hypocalcemia is rare.

DIAGNOSIS

There is no specific test. Diagnostically sensitive findings in a patient with suspected or proven infection include fever or hypothermia, tachypnea, tachycardia, and leukocytosis or leukopenia (Table 124-1); acutely altered mental status, thrombocytopenia, or hypotension also suggests the diagnosis. The septic response can be quite variable, however. In one study, 36% of patients with severe sepsis had a normal temperature, 40% had a normal respiratory rate, 10% had a normal pulse rate, and 33% had normal white blood cell counts. Moreover, the systemic responses of uninfected patients with other conditions may be similar to those characteristic of sepsis. Noninfectious etiologies ofSIRS(Table 124-1) include pancreatitis, burns, trauma, adrenal insufficiency, pulmonary embolism, dissecting or ruptured aortic aneurysm, myocardial infarction, occult hemorrhage, cardiac tamponade, post-cardiopulmonary bypass syndrome, anaphylaxis, and drug overdose.

Definitive etiologic diagnosis requires isolation of the microorganism from blood or a local site of infection. At least two blood samples (10 mL each) should be obtained (from different venipuncture sites) for culture. Because gram-negative bacteremia is typically low-grade (<10 organisms per milliliter of blood), multiple blood cultures or prolonged incubation of cultures may be necessary; *S. aureus* grows more readily and is detectable in blood cultures within 48 h in most instances. In many cases, blood cultures are negative; this result can reflect prior antibiotic administration, the presence of slow-growing or fastidious organisms, or the absence of microbial invasion of the bloodstream. In these cases, Gram's staining and culture of material from the primary site of infection or of infected cutaneous lesions may help establish the microbial etiology. The skin and mucosae should be examined carefully and repeatedly for lesions that might yield diagnostic information. With overwhelming bacteremia (e.g., pneumococcal sepsis in splenectomized individuals or fulminant meningococcemia), microorganisms are sometimes visible on buffy coat smears of peripheral blood.

Detection of endotoxin in blood by the limulus lysate test may portend a poor outcome, but this assay is not useful for diagnosing gram-negative bacterial infections, including gram-negative bacteremia. Although blood levels ofIL-6 also may correlate with prognosis, cytokine assays are poorly standardized and currently have limited clinical value.

TREATMENT

Patients in whom sepsis is suspected must be managed expeditiously. This task is best accomplished in an intensive care unit by personnel who are experienced in the care of the critically ill. Successful management requires urgent measures to treat the local site of infection, to provide hemodynamic and respiratory support, and to eliminate the offending microorganism. The outcome is also influenced by the patient's underlying disease, which should be managed aggressively.

Antimicrobial Agents Antimicrobial chemotherapy should be initiated as soon as samples of blood and other relevant sites have been cultured. The choice of initial therapy is based on knowledge of the likely pathogens at specific sites of local infection. Available information about patterns of antimicrobial susceptibility among bacterial isolates from the community, the hospital, and the patient also should be taken into account. It is important, pending culture results, to initiate empirical antimicrobial therapy

that is effective against both gram-positive and gram-negative bacteria (Table 124-3). Maximal recommended doses of antimicrobial drugs should be given intravenously, with adjustment for impaired renal function when necessary. When culture results become available, the regimen can often be simplified, as a single antimicrobial agent is frequently adequate for the treatment of a known pathogen. Most patients require antimicrobial therapy for at least 1 week; the duration of treatment is typically influenced by factors such as the site of tissue infection, the adequacy of surgical drainage, the patient's underlying disease, and the antimicrobial susceptibility of the bacterial isolate(s).

Removal of the Source of Infection Removal or drainage of a focal source of infection is essential. Sites of occult infection should be sought carefully. Indwelling intravenous catheters should be removed, the tip rolled over a blood agar plate for quantitative culture, and a new catheter inserted at a different site. Foley and drainage catheters should be replaced. The possibility of paranasal sinusitis (often caused by gram-negative bacteria) should be considered if the patient has undergone nasal intubation. In the neutropenic patient, cutaneous sites of tenderness and erythema, particularly in the perianal region, must be carefully sought. In patients with sacral or ischial decubitus ulcers, it is important to exclude pelvic or other soft-tissue pus collections (by computed tomography or magnetic resonance imaging, if necessary). In patients with severe sepsis arising from the urinary tract, sonography or computed tomography should be used to rule out ureteral obstruction, perinephric abscess, and renal abscess. These studies are not so urgent in patients with less severe urosepsis, provided that a clinical response is evident within 48 to 72 h.

Hemodynamic, Respiratory, and Metabolic Support (See also Chap. 38) The primary goal is to restore adequate oxygen and substrate delivery to the tissues. Adequate organ perfusion is essential. Effective intravascular volume depletion is common in patients with sepsis, and initial management of hypotension should include the administration of intravenous fluids, typically 1 to 2 L of normal saline over 1 to 2 h. The pulmonary capillary wedge pressure or the central venous pressure must be monitored in patients with refractory shock or underlying cardiac or renal disease. To avoid pulmonary edema, the pulmonary capillary wedge pressure should be maintained between 12 and 16 mmHg or the central venous pressure between 10 and 12 cmH_2O. The urine output rate should be kept above 30 mL/h by continuing fluid administration; a diuretic such as furosemide may be used if needed. In about one-third of patients, hypotension and organ hypoperfusion respond to fluid resuscitation; a reasonable goal is to maintain a mean arterial blood pressure of >60 mmHg (systolic pressure,>90 mmHg) and a cardiac index of^{3}4 (L/min)/m_2. If these guidelines cannot be met by volume infusion, inotropic and vasopressor therapy is indicated (Chap. 38). Circulatory adequacy is also assessed by clinical parameters (mentation, urine output, skin perfusion) and, when possible, by measurements of oxygen delivery and consumption.

Adrenal insufficiency should be considered in septic patients with refractory hypotension, fulminant *N. meningitidis* bacteremia, prior glucocorticoid use, disseminated tuberculosis, or AIDS. The cosyntropin (a_{1-24}-ACTH) stimulation test (Chap. 331) may suggest absolute or partial adrenal insufficiency. Supplemental hydrocortisone (50 mg intravenously every 6 h) may be given while the results of the cosyntropin test are awaited.

Ventilator therapy is indicated for progressive hypoxemia, hypercapnia, neurologic deterioration, or respiratory muscle failure. Sustained tachypnea (respiratory rate,>30 breaths/min) is frequently a harbinger of impending respiratory collapse; mechanical ventilation is often initiated to ensure adequate oxygenation, divert blood from the muscles of respiration, prevent aspiration of oropharyngeal contents, and reduce the cardiac afterload. Blood or erythrocyte transfusion is indicated if oxygen delivery is compromised by a low hemoglobin concentration (<8 to 10 g/dL).

Bicarbonate is sometimes administered for severe metabolic acidosis (arterial pH < 7.2).DIC, if complicated by major bleeding, should be treated with transfusion of fresh-frozen plasma and platelets. Successful treatment of the underlying infection is essential to reverse both acidosis and DIC.

These are consensus recommendations; none of these generally accepted components of resuscitative care has been validated in randomized clinical trials.

General Support In patients with prolonged severe sepsis (i.e., that lasting more than 2 or 3 days), nutritional supplementation may reduce the impact of protein hypercatabolism; available evidence favors the enteral delivery route. Recovery is also assisted by preventing skin breakdown, deep venous thrombosis, nosocomial infections, and stress ulcers.

Other Measures Despite aggressive management, many patients with severe sepsis or septic shock die. Two kinds of agents that may help prevent these deaths are being investigated: (1) drugs that neutralize bacterial endotoxin, thereby potentially benefiting the fraction (approximately half) of septic patients who have gram-negative bacterial infection, and (2) drugs that interfere with one or more mediators of the inflammatory response and may benefit all patients with sepsis.

Antiendotoxin Agents Lipid A, the toxic moiety of endotoxin, is conserved in theLPS of gram-negative bacteria. Despite much effort to develop drugs that bind lipid A and neutralize endotoxin in vivo, the potential of endotoxin as a target for therapeutic intervention remains controversial. In placebo-controlled clinical trials, two monoclonal antibodies to endotoxin did not prevent the death of patients with severe gram-negative bacterial sepsis. In retrospective studies, these antibodies did not bind to LPS with high affinity, and one was reported to be a polyreactive autoantibody. A theoretically more promising agent is bactericidal permeability-increasing protein, a human neutrophil protein that neutralizes the toxicity of lipid A and may be bactericidal to many gram-negative bacteria. In one clinical trial, this protein decreased morbidity and mortality among children with fulminant meningococcemia. Other investigational drugs include nontoxic lipid A analogs that reduce host responses to endotoxins and lipoproteins (such as high-density lipoprotein) that bind and neutralize endotoxin in the circulation and can remove it from the surfaces of myeloid cells.

Antimediator Agents Other adjunctive therapies are intended to control the inflammatory response, regardless of the microbial stimulus. However, numerous agents that directly or indirectly interfere with the actions of inflammatory mediators have not prevented the death of patients with severe sepsis or septic shock. Many

factors have probably contributed to the unsuccessful outcomes of these trials, including problems with study design (inappropriate end points, inadequate sample size, population heterogeneity, multiple covariates) and drug administration (wrong dose, time, or duration of administration). Anti-inflammatory drugs tested in clinical trials include methylprednisolone, ibuprofen, recombinant IL-1Ra, genetically engineered soluble receptors forTNF-a, and monoclonal antibodies to TNF-a. Because TNF-a andIL-1bdoubtless play key roles in antimicrobial host defense, neutralizing these cytokines could be detrimental in some cases. In addition, studies suggest that many anti-inflammatory molecules, including soluble TNF receptors and IL-1Ra, may already be present at high concentrations in the plasma of patients with septic shock. Identifying beneficial regimens of treatment with drugs that neutralize TNF-a and IL-1bmay therefore be very difficult. Clinical trials are testing drugs (antithrombin, activated protein C, tissue factor pathway inhibitor) intended to prevent or reverse microthombosis and evaluating regimens in which low doses of glucocorticoids are administered for prolonged periods.

All of the more recent clinical trials have enrolled patients with severe sepsis or septic shock. Neither the ability of adjunctive agents to prevent severe sepsis or septic shock in high-risk patients nor the value of combination therapy with two or more adjunctive drugs has been tested.

PROGNOSIS

Approximately 20 to 35% of patients with severe sepsis and 40 to 60% of patients with septic shock die within 30 days. Others die within the ensuing 6 months. Late deaths often result from poorly controlled infection, complications of intensive care, failure of multiple organs, or the patient's underlying disease.

Several prognostic stratification systems indicate that factoring in the patient's age, underlying condition, and various physiologic variables can yield estimates of the risk of dying of severe sepsis. Of the individual covariates, the severity of underlying disease most strongly influences the risk of dying. Septic shock is also a strong predictor of short- and long-term mortality. Case-fatality rates are similar for culture-positive and culture-negative severe sepsis.

PREVENTION

Prevention offers the best opportunity to reduce morbidity and mortality. Most episodes of severe sepsis and septic shock are nosocomial. These cases might be prevented by reducing the number of invasive procedures undertaken, by limiting the use (and duration of use) of indwelling vascular and bladder catheters, by reducing the incidence and duration of profound neutropenia (<500 neutrophils/uL), and by more aggressively treating localized nosocomial infections. Indiscriminate use of antimicrobial agents and glucocorticoids should be avoided, and optimal infection-control measures (Chap. 134) should be used. In addition, prompt and aggressive management of patients with sepsis is imperative. Studies indicate that 50 to 70% of patients who develop nosocomial severe sepsis or septic shock have experienced a less severe stage of the septic response (e.g.,SIRS, sepsis) on at least one previous day in the hospital. Research is needed to identify patients at high risk for severe sepsis and to develop adjunctive

agents that can damp the septic response before organ dysfunction or hypotension occurs.

125. FEVER OF UNKNOWN ORIGIN - *Jeffrey A. Gelfand*

DEFINITION AND CLASSIFICATION

Fever of unknown origin (FUO) was defined by Petersdorf and Beeson in 1961 as (1) temperatures >38.3°C (101°F) on several occasions; (2) a duration of fever of >3 weeks; and (3) failure to reach a diagnosis despite 1 week of inpatient investigation. While this classification has stood for more than 30 years, Durack and Street have proposed a new system for classification of FUO: (1) classic FUO; (2) nosocomial FUO; (3) neutropenic FUO; and (4) FUO associated with HIV infection (Table 125-1).

Classic FUO ClassicFUOcorresponds closely to the earlier definition of FUO, differing only with regard to the prior requirement for 1 week's study in the hospital. The new definition is broader, stipulating three outpatient visits or 3 days in the hospital without elucidation of a cause or 1 week of "intelligent and invasive" ambulatory investigation.

Nosocomial FUO In nosocomialFUO, a temperature of³38.3°C (101°F) develops on several occasions in a hospitalized patient who is receiving acute care and in whom infection was not manifest or incubating on admission. Three days of investigation, including at least 2 days' incubation of cultures, is the minimum requirement for this diagnosis.

Neutropenic FUO NeutropenicFUO is defined as a temperature of³38.3°C (101°F) on several occasions in a patient whose neutrophil count is <500/uL or is expected to fall to that level in 1 to 2 days. The diagnosis of neutropenic FUO is invoked if a specific cause is not identified after 3 days of investigation, including at least 2 days' incubation of cultures.

HIV-Associated FUO FUOassociated with HIV infection is defined by a temperature of³38.3°C (101°F) on several occasions over a period of>4 weeks for outpatients or>3 days for hospitalized patients with HIV infection. This diagnosis is invoked if appropriate investigation over 3 days, including 2 days' incubation of cultures, reveals no source.

Adoption of these categories ofFUO on a wide scale in the literature would allow a more rational compilation of data regarding these disparate groups. In the remainder of this chapter, the discussion will focus on classic FUO unless otherwise specified.

CAUSES OF CLASSIC FUO

Table 125-2 summarizes the findings of several large studies ofFUOcarried out since the advent of the antibiotic era, including a prospective study of 167 adult patients with FUO encompassing all 8 university hospitals in the Netherlands and using a standardized protocol in which the first author reviewed every patient. Coincident with the widespread use of antibiotics, increasingly useful diagnostic technologies -- both noninvasive and invasive -- have been developed. Newer studies reflect not only changing patterns of disease but also the impact of diagnostic techniques that make it possible to eliminate many patients with specific illness from the FUO category. The ubiquitous use of microbiologic cultures and the widespread use of potent broad-spectrum antibiotics may have decreased the number of infections causing FUO.

The wide availability of ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) has enhanced the detection of occult neoplasms and lymphomas in patients previously thought to have FUO. Likewise, the widespread availability of highly specific and sensitive immunologic testing has reduced the number of undetected cases of systemic lupus erythematosus and other autoimmune diseases.

Several generalizations can be made. Infections, especially extrapulmonary tuberculosis, remain the leading diagnosable cause ofFUO. Prolonged mononucleosis syndromes caused by Epstein-Barr virus, cytomegalovirus (CMV), or HIV are conditions whose consideration as a cause of FUO is sometimes confounded by delayed antibody responses. Intraabdominal abscesses (sometimes poorly localized) and renal, retroperitoneal, and paraspinal abscesses continue to be difficult to diagnose. Renal malacoplakia, with submucosal plaques or nodules involving the urinary tract, may cause FUO and is often fatal if untreated. It is associated with coliform infection, is seen most often in patients with defects of intracellular bacterial killing, and is treated with fluoroquinolones or trimethoprim-sulfamethoxazole. Occasionally, other organs may be involved. Osteomyelitis, especially where prosthetic devices have been implanted, and infective endocarditis must be considered. Although true culture-negative infective endocarditis is rare, one may be misled by slow-growing organisms of the HACEK group (*Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*;Chap. 150), *Bartonella* spp. (previously *Rochalimaea*), *Legionella* spp., *Coxiella burnetii*, *Chlamydia psittaci*, and fungi. Prostatitis, dental abscesses, sinusitis, and cholangitis continue to be sources of occult fever.

Fungal disease, most notably histoplasmosis involving the reticuloendothelial system, may causeFUO. FUO with headache should prompt examination of spinal fluid for *Cryptococcus neoformans*. Malaria (which may result from transfusion, the failure to take a prescribed prophylactic agent, or infection with a drug-resistant strain) continues to be a cause, particularly of nonsynchronized FUO. A related protozoan species, *Babesia*, may cause FUO and is increasing in incidence.

In most earlier series, neoplasms were the next most common cause ofFUOafter infections (Table 125-3). In the two most recent series, a decrease in the percentage of FUO cases due to malignancy was attributed to improvement in diagnostic technologies. This observation does not diminish the importance of considering neoplasia in the initial diagnostic evaluation of a patient with fever. A number of patients in these series had temporal arteritis, adult Still's disease, drug-related fever, and factitious fever. In recent series, approximately 25 to 30% of cases of FUO have remained undiagnosed. The general term *noninfectious inflammatory diseases* applies to systemic rheumatologic or vasculitic diseases such as polymyalgia rheumatica, lupus, and adult Still's disease as well as to granulomatous diseases such as sarcoidosis and Crohn's and granulomatous hepatitis.

In the elderly, multisystem disease is the most frequent cause ofFUO, giant cell arteritis being the leading etiologic entity in this category. Tuberculosis is the most common infection causing FUO in the elderly, and colon cancer is an important cause of FUO with malignancy.

Many diseases have been grouped in the various studies as "miscellaneous." On this list are drug fever, pulmonary embolism, factitious fever, familial Mediterranean fever, and Fabry's disease.

A drug-related etiology must be considered in any case of prolonged fever. Any febrile pattern may be elicited by a drug, and both relative bradycardia and hypotension are uncommon. Eosinophilia and/or rash is found in only one-fifth of patients with drug fever, which usually begins 1 to 3 weeks after the start of therapy and remits 2 to 3 days after therapy is stopped. Virtually all classes of drugs cause fever, but antimicrobials (especially b-lactam antibiotics), cardiovascular drugs (e.g., quinidine), antineoplastic drugs, and drugs acting on the central nervous system (e.g., phenytoin) are particularly common causes.

It is axiomatic that, as the duration of fever increases, the likelihood of an infectious cause decreases (Table 125-4). In a series of 347 patients referred to the National Institutes of Health from 1961 to 1977, only 6% had an infection. A significant proportion (9%) had factitious fevers -- i.e., fevers due either to false elevations of temperature or to self-induced disease. A substantial number of these factitious cases were in young women in the health professions. It is worth noting that 8% of the patients with prolonged fevers (some of whom had completely normal liver function studies) had granulomatous hepatitis, and 6% had adult Still's disease. After prolonged investigation, 19% of cases still had no specific diagnosis. A total of 27% of patients either had no actual fever during the weeks of inpatient observation or had an exaggerated circadian temperature rhythm without chills, elevated pulse, or other abnormalities.

The conditions that may be considered in a differential diagnosis of classicFUO in adults are listed in Table 125-5. This list applies strictly to the United States; the frequency of global travel underscores the need for a detailed travel history, and the continuing emergence of new infectious diseases makes this listing potentially incomplete.

SPECIALIZED DIAGNOSTIC STUDIES

Classic FUO Certain specific diagnostic maneuvers become critical in dealing with prolonged fevers. If factitious fever is suspected, electronic thermometers should be used, temperature-taking should be supervised, and simultaneous urine and body temperatures should be measured. Any tissue removed during prior relevant surgery should be reexamined; slides should be requested, and, if need be, paraffin blocks of fixed pathologic material should be reexamined and additional special studies performed. Relevant x-rays should be reexamined; reviewing of prior radiologic reports may be insufficient. Serum should be set aside in the laboratory as soon as possible and retained for future examination for rising antibody titers. *Febrile agglutinins* is a vague term that in most laboratories refers to serologic studies for salmonellosis, brucellosis, and rickettsial diseases. These studies are seldom useful, having low sensitivity and variable specificity. Rising titers of antibody to *Brucella* (Chap. 160) are usually diagnostic, but false-positive results may be obtained in typhoid fever, tularemia, and yersinial infections. Infection with *Brucella canis* may be missed with standard antibody tests for *Brucella*. *Salmonella* infection (Chap. 156) elevates antibody titers to the H and O antigens. High titers of antibody to the H antigen persist for years and may reflect previous infection or immunization. Serology for *Yersinia enterocolitica* may be

useful. The measurement of specific antirickettsial titers should be requested for the diagnosis of Rocky Mountain spotted fever and Q fever. Multiple blood samples (no fewer than three, rarely more than six), including samples for anaerobic culture, should be cultured in the laboratory for at least 2 weeks to ensure that any HACEK-group organisms that may be present have ample time to grow (Chap. 150). Lysis-centrifugation blood culture techniques should be employed in cases where prior antimicrobial therapy or fungal or atypical mycobacterial infection is suspected. Blood culture media should be supplemented with L-cysteine or pyridoxal to assist in the isolation of nutritionally variant streptococci. It should be noted that sequential cultures positive for multiple organisms may reflect self-injection of contaminated substances. Urine cultures, including cultures for mycobacteria, fungi, andCMV, are indicated. Blood, urine, or cerebrospinal fluid (CSF) can now be tested for a variety of pathogens such as CMV or hepatitis C virus by using the polymerase chain reaction (PCR) to amplify and hence detect viral nucleic acid (Chap. 121). Liver biopsy, even when the results of liver function studies are normal, should be considered and pursued if the diagnosis remains elusive. Specimens should be cultured for mycobacteria and fungi. Likewise, bone marrow biopsy (not simple aspiration) should be used to obtain specimens for histology and culture. The blood smear should be examined for *Plasmodium*, *Babesia*, *Trypanosoma*, *Leishmania*, and *Borrelia*.

In anFUOworkup, the erythrocyte sedimentation rate (ESR) should be determined. Striking elevation of the ESR and anemia of chronic disease are frequently seen in association with giant cell arteritis or polymyalgia rheumatica, common causes of FUO in patients over 50 years of age. Still's disease is also suggested by elevations of ESR, leukocytosis, and anemia and is often accompanied by arthralgias, polyserositis (pleuritis, pericarditis), lymphadenopathy, splenomegaly, and rash. Antinuclear antibody, antineutrophil cytoplasmic antibody, rheumatoid factor, and serum cryoglobulins should be measured to rule out other collagen vascular diseases and vasculitis. Another cause of an extremely high ESR may be a false-positive value attributable to a cold agglutinin with a broad thermal amplitude. The ESR test is nonspecific, yielding values that depend on certain serum proteins (most notably fibrinogen) known to interfere with the zeta-potential that keeps erythrocytes from clumping. When fibrinogen levels go up, the zeta-potential is inhibited, erythrocytes clump, and the ESR is high. A cold agglutinin, by binding to erythrocytes, can produce a false-positive agglutinin that mimics an acute-phase response; cold agglutinins may be seen in *Mycoplasma* and Epstein-Barr virus infections and in lymphomas.

With rare exceptions, the intermediate-strength purified protein derivative (PPD) skin test should be used to screen for tuberculosis in patients with classicFUO. Concurrent control tests, such as the CMI test (Connaught Labs, Swiftwater, PA), which is especially effective, should be employed. It should be kept in mind that both the PPD skin test and control tests may yield negative results in miliary tuberculosis, sarcoidosis, Hodgkin's disease, malnutrition, or AIDS. Noninvasive procedures should include an upper gastrointestinal contrast study with small-bowel follow-through and barium enema to include the terminal ileum and cecum. Chest x-rays should be repeated if new symptoms arise. In some cases, pulmonary function studies may be necessary. A diminished carbon monoxide diffusing capacity may indicate a restrictive lung disease such as sarcoidosis, even with a normal chest x-ray. In such cases, transbronchial biopsy may prove diagnostic. Flexible colonoscopy may be advisable, since colon

carcinoma is a cause of FUO and easily escapes detection by ultrasound andCT.

CTof the chest and abdomen should be performed. If a spinal or paraspinal lesion is suspected, however,MRI is preferred. MRI may be superior to CT in demonstrating intraabdominal abscesses and aortic dissection, but the relative utility of MRI and CT in the diagnosis of FUOis unknown. At present, it appears that abdominal CT, with oral and intravenous contrast, should be used unless MRI is specifically indicated. Arteriography may be useful for patients in whom systemic necrotizing vasculitis is suspected. Saccular aneurysms may be seen, most commonly in renal or hepatic vessels, and may permit diagnosis of arteritis when biopsy is difficult.Figure 125-1 shows a renal angiogram of a patient with polyarteritis nodosa. Ultrasonography of the abdomen is useful for the investigation of the hepatobiliary tract, kidneys, spleen, and pelvis. Echocardiography may be helpful in an evaluation for bacterial endocarditis, pericarditis, nonbacterial thrombotic endocarditis, and atrial myxomas. Transesophageal echocardiography is especially sensitive for these lesions.

Radionuclide scanning procedures using technetium (Tc) 99m sulfur colloid, gallium (Ga) 67 citrate, or indium (In) 111-labeled leukocytes or immunoglobulin may be useful in identifying and/or localizing inflammatory processes. In a recent study, Ga scintigraphy yielded useful diagnostic information in almost one-third of cases, and it was suggested that this procedure might actually be used before other imaging techniques if no specific organ is suspected of being abnormal. Tc bone scan should be undertaken to look for osteomyelitis or bony metastases;^{67}Ga scan may be used to identify sarcoidosis (Chap. 318) or *Pneumocystis carinii* (Chap. 209) in the lungs or Crohn's disease (Chap. 287) in the abdomen.^{111}In-labeled white blood cell (WBC) scan may be used to locate abscesses;^{111}In-labeled immunoglobulin scan also shows promise in this regard. With^{67}Ga,^{111}In-WBC, and^{111}In-immunoglobulin scans, false-positive and false-negative findings are common.

Biopsy of the liver and bone marrow should be considered routine in the workup ofFUO if the studies mentioned above are unrevealing or if fever is prolonged. It goes without saying that areas of suspected abnormality should be sampled for pathologic examination whenever practical. When possible, a section of the tissue block should be retained for further sections or stains.PCRtechnology makes it possible to identify and speciate mycobacterial DNA in paraffin-embedded, fixed tissues. Thus, in some cases, it is possible to make a retrospective diagnosis based on studies of long-fixed pathologic tissues. In a patient over age 50 (or occasionally in a younger patient) with the appropriate symptoms and laboratory findings, "blind biopsy" of one or both temporal arteries may yield a diagnosis of arteritis. If noted, tenderness or decreased pulsation should guide the selection of a site for biopsy. Lymph node biopsy may be helpful if nodes are enlarged, but inguinal nodes are often palpable and are seldom diagnostically useful.

Exploratory laparotomy has been performed when all other diagnostic procedures fail but has largely been replaced by modern imaging and guided-biopsy techniques. Laparoscopic biopsy may provide more adequate guided sampling of lymph nodes or liver.

Nosocomial FUO The primary considerations in diagnosing nosocomialFUO are the

underlying susceptibility of the patient coupled with the potential complications of hospitalization. The original surgical or procedural field is the place to begin a directed physical and laboratory examination for abscesses, hematomas, or infected foreign bodies. More than 50% of patients with nosocomial FUO are infected, and intravascular lines, septic phlebitis, and prostheses are all suspect. In this setting, the approach is to focus on sites where occult infections may be sequestered, such as the sinuses of intubated patients or a prostatic abscess in a man with a urinary catheter. *Clostridium difficile* colitis may be associated with fever and leukocytosis before the onset of diarrhea. In approximately 25% of patients with nosocomial FUO, the fever has a noninfectious cause. Among these causes are acalculous cholecystitis, deep vein thrombophlebitis, and pulmonary embolism. Drug fever, transfusion reactions, alcohol/drug withdrawal, adrenal insufficiency, thyroiditis, pancreatitis, gout, and pseudogout are among the many possible causes to consider. As in classic FUO, repeated meticulous physical examinations, coupled with focused diagnostic techniques, are imperative. Multiple blood, wound, and fluid cultures are mandatory. The pace of diagnostic tests is accelerated, and the threshold for procedures -- CTscans, ultrasonography,^{111}In-WBC scans, noninvasive venous studies -- is low. Even so, 20% of cases of nosocomial FUO may go undiagnosed.

Like diagnostic measures, therapeutic maneuvers must be swift and decisive, as many patients are already critically ill. Intravenous lines must be changed (and cultured), drugs stopped for 72 h, and empirical therapy started if bacteremia is a threat. In many hospital settings, empirical antibiotic coverage for nosocomial FUO now includes vancomycin for methicillin-resistant *Staphylococcus aureus* as well as broad-spectrum gram-negative coverage with piperacillin/tazobactam, ticarcillin/clavulanate, imipenem, or meropenem. Practice guidelines covering many of these issues have been published jointly by the Infectious Diseases Society of America (IDSA) and the Society for Critical Care Medicine and can be accessed on the IDSA website (http://www.idsociety.org/practice/index.html).

Neutropenic FUO (See also Chap. 85) Neutropenic patients are susceptible to focal bacterial and fungal infections, to bacteremic infections, to infections involving catheters (including septic thrombophlebitis), and to perianal infections. *Candida* and *Aspergillus* infections are common. Infections due to herpes simplex virus orCMV are sometimes causes ofFUO in this group. While the duration of illness may be short in these patients, the consequences of untreated infection may be catastrophic, with 50 to 60% infected, and 20% bacteremic. TheIDSA has published extensive practice guidelines covering these critically ill neutropenic patients; these guidelines appear on the website cited in the previous section. In these patients, severe mucositis, quinolone prophylaxis, colonization with methicillin-resistant *S. aureus*, obvious catheter-related infection, or hypotension would dictate the use of vancomycin plus ceftazidime or imipenem to provide empirical coverage for bacterial sepsis.

HIV-Associated FUO HIV infection alone may be a cause of fever. Infection due to *Mycobacterium avium* or *Mycobacterium intracellulare*, tuberculosis, toxoplasmosis,CMVinfection, *P. carinii* infection, salmonellosis, cryptococcosis, histoplasmosis, non-Hodgkin's lymphoma, and (of particular importance) drug fever are all possible causes ofFUO. Mycobacterial infection can be diagnosed by blood cultures and by liver, bone marrow, and lymph node biopsies. ChestCTshould be performed to

identify enlarged mediastinal nodes. Serologic studies may reveal cryptococcal antigen, and ^{67}Ga scan may help identify *P. carinii* pulmonary infection. More than 80% of HIV patients with FUO are infected, but drug fever and lymphoma remain important considerations.**Treatment of HIV-associated FUO depends on many factors and is discussed in Chap. 309.*

TREATMENT

The emphasis in patients with classicFUO is on continued observation and examination, with the avoidance of "shotgun" empirical therapy. Empirical treatment for endocarditis, for example, should be avoided unless there are specific reasons beyond fever to invoke this diagnosis. Every patient with FUO should undergo an exhaustive examination for tuberculosis. If thePPD skin test is positive or if granulomatous hepatitis or other granulomatous disease is present with anergy (and sarcoid seems unlikely), then a therapeutic trial with isoniazid and rifampin (and possibly a third drug) should be undertaken, with treatment usually continued for up to 6 weeks. A failure of the fever to respond over this period suggests an alternative diagnosis.

The response of rheumatic fever and Still's disease to aspirin and nonsteroidal anti-inflammatory agents (NSAIDs) may be dramatic. The effects of glucocorticoids on temporal arteritis, polymyalgia rheumatica, and granulomatous hepatitis are equally dramatic. Colchicine is highly effective in preventing attacks of familial Mediterranean fever but is of little use once an attack is well under way. The ability of glucocorticoids and NSAIDs to mask fever while permitting the spread of infection dictates that their use be avoided unless infection has been largely ruled out and unless inflammatory disease is both probable and debilitating or threatening.

When no underlying source ofFUO is identified after prolonged observation (>6 months), the prognosis is generally good, however vexing the fever may be to the patient. Under such circumstances, debilitating symptoms are treated withNSAIDs, and glucocorticoids are the last resort. The initiation of empirical therapy does not mark the end of the diagnostic workup; rather, it commits the physician to continued thoughtful reexamination and evaluation. Patience, compassion, equanimity, and intellectual flexibility are indispensable attributes for the clinician in dealing successfully with FUO.

ACKNOWLEDGEMENT

Sheldon M. Wolff, MD, now deceased, was an author of a previous version of this chapter. It is to his memory that the chapter is dedicated.

126. INFECTIVE ENDOCARDITIS - *Adolf W. Karchmer*

INTRODUCTION

The proliferation of microorganisms on the endothelium of the heart results in infective endocarditis. The prototypic lesion at the site of infection, the *vegetation* (see Plate IID-59,Fig. 126-CD1), is a mass of platelets, fibrin, microcolonies of microorganisms, and scant inflammatory cells. Infection most commonly involves heart valves (either native or prosthetic) but may also occur on the low-pressure side of the ventricular septum at the site of a defect, on the mural endocardium where it is damaged by aberrant jets of blood or foreign bodies, or on intracardiac devices themselves. The analogous process involving arteriovenous shunts, arterioarterial shunts (patent ductus arteriosus), or a coarctation of the aorta is called *infective endarteritis*.

Endocarditis may be classified according to the temporal evolution of disease, the site of infection, the cause of infection, or a predisposing risk factor such as injection drug use. While each classification criterion provides therapeutic and prognostic insight, the methods overlap and none is sufficient alone. The classification of endocarditis as acute and subacute was initially used to describe the illness and the time elapsed until death; presently it is applied to the features and progression of infection until diagnosis. *Acute endocarditis* is a hectically febrile illness, rapidly damages cardiac structures, hematogenously seeds extracardiac sites, and, if untreated, progresses to death within weeks. *Subacute endocarditis* follows an indolent course; causes structural cardiac damage only slowly, if at all; rarely causes metastatic infection; and is gradually progressive unless complicated by a major embolic event or ruptured mycotic aneurysm.

In developed countries, the incidence of endocarditis ranges from 1.5 to 6.2 cases per 100,000 population per year. In the late 1980s in a metropolitan area of the United States (Philadelphia), endocarditis occurred in 9.3 persons per 100,000 population per year. However, half of these cases arose as a consequence of injection drug use. The incidence of endocarditis is notably increased among the elderly. The cumulative rate of prosthetic valve endocarditis is 1.5 to 3.0% at 1 year after valve replacement and 3 to 6% at 5 years; the risk is greatest during the first 6 months after valve replacement.

ETIOLOGY

A vast array of microorganisms, including many species of bacteria and fungi, have been reported to cause sporadic episodes of endocarditis. Nevertheless, a small number of bacterial species cause the majority of cases (Table 126-1). The causative microorganisms vary somewhat among the major clinical types of endocarditis, in part because of the different portals of entry. The oral cavity, skin, and upper respiratory tract are the respective primary portals for the viridans streptococci, staphylococci, and HACEK organisms (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*) causing community-acquired native valve endocarditis. *Streptococcus bovis* originates from the gastrointestinal tract, where it is associated with polyps and colonic tumors, and enterococci enter the bloodstream from the genitourinary tract. Nosocomial native valve endocarditis is largely the consequence of bacteremia arising from intravascular catheters and less commonly from nosocomial wound and urinary tract

infection. Endocarditis complicates 6 to 25% of episodes of catheter-associated *Staphylococcus aureus* bacteremia; higher rates are detected by careful transesophageal echocardiography (TEE) screening (see "Echocardiography," below).

Prosthetic valve endocarditis arising within 2 months of valve surgery is generally the result of intraoperative contamination of the prosthesis or a bacteremic postoperative complication. The nosocomial nature of these infections is reflected in their primary microbial causes: coagulase-negative staphylococci, *S. aureus*, facultative gram-negative bacilli, diphtheroids, and fungi. The portals of entry and organisms causing cases beginning >12 months after surgery are similar to those in community-acquired native valve endocarditis. Epidemiologic evidence suggests that prosthetic valve endocarditis due to coagulase-negative staphylococci that presents between 2 and 12 months after surgery is often nosocomial in origin but with a delayed onset. At least 85% of coagulase-negative staphylococci that cause prosthetic valve endocarditis within 12 months of surgery are methicillin-resistant; the rate of methicillin resistance decreases to 25% among coagulase-negative staphylococci causing prosthetic endocarditis that presents >1 year after valve surgery.

Transvenous pacemaker lead and/or implanted defibrillator-associated endocarditis is usually a nosocomial infection. The majority of episodes occur within weeks of implantation or generator change and are caused by *S. aureus* or coagulase-negative staphylococci.

Endocarditis occurring among injection drug users, especially when infection involves the tricuspid valve, is commonly caused by *S. aureus* strains, many of which are methicillin-resistant. The causes of left-sided valve infection in addicts are more varied, and the involved valves have often been damaged by prior episodes of endocarditis. A number of these cases are caused by *Pseudomonas aeruginosa* and *Candida* species, and sporadic cases are due to unusual organisms such as *Bacillus*, *Lactobacillus*, and *Corynebacterium* species. Polymicrobial endocarditis occurs more frequently in injection drug users than in patients who do not inject drugs. The presence of HIV in this population does not significantly impact the causes of endocarditis.

From 5 to 15% of patients with endocarditis have negative blood cultures; in one-third to one-half of these cases, cultures are negative because of prior antibiotic exposure. The remainder of these patients are infected by fastidious organisms, such as pyridoxal-requiring streptococci (now designated *Abiotrophia* species), the gram-negative coccobacillary HACEK organisms, *Bartonella henselae*, or *Bartonella quintana*. Some fastidious organisms that cause endocarditis have characteristic epidemiologic settings (e.g., *Coxiella burnetii* in Europe, *Brucella* species in the Middle East). *Tropheryma whippelii* causes an indolent, culture-negative, afebrile form of endocarditis.

PATHOGENESIS

Unless it is injured, the normal endothelium is resistant to infection by most bacteria and to thrombus formation. Endothelial injury (e.g., at the site of impact of high-velocity jets or on the low-pressure side of a cardiac structural lesion) causes aberrant flow and allows either direct infection by virulent organisms or the development of an uninfected

platelet-fibrin thrombus -- a condition called *nonbacterial thrombotic endocarditis* (NBTE). The thrombus subsequently serves as a site of bacterial attachment during transient bacteremia. The cardiac lesions most commonly resulting in NBTE are mitral regurgitation, aortic stenosis, aortic regurgitation, ventricular septal defects, and complex congenital heart disease. These lesions result from rheumatic heart disease (particularly in the developing world, where rheumatic fever remains prevalent), mitral valve prolapse, degenerative heart disease, and congenital malformations. NBTE also arises as a result of a hypercoagulable state; this phenomenon gives rise to the clinical entity of *marantic endocarditis* (seen in patients with malignancy) and to bland vegetations complicating systemic lupus erythematosus and the antiphospholipid antibody syndrome.

Organisms that cause endocarditis generally enter the bloodstream from mucosal surfaces, the skin, or sites of focal infection. Except for more virulent bacteria (e.g., *S. aureus*) that can adhere directly to intact endothelium or exposed subendothelial tissue, microorganisms in the blood adhere to thrombi. If resistant to the bactericidal activity of serum and the microbicidal peptides released by platelets, the organisms proliferate and either stimulate tissues to produce a procoagulant or themselves exert procoagulant activity leading to further platelet-fibrin deposition and vegetation formation. Although an enormous variety of microorganisms circulate transiently in the bloodstream, only a limited number commonly cause endocarditis. The etiologic organisms of endocarditis bear surface components that facilitate adherence to injured endothelium and host proteins or to thrombi. Experiments suggest that fibronectin receptors present on many gram-positive bacteria, clumping factor (a fibrinogen-binding surface protein) on *S. aureus*, and dextrans on streptococci facilitate adherence. Organisms become enmeshed in the growing platelet-fibrin vegetation and, in the absence of host defenses, proliferate to form dense microcolonies. More than 90% of the organisms in vegetations are metabolically inactive (nongrowing) and thus are relatively resistant to killing by antimicrobial agents. Proliferating surface organisms are shed into the bloodstream continuously, whereupon some are cleared by the reticuloendothelial system and others are redeposited on the vegetation and stimulate further vegetation growth.

The pathophysiologic consequences and clinical manifestations of endocarditis -- other than constitutional symptoms, which are probably a result of cytokine production -- arise from damage to intracardiac structures; embolization of vegetation fragments, leading to infection or infarction of remote tissues; hematogenous infection of sites during bacteremia; and tissue injury due to the deposition of circulating immune complexes or immune responses to deposited bacterial antigens.

CLINICAL MANIFESTATIONS

The clinical syndrome of infective endocarditis is highly variable, may involve multiple organs, and spans a continuum between acute and subacute presentations. Native valve endocarditis (whether acquired in the community or nosocomially), prosthetic valve endocarditis, and endocarditis due to injection drug use share clinical and laboratory manifestations (Table 126-2). Although the relationship is not absolute, the causative microorganism is primarily responsible for the temporal course of endocarditis. b-Hemolytic streptococci, *S. aureus*, and pneumococci typically result in an acute course, although *S. aureus* occasionally causes subacute disease.

Endocarditis caused by *Staphylococcus lugdunensis* (a coagulase-negative species) or by enterococci may present acutely. Subacute endocarditis is typically caused by viridans streptococci, enterococci, coagulase-negative staphylococci, and the HACEK group. Endocarditis caused by *Bartonella* species and the agent of Q fever, *C. burnetii*, is exceptionally indolent.

The clinical features of endocarditis are nonspecific. However, these symptoms in a febrile patient with valvular abnormalities or a behavior pattern (injection drug use) that predisposes to endocarditis suggest the diagnosis, as do bacteremia with organisms that frequently cause endocarditis, otherwise unexplained arterial emboli, and progressive cardiac valvular incompetence. In patients with subacute presentations, fever is typically low-grade and rarely exceeds 39.4°C (103°F); in contrast, temperatures between 39.4 and 40°C (103 and 104°F) are often noted in acute endocarditis. Fever may be blunted or absent in patients who are elderly or severely debilitated or who have marked cardiac or renal failure.

Cardiac Manifestations Although heart murmurs are usually indicative of the predisposing cardiac pathology rather than of endocarditis, valvular damage and ruptured chordae may result in new regurgitant murmurs. In acute endocarditis involving a normal valve, murmurs are heard on presentation in only 30 to 45% of patients but ultimately are detected in 85%. Congestive heart failure develops in 30 to 40% of patients; it is usually a consequence of valvular dysfunction but occasionally is due to endocarditis-associated myocarditis or an intracardiac fistula. The temporal progression of heart failure is variable and depends upon the severity of valvular dysfunction; failure due to aortic valve dysfunction progresses more rapidly than that due to mitral valve dysfunction. Extension of infection beyond valve leaflets into adjacent annular or myocardial tissue results in perivalvular abscesses, which in turn may cause fistulae (from the root of the aorta into cardiac chambers or between cardiac chambers) with new murmurs. Abscesses may burrow from the aortic valve annulus through the epicardium, causing pericarditis. Extension of infection into paravalvular tissue adjacent to either the right or the noncoronary cusp of the aortic valve may interrupt the conduction system in the upper interventricular septum, leading to varying degrees of heart block. Although perivalvular abscesses arising from the mitral valve may potentially interrupt conduction pathways near the atrioventricular node or in the proximal bundle of His, such interruption occurs infrequently. Emboli to a coronary artery may result in myocardial infarction; nevertheless, embolic transmural infarcts are rare.

Noncardiac Manifestations (Figs. 19-CD2,124-CD2, and126-CD2) The classic nonsuppurative peripheral manifestations of subacute endocarditis are related to the duration of infection and, with early diagnosis and treatment, have become infrequent. In contrast, septic embolization mimicking some of these lesions (subungual hemorrhage, (Fig. 19-CD4). Osler's nodes,Fig. 126-CD3) is common in patients with acute *S. aureus* endocarditis (see Plate IID-58). Musculoskeletal symptoms, including nonspecific inflammatory arthritis and back pain, usually remit promptly with treatment but must be distinguished from the symptoms of focal metastatic infection. Hematogenously seeded focal infection may involve any organ but most often is clinically evident in the skin, spleen, kidneys, skeletal system, and meninges. Arterial emboli, which may be asymptomatic and discovered only at autopsy, are clinically

apparent in up to 50% of patients. Vegetations>10 mm in diameter (as measured by echocardiography) and those located on the mitral valve are more likely to embolize than are smaller or nonmitral vegetations. Embolic events -- often with infarction -- involving the extremities, spleen, kidneys (Fig. 126-1), bowel, or brain are often noted at presentation. With antibiotic treatment, the frequency of embolic events decreases from 13 per 1000 patient-days during the initial week to 1.2 per 1000 patient-days after the third week. Emboli occurring late during or after effective therapy do not in themselves constitute evidence of failed antimicrobial treatment. Neurologic symptoms, most often resulting from embolic strokes, occur in up to 40% of patients. Other neurologic complications include aseptic or purulent meningitis, intracranial hemorrhage due to hemorrhagic infarcts or ruptured mycotic aneurysms, seizures, and encephalopathy. Microabscesses in brain and meninges occur commonly in *S. aureus* endocarditis; surgically drainable abscesses are infrequent.

Immune complex deposition on the glomerular basement membrane causes diffuse hypocomplementemic glomerulonephritis and renal dysfunction, which typically improve with effective antimicrobial therapy. Embolic renal infarcts cause flank pain and hematuria but rarely cause renal dysfunction.

Manifestations of Specific Predisposing Conditions Among injection drug users, infection involving valves on the left side of the heart presents with the typical clinical features of endocarditis. In almost 50% of patients with endocarditis associated with injection drug use, infection is limited to the tricuspid valve. These patients present with fever, faint or no murmur, and (in 75% of cases) prominent pulmonary findings, including cough, pleuritic chest pain, nodular pulmonary infiltrates, and occasionally pyopneumothorax.

Nosocomial endocarditis (defined as that which results from hospital care within the prior month and most commonly presenting as intravascular catheter-associated bacteremia), if not associated with a retained intracardiac device, has typical manifestations. Endocarditis associated with flow-directed pulmonary artery catheters is often cryptic, with symptoms masked by comorbid critical illness, and is commonly diagnosed at autopsy. Transvenous pacemaker lead and/or implanted defibrillator-associated endocarditis commonly follows initial implantation or a generator unit change; may be associated with obvious or cryptic generator pocket infection; and results in fever, minimal murmur, and pulmonary symptoms similar to those encountered in addicts with tricuspid endocarditis.

Prosthetic valve endocarditis presents with typical clinical features. Cases arising within 60 days of valve surgery (early onset) lack peripheral vascular manifestations and may be obscured by comorbidity associated with recent surgery. In both early-onset and more delayed presentations, paravalvular infection is common and often results in partial valve dehiscence, regurgitant murmurs, congestive heart failure, or disruption of the conduction system.

DIAGNOSIS

The Duke Criteria The diagnosis of infective endocarditis is established with certainty only when vegetations obtained at cardiac surgery, at autopsy, or from an artery (an

embolus) are examined histologically and microbiologically. Nevertheless, a highly sensitive and specific diagnostic schema -- known as the *Duke criteria* -- has been developed on the basis of clinical, laboratory, and echocardiographic findings (Table 126-3). Documentation of two major criteria, of one major and three minor criteria, or of five minor criteria allows a clinical diagnosis of definite endocarditis. The diagnosis of endocarditis is rejected if an alternative diagnosis is established, if symptoms resolve and do not recur with £4 days of antibiotic therapy, or if surgery or autopsy after £4 days of antimicrobial therapy yields no histologic evidence of endocarditis. Illnesses not classified as definite endocarditis or rejected are considered cases of possible infective endocarditis. When pathologically confirmed cases have been scored retrospectively by these criteria, 90% fulfill the definition of definite or possible endocarditis; 10% are rejected (primarily because of an incomplete echocardiographic evaluation). In comparison with expert opinion, the Duke criteria identify cases considered to be endocarditis but also accept a small percentage of cases rejected by the experts. This potential for a false-positive diagnosis is the major deficiency in this schema when used clinically. If all patients with a diagnosis of definite or possible endocarditis are fully treated for endocarditis, this reduced specificity results in excess treatment for some patients. A modification of the schema has been proposed in order to increase its specificity without significantly reducing its sensitivity. This modification would require documentation of at least one major or three minor criteria for cases to be categorized as possible endocarditis.

The roles of bacteremia and echocardiographic findings in the diagnosis of endocarditis are appropriately emphasized in the Duke criteria. That multiple blood cultures obtained over time are positive is consistent with the known continuous low-density nature of bacteremia in patients with endocarditis (£100 organisms per milliliter). Among untreated endocarditis patients who ultimately have a positive blood culture, 95% of all blood cultures are positive, and in 98% of cases one of the initial two sets of cultures yields the microorganism. The diagnostic criteria attach significance to the species of organism isolated from blood cultures. To fulfill a major criterion, the isolation of an organism that causes both endocarditis and bacteremia in the absence of endocarditis (e.g., *S. aureus*, enterococci) must take place repeatedly (i.e., persistent bacteremia) and in the absence of a primary focus of infection. Organisms that rarely cause endocarditis but commonly contaminate blood cultures (e.g., diphtheroids, coagulase-negative species) must be isolated repeatedly if their isolation is to serve as a major criterion.

Blood Cultures Isolation of the causative microorganism from blood cultures is critical not only for diagnosis but also for determination of antimicrobial susceptibility and planning of treatment. In the absence of prior antibiotic therapy, a total of three blood culture sets, ideally with the first separated from the last by at least 1 h, should be obtained from different venipuncture sites over 24 h. If the cultures remain negative after 48 to 72 h, two or three additional blood cultures, including a lysis-centrifugation culture, should be obtained, and the laboratory should be asked to pursue fastidious microorganisms by prolonging incubation time and performing special subcultures. Empirical antimicrobial therapy should not be administered initially to hemodynamically stable patients with subacute endocarditis, especially those who have received antibiotics within the preceding 2 weeks; thus, if necessary, additional blood cultures can be obtained without the confounding effect of empirical treatment. Patients with

acute endocarditis or with deteriorating hemodynamics that may require urgent surgery should be treated empirically immediately after obtaining the initial three sets of blood cultures.

Non-Blood-Culture Tests for the Etiologic Agent Serologic tests can be used to identify some organisms causing endocarditis that are difficult to recover by blood culture: *Brucella*, *Bartonella*, *Legionella*, and *C. burnetii*. Pathogens can also be identified in vegetations by culture, by microscopic examination with special stains, and by use of polymerase chain reaction to recover unique microbial DNA or 16S rRNA.

Echocardiography Cardiac imaging with echocardiography allows anatomic confirmation of infective endocarditis, sizing of vegetations, detection of intracardiac complications, and assessment of cardiac function. A two-dimensional study with color flow and continuous as well as pulsed Doppler is optimal. Transthoracic echocardiography (TTE) is noninvasive and exceptionally specific; however, it cannot image vegetations<2 mm in diameter, and in 20% of patients it is technically inadequate because of emphysema or body habitus. Thus, TTE detects vegetations in only 65% of patients with definite clinical endocarditis (i.e., it has a sensitivity of 65%). Moreover, TTE is not adequate for evaluating prosthetic valves or detecting intracardiac complications. Transesophageal echocardiography (TEE) is safe and significantly more sensitive than TTE. It detects vegetations in>90% of patients with definite endocarditis; nevertheless, false-negative studies are noted in 6 to 18% of endocarditis patients. TEE is the optimal method for the diagnosis of prosthetic endocarditis or the detection of myocardial abscess, valve perforation, or intracardiac fistulae.

Experts favor echocardiographic evaluation of all patients with a clinical diagnosis of endocarditis; however, the test should not be used to screen patients with otherwise explained positive blood cultures or patients with unexplained fever. In patients with a low pretest likelihood of endocarditis (<5%), a high-qualityTTE that is negative is sufficient to exclude endocarditis. For patients whose habitus makes them difficult to study with TTE and for those who may have prosthetic valve endocarditis or who are at high risk of intracardiac complications,TEE is the preferred imaging modality. For patients with a pretest probability of endocarditis ranging from 5 to 50%, initial evaluation by TEE -- in lieu of a sequential strategy of TTE, which, if negative, will be followed by TEE -- is cost-effective. A negative TEE when endocarditis is likely does not exclude the diagnosis but rather warrants repetition of the study in 7 to 10 days with optimal multiplanar technique.

Other Studies Many laboratory studies that do not aid in diagnostic evaluation are nevertheless important in the management of patients with endocarditis; these studies include complete blood counts, creatinine measurement, chest radiography, and electrocardiography. The erythrocyte sedimentation rate, C-reactive protein level, circulating immune complex titer, and rheumatoid factor concentration are commonly increased in endocarditis (Table 126-2). Cardiac catheterization is useful only to assess coronary artery patency in older individuals who are to undergo surgery for endocarditis.

TREATMENT

Antimicrobial Therapy It is difficult to eradicate bacteria from the avascular vegetation

in infective endocarditis because this site is relatively inaccessible to host defenses and because the bacteria are nongrowing and metabolically inactive. Since all bacteria in the vegetation must be killed, therapy for endocarditis must be bactericidal and must be given for prolonged periods. Antibiotics are generally given parenterally and must reach high serum concentrations that will, through passive diffusion, lead to effective concentrations in the depths of the vegetation. The choice of effective therapy requires precise knowledge of the susceptibility of the causative microorganisms. The initiation of treatment before a cause is defined must balance the need to establish a microbiologic diagnosis against the potential progression of disease or the need for urgent surgery (see "Blood Cultures" above). The individual vulnerabilities of the patient should be weighed in the selection of therapy -- e.g., allergies, end-organ dysfunction, interactions with concomitant medications, and risks of adverse events.

Although given for several weeks longer, the regimens recommended for the treatment of endocarditis involving prosthetic valves (except for staphylococcal infections) are similar to those used to treat native valve infection (Table 126-4). Recommended doses and duration of therapy should be adhered to unless alterations are required by adverse events.

Organism-Specific Therapies

STREPTOCOCCI Although most strains of viridans streptococci and *S. bovis* that cause endocarditis are susceptible to penicillin [minimum inhibitory concentration (MIC) £0.1 ug/mL], recent reports indicate increasing penicillin resistance among viridans streptococci recovered from blood cultures. In the selection of optimal therapy, the penicillin MIC must be determined (Table 126-4). The 2-week penicillin/gentamicin regimen should not be used to treat complicated native valve infection or prosthetic valve endocarditis. Although small studies have suggested that a 2-week regimen of single daily doses of ceftriaxone (2 g IV) plus gentamicin (3 mg/kg) or netilmicin (4 mg/kg) is effective for penicillin-susceptible streptococcal endocarditis, the data are not sufficient to support routine use of this regimen. Penicillin/gentamicin is recommended for the treatment of endocarditis caused by group B streptococci.

ENTEROCOCCI Enterococci are resistant to oxacillin, nafcillin, and the cephalosporins and are inhibited only by penicillin, ampicillin, teicoplanin (not available in the United States), and vancomycin. To kill enterococci requires the synergistic interaction of a cell wall-active antibiotic (penicillin, ampicillin, vancomycin, or teicoplanin) that is effective at achievable serum concentrations and an aminoglycoside (gentamicin or streptomycin) to which the isolate does not exhibit high-level resistance. An isolate's resistance to cell wall-active agents or ability to replicate in the presence of gentamicin at³500 ug/mL or streptomycin at 2000 ug/mL -- a phenomenon called *high-level aminoglycoside resistance* -- indicates that the ineffective antimicrobial cannot participate in the interaction to produce killing. High-level resistance to gentamicin predicts that tobramycin, netilmicin, amikacin, and kanamycin will also be ineffective. In fact, even when enterococci are not highly resistant to gentamicin, it is difficult to predict the ability of these other aminoglycosides to participate in synergistic killing; consequently, they should not in general be used to treat enterococcal endocarditis.

Clearly, enterococci causing endocarditis must be tested for high-level resistance to

streptomycin and gentamicin, b-lactamase production, and susceptibility to penicillin and ampicillin (MIC,£16 ug/mL) and to vancomycin (MIC,£8 ug/mL). If the isolate producesb-lactamase, ampicillin/sulbactam or vancomycin can be used as the cell wall-active component; if the penicillin/ampicillin MIC is>16 ug/mL, vancomycin can be considered; and if the vancomycin MIC is >8 ug/mL, penicillin or ampicillin may be considered. Based on the absence of high-level resistance, gentamicin or streptomycin should be used as the aminoglycoside. If there is high-level resistance to both these drugs, no aminoglycoside should be given; instead, an 8- to 12-week course of a single cell wall-active agent is suggested. If single-drug therapy fails or the isolate is resistant to all of the commonly used agents, surgical treatment is advised. The role of newer agents potentially active against multidrug-resistant enterococci (quinupristin/dalfopristin, linezolid, and daptomycin) in the treatment of endocarditis has not been established.

STAPHYLOCOCCI The regimens used to treat staphylococcal endocarditis are not based upon coagulase production but rather upon the presence or absence of a prosthetic valve or foreign device, the native valve(s) involved, and the resistance of the isolate to penicillin and methicillin. Penicillinase is produced by 95% of staphylococci; thus, all isolates should be considered penicillin-resistant until shown not to produce this enzyme. The addition of gentamicin (if the isolate is susceptible) to a b-lactam antibiotic to enhance therapy for native mitral or aortic valve endocarditis is optional. Its addition hastens eradication of bacteremia but does not improve survival rates. If added, gentamicin should be limited to the initial 3 to 5 days of therapy to avoid nephrotoxicity. Gentamicin generally is not added to the vancomycin regimen in this setting.

Methicillin-susceptible *S. aureus* endocarditis that is uncomplicated and limited to the tricuspid or pulmonic valve -- a condition occurring almost exclusively in injection drug users -- can often be treated with a 2-week course that combines oxacillin or nafcillin (but not vancomycin) with gentamicin. Prolonged fevers (³5 days) during therapy suggest that these patients should receive standard therapy.

Staphylococcal prosthetic valve endocarditis is treated for 6 to 8 weeks with a multidrug regimen. Rifampin is an essential component because it kills staphylococci that are adherent to foreign material. Two other agents (selected on the basis of susceptibility testing) are combined with rifampin to prevent in vivo emergence of resistance. Because many staphylococci, particularly methicillin-resistant *S. aureus* and *S. epidermidis*, are resistant to gentamicin, the utility of gentamicin should be established before rifampin treatment is begun. If the isolate is resistant to gentamicin, another aminoglycoside or a fluoroquinolone (chosen in light of susceptibility results) should be substituted.

OTHER ORGANISMS Although penicillin is the therapy of choice for endocarditis caused by *S. pneumoniae*, therapy should be initiated with ceftriaxone and vancomycin until susceptibility to penicillin is established. *P. aeruginosa* endocarditis is treated with an antipseudomonal penicillin (ticarcillin or piperacillin) and high doses of tobramycin (8 mg/kg per day in three divided doses). Endocarditis caused by Enterobacteriaceae is treated with a potentb-lactam antibiotic plus an aminoglycoside. Corynebacterial endocarditis is treated with penicillin plus an aminoglycoside (if the organism is susceptible to the aminoglycoside) or with vancomycin, which is highly bactericidal for most strains. Therapy for *Candida* endocarditis consists of amphotericin B plus

flucytosine and early surgery; long-term (if not indefinite) suppression with fluconazole is used increasingly.

Empirical Therapy In designing and executing therapy without culture data (i.e., before culture results are known or when cultures are negative), clinical and epidemiologic clues to etiology must be weighed, and both the pathogens associated with the specific endocarditis syndrome and the hazards of suboptimal therapy must be considered. Thus, empirical therapy for acute endocarditis in an injection drug user should cover methicillin-resistant *S. aureus* and gram-negative bacilli. The initiation of treatment with vancomycin plus gentamicin immediately after blood is obtained for cultures covers these as well as many other potential causes. In treating culture-negative episodes, marantic endocarditis must be excluded and fastidious organisms sought serologically. In the absence of confounding prior antibiotic therapy, it is unlikely that *S. aureus* or enterococcal infection will present with negative blood cultures. Thus, in this situation, these organisms are not the determinants of therapy for subacute endocarditis. Blood culture-negative native valve endocarditis is treated with ceftriaxone (or ampicillin) plus gentamicin; these two antimicrobials plus vancomycin should be used if prosthetic valves are involved.

Outpatient Antimicrobial Therapy Fully compliant patients who have sterile blood cultures, are afebrile during therapy, and have no clinical or echocardiographic findings that suggest an impending complication may complete therapy as outpatients. Careful follow-up and a stable home setting are necessary, as are predictable intravenous access and selection of antimicrobials that are stable in solution.

Monitoring Antimicrobial Therapy The serum bactericidal titer -- the highest dilution of the patient's serum during therapy that kills 99.9% of the standard inoculum of the infecting organism -- is no longer recommended for assessment of patients receiving standard regimens. However, in the treatment of endocarditis caused by unusual organisms, this measurement, although not standardized and difficult to interpret, may provide a patient-specific assessment of in vivo antibiotic effect. Serum concentrations of aminoglycosides and vancomycin should be monitored.

Antibiotic toxicities, including allergic reactions, occur in 25 to 40% of patients and commonly arise during the third week of therapy. Blood tests to detect antibiotic-specific potential end-organ toxicity should be performed periodically.

In most patients effective antibiotic therapy results in subjective improvement and resolution of fever within 5 to 7 days. Blood cultures should be repeated daily until sterile, rechecked if there is recrudescent fever, and performed again 4 to 6 weeks after therapy to document cure. Blood cultures become sterile within 2 days after the start of appropriate therapy when infection is caused by viridans streptococci, enterococci, or HACEK organisms. In *S. aureus* endocarditis,b-lactam therapy results in sterile cultures in 3 to 5 days, whereas positive cultures may persist for 7 to 9 days with vancomycin treatment. When fever persists for 7 days in spite of appropriate antibiotic therapy, patients should be evaluated for paravalvular abscess and for extracardiac abscesses (spleen, kidney) or complications (embolic events). Recrudescent fever raises the question of these complications but also of drug reactions or complications of hospitalization. Serologic abnormalities (e.g., erythrocyte sedimentation rate,

rheumatoid factor) resolve slowly and do not reflect response to treatment. Vegetations become smaller with effective therapy, but at 3 months after cure half are unchanged and 25% are slightly larger.

Surgical Treatment Intracardiac and central nervous system complications of endocarditis are important causes of the morbidity and mortality associated with this infection. In some cases, effective treatment for these complications requires surgery. Most of the clinical indications for surgical treatment of endocarditis are not absolute (Table 126-5). The risks and benefits as well as the timing of surgical treatment must therefore be individualized.

Intracardiac Surgical Indications Most surgical interventions are clearly warranted by intracardiac findings, often detected by echocardiography. Because of the highly invasive nature of prosthetic valve endocarditis, as many as 40% of affected patients merit surgical treatment. In many patients, coincident rather than single intracardiac events necessitate surgery.

CONGESTIVE HEART FAILURE Moderate to severe refractory congestive heart failure caused by new or worsening valve dysfunction is the major indication for cardiac surgical treatment of endocarditis. Of patients with moderate to severe heart failure due to valve dysfunction who are treated medically, 60 to 90% die within 6 months. In the setting of similar hemodynamic dysfunction, surgical treatment is associated with mortality rates of 20 to 40% with native valve endocarditis and 35 to 55% with prosthetic valve infection. Surgery may be required to relieve functional stenosis due to large vegetations or to restore competence to damaged regurgitant valves.

PERIVALVULAR INFECTION This complication, which occurs in 10 to 15% of native valve and 45 to 60% of prosthetic valve infections, is suggested by persistent unexplained fever during appropriate therapy, new electrocardiographic conduction disturbances, and pericarditis. Extension can occur from any valve but is most common with aortic valve infection.TEE with color Doppler is the test of choice to detect perivalvular abscesses (sensitivity, ³85%). Although occasional perivalvular infections are cured medically, surgery is warranted when fever persists, fistulae develop, prostheses are dehisced and unstable, and infection relapses after appropriate treatment. Cardiac rhythm must be monitored since high-grade heart block may require insertion of a pacemaker.

UNCONTROLLED INFECTION Continued positive blood cultures or otherwise unexplained persistent fevers (in patients with either blood culture-positive or -negative endocarditis) despite optimal antibiotic therapy may reflect uncontrolled infection and warrant surgery. Surgical treatment is also advised for endocarditis caused by those organisms against which clinical experience indicates that effective antimicrobial therapy is lacking. This category includes infections caused by yeasts, fungi, *P. aeruginosa*, other highly resistant gram-negative bacilli, *Brucella* species, and probably *C. burnetii*.

S. AUREUS ENDOCARDITIS Mortality rates for *S. aureus* prosthetic valve endocarditis exceed 70% with medical treatment but are reduced to 25% with surgical treatment. In patients with intracardiac complications associated with *S. aureus* prosthetic valve

infection, surgical treatment reduces mortality by twentyfold. Surgical treatment should be considered for patients with *S. aureus* native aortic or mitral valve infection who haveTTE-demonstrable vegetations and remain septic during the initial week of therapy. Isolated tricuspid valve endocarditis, even with persistent fever, rarely requires surgery.

PREVENTION OF SYSTEMIC EMBOLI Mortality and persisting morbidity due to emboli are largely limited to patients suffering occlusion of cerebral or coronary arteries. Echocardiographic determination of vegetation size and anatomy, although predictive of patients at high risk of systemic emboli, does not identify those patients in whom the benefits of surgery to prevent emboli clearly exceed the risks of the surgical procedure. Net benefits favoring surgery are most likely when the risk of embolism is high and other surgical benefits can be achieved simultaneously -- e.g., repair of a moderately dysfunctional valve or debridement of a paravalvular abscess.

Timing of Cardiac Surgery Surgery to correct valvular dysfunction and progressive congestive heart failure should not be delayed simply to permit additional antibiotic therapy, since this course of action increases the risk of mortality. Similarly, surgery should not be delayed when the indication is uncontrolled or perivalvular infection. Delay is justified only when infection is controlled and congestive heart failure is fully compensated with medical therapy. Recrudescent endocarditis involving a prosthetic valve follows surgery in 2% of patients with culture-positive native valve endocarditis and 15% of patients with active prosthetic valve endocarditis. These risks are more acceptable than the high mortality rates that result when surgery is inappropriately delayed or not performed.

Among patients who have experienced a neurologic complication of endocarditis, further neurologic deterioration can occur as a consequence of cardiac surgery. The risk of significant neurologic exacerbation is related to the interval between the complication and surgery. Where feasible, cardiac surgery should be delayed for 2 to 3 weeks after a nonhemorrhagic embolic stroke and for 4 weeks after a hemorrhagic embolic stroke. A ruptured mycotic aneurysm should be clipped and cerebral edema allowed to resolve prior to cardiac surgery.

Extracardiac Complications Splenic abscess develops in 3 to 5% of patients with endocarditis. Effective therapy requires either computed tomography-guided percutaneous drainage or splenectomy. Mycotic aneurysms occur in 2 to 15% of endocarditis patients; half of these cases involve the cerebral arteries and present as headaches, focal neurologic symptoms, or hemorrhage. Cerebral aneurysms should be monitored by angiography. Some will resolve, but those that persist, enlarge, or leak should be treated surgically if possible. Extracerebral aneurysms present as local pain, a mass, local ischemia, or bleeding; generally these aneurysms are treated by resection.

OUTCOME

The outcome of infective endocarditis is affected by a variety of factors, some of which are interrelated. Factors with an adverse impact include older age, severe comorbid conditions, delayed diagnosis, involvement of prosthetic valves or the aortic valve, an invasive (*S. aureus*) or antibiotic-resistant (*P. aeruginosa*, yeast) pathogen, intracardiac

complications, and major neurologic complications. Death and poor outcome often are related not to failure of antibiotic therapy but rather to the interactions of comorbidities and endocarditis-related end-organ complications. The overall survival rate for patients with native valve endocarditis caused by viridans streptococci, HACEK organisms, or enterococci (susceptible to synergistic therapy) ranges from 85 to 90%. For *S. aureus* native valve endocarditis in patients who do not inject drugs, survival rates are 55 to 70%, whereas 85 to 90% of injection drug users survive this infection. Prosthetic valve endocarditis beginning within 2 months of valve replacement results in mortality rates of 40 to 50%, whereas rates are only 10 to 20% in later-onset cases.

PREVENTION

Antibiotics have been administered in conjunction with selected procedures considered to entail a risk for bacteremia and endocarditis. The benefits of antibiotic prophylaxis are not established and in fact may be modest: only 50% of patients with native valve endocarditis knew that they had a valve lesion predisposing to infection, most endocarditis cases do not follow a procedure, and 35% of cases are caused by organisms not targeted by prophylaxis. Dental treatments, the procedures most widely accepted as predisposing to endocarditis, are no more frequent during the 3 months preceding this diagnosis than in uninfected matched controls. Nevertheless, an expert committee of the American Heart Association, along with similar advisory groups in other developed countries, has identified procedures that may precipitate bacteremia with organisms that cause endocarditis (Table 126-6), patients who should receive prophylaxis based on the relative risk for developing endocarditis and the severity of subsequent infection (Table 126-7), and regimens that may be used for prophylaxis (Table 126-8). Except for an isolated secundum atrial septal defect and a totally corrected patent ductus arteriosus, ventricular septal defect, or pulmonary stenosis, patients with congenital heart defects continue to experience high rates of endocarditis despite total surgical correction of the defect. In vulnerable patients, maintaining good dental hygiene and aggressively treating local infections may reduce the risk of endocarditis.

127. INFECTIOUS COMPLICATIONS OF BITES AND BURNS - *Lawrence C. Madoff*

The skin is an essential component of the nonspecific immune system, protecting the host from potential pathogens in the environment. Breaches in this protective barrier thus represent a form of immunocompromise that predisposes the patient to infection. Bites and scratches from animals and humans allow the inoculation of microorganisms past the skin's protective barrier into deeper, susceptible host tissues. Thermal burns may cause massive destruction of the integument as well as derangements in humoral and cellular immunity, enabling environmental opportunists and components of the host's own skin flora to cause infection.

ANIMAL BITES AND SCRATCHES

Each year in the United States, between 1 and 2 million animal-bite wounds are sustained; the vast majority are inflicted by pet dogs and cats, which number more than 100 million. Other bite wounds are a consequence of encounters with animals in the wild or in occupational settings. While many of these wounds require minimal or no therapy, a significant number result in infection, which may be life-threatening. The microbiology of bite-wound infections in general reflects the oropharyngeal flora of the biting animal, although organisms from the soil, the skin of the animal and victim, and the animal's feces may also be involved.

Dog Bites Dogs are responsible for approximately 80% of bite wounds, an estimated 15 to 20% of which become infected. A study for the period 1992 through 1994 found that dog bites resulted in more than 900 emergency department visits each day in the United States. Most dog bites are provoked and are inflicted by the victim's pet or by a dog known to the victim. These bites frequently occur during efforts to break up a dogfight. Victims tend to be male, and bites most often involve a lower extremity. Infection typically manifests 8 to 24 h after the bite as pain at the site of injury with cellulitis accompanied by purulent, sometimes foul-smelling discharge. Septic arthritis and osteomyelitis may develop if the canine tooth penetrates synovium or bone. Systemic manifestations such as fever, lymphadenopathy, and lymphangitis may also occur. The microbiology of dog-bite wound infections is usually mixed and includesa-hemolytic streptococci, *Pasteurella* spp., *Staphylococcus* spp., *Eikenella corrodens*, and *Capnocytophaga canimorsus* (formerly designated DF-2). Many wounds also include anaerobic bacteria such as *Actinomyces*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp.

While most infections resulting from dog-bite injuries are localized to the area of injury, many of the microorganisms involved are capable of causing systemic infection, including bacteremia, meningitis, brain abscess, endocarditis, and chorioamnionitis. These infections are particularly likely in hosts with edema or compromised lymphatic drainage in the involved extremity (e.g., following a bite on the arm after radical or modified radical mastectomy) and in patients who are immunocompromised by medication or disease (e.g., glucocorticoid use, systemic lupus erythematosus, acute leukemia, or hepatic cirrhosis). In addition, dog bites and scratches may result in systemic illnesses such as rabies (Chap. 197) and tetanus (Chap. 143).

Infection with *C. canimorsus* following dog-bite wounds may result in fulminant sepsis,

disseminated intravascular coagulation, and renal failure, particularly in hosts who have impaired hepatic function, who have undergone splenectomy, or who are immunosuppressed. This organism is a thin gram-negative rod that is difficult to culture on most solid media but grows in a variety of liquid media. The bacteria are occasionally seen within polymorphonuclear leukocytes on Wright-stained smears of peripheral blood from septic patients.

Cat Bites Although less common than dog bites, cat bites and scratches result in infection in more than half of all cases. Because the narrow, sharp feline incisors penetrate deeply into tissue, cat bites are more likely than dog bites to cause septic arthritis and osteomyelitis; the development of these conditions is particularly likely when punctures are located over or near a joint, especially in the hand. Women sustain cat bites more frequently than do men. These bites most often involve the hands and arms. Both bites and scratches from cats are prone to infection from organisms in the cat's oropharynx. *Pasteurella multocida*, a normal component of the feline oral flora, is a small gram-negative coccobacillus implicated in the majority of cat-bite wound infections. Like that of dog-bite wound infections, however, the microflora of cat-bite wound infections is usually mixed. Other microorganisms causing infection after cat bites are similar to those causing dog-bite wound infections.

The same risk factors for systemic infection following dog-bite wounds apply to cat-bite wounds. *Pasteurella* infections tend to advance rapidly, often within hours, causing severe inflammation accompanied by purulent drainage; *Pasteurella* may also be spread by respiratory droplets from animals, resulting in pneumonia or bacteremia. Like dog-bite wounds, cat-bite wounds may result in the transmission of rabies or in the development of tetanus. Infection with *Bartonella henselae* causes cat-scratch disease (Chap. 163) and is an important late consequence of cat bites and scratches. Tularemia (Chap. 161) has also been reported to follow cat bites.

Other Animal Bites Infections have been attributed to bites from many animal species, often as a consequence of occupational exposure (farmers, laboratory workers, veterinarians) or recreational exposure (hunters and trappers, wilderness campers, owners of exotic pets). Generally, the microflora of bite wounds reflects the oral flora of the biting animal. Most members of the cat family, including feral cats, harbor *P. multocida*. Bite wounds from aquatic animals such as alligators or piranhas may contain *Aeromonas hydrophila*. Venomous snakebites (Chap. 397) result in severe inflammatory responses and tissue necrosis -- conditions that render these injuries prone to infection. The snake's oral flora includes many species of aerobes and anaerobes, such as *Pseudomonas aeruginosa*, *Proteus* spp., *Staphylococcus epidermidis*, *Bacteroides fragilis*, and *Clostridium* spp. Bites from nonhuman primates are highly susceptible to infection with pathogens similar to those isolated from human bites (which are discussed later in this chapter). Bites from Old World monkeys (*Macaca*) may also result in the transmission of B virus (*Herpesvirus simiae*, cercopithecine herpesvirus), a cause of serious infection of the human central nervous system. Bites of seals, walruses, and polar bears may cause a chronic suppurative infection known as *seal finger*, which is probably due to one or more species of *Mycoplasma* colonizing these animals.

Small rodents, including rats, mice, and gerbils, as well as animals that prey on rodents may transmit *Streptobacillus moniliformis* (a microaerophilic, pleomorphic gram-negative

rod) or *Spirillum minor* (a spirochete), which cause a clinical illness known as *rat-bite fever*. The vast majority of cases in the United States are streptobacillary, whereas *Spirillum* infection occurs mainly in Asia.

In the United States, the risk of rodent bite mainly affects laboratory workers or inhabitants of rodent-infested dwellings (particularly children). Rat-bite fever is distinguished from acute bite-wound infection by its typical manifestation after the initial wound has healed. Streptobacillary disease follows an incubation period of 3 to 10 days. Fever, chills, myalgias, headache, and severe migratory arthralgias are usually followed by a maculopapular rash, which characteristically involves the palms and soles and may become confluent or purpuric. Complications include endocarditis, myocarditis, meningitis, pneumonia, and abscesses in many organs. *Haverhill fever* is an *S. moniliformis* infection acquired from contaminated milk or drinking water and has similar manifestations. Streptobacillary rat-bite fever was frequently fatal in the preantibiotic era. The differential diagnosis includes Rocky Mountain spotted fever, Lyme disease, leptospirosis, and secondary syphilis. The diagnosis is made by direct observation of the causative organisms in tissue or blood, by culture on enriched media, or by serologic testing with specific agglutinins.

Spirillum infection (referred to in Japan as *sodoku*) causes pain and purple swelling at the site of the initial bite, with associated lymphangitis and regional lymphadenopathy, after an incubation period of 1 to 4 weeks. The systemic illness includes fever, chills, and headache. The original lesion may eventually progress to an eschar. The infection is diagnosed by direct visualization of the spirochetes in blood or tissue or by animal inoculation.

Human Bites Human bites may be self-inflicted; may be sustained by medical personnel caring for patients; or may take place during fights, domestic abuse, or sexual activity. Human bites more frequently become infected than do bites inflicted by other animals. These infections reflect the diverse oral microflora of humans, which includes multiple species of aerobic and anaerobic bacteria. Common aerobic isolates include viridans streptococci, *Staphylococcus aureus*, *E. corrodens* (which is particularly common in clenched-fist injury; see below), and *Haemophilus influenzae*. Anaerobic species, including *Fusobacterium nucleatum* and *Prevotella*, *Porphyromonas*, and *Peptostreptococcus* spp., are isolated from 50% of human-bite wound infections; many of these isolates produceb-lactamases. The oral flora of hospitalized and debilitated patients often includes Enterobacteriaceae in addition to the usual organisms. Both HIV and hepatitis B virus have been reported to be transmitted by human bite, but these instances appear to be quite rare.

Human bites are categorized as "occlusional" injuries, which are inflicted by actual biting, and "clenched-fist" injuries, which are sustained when the fist of one individual strikes the teeth of another, causing traumatic laceration of the hand. For several reasons, clenched-fist injuries result in particularly serious infections. The deep spaces of the hand, including the bone, joint, and tendons, are frequently inoculated with organisms in the course of such injuries. The clenched position of the fist during injury, followed by extension of the hand, may further promote the introduction of bacteria as contaminated tendons retract beneath the skin's surface. Moreover, medical attention is often sought only after frank infection develops.

TREATMENT

Initial Assessment A careful history should be elicited, including the type of biting animal, the type of attack (provoked or unprovoked), and the amount of time elapsed since injury. Local and regional authorities should be contacted to determine whether an individual species could be rabid and/or to locate and observe the biting animal when rabies prophylaxis may be indicated (Chap. 197). Suspicious human-bite wounds should provoke careful questioning regarding domestic or child abuse. Details on antibiotic allergies, immunosuppression, splenectomy, liver disease, mastectomy, and immunization history should be obtained. The wound should be inspected carefully for evidence of infection, including redness, exudate, and foul odor. The type of wound (puncture, laceration, or scratch); the depth of penetration; and the possible involvement of joints, tendons, nerves, and bone should be assessed. It is often useful to include a diagram or photograph of the wound in the medical record. In addition, a general physical examination should be conducted and should include an assessment of vital signs as well as an evaluation for evidence of lymphangitis, lymphadenopathy, dermatologic lesions, and functional limitations. Injuries to the hand warrant consultation with a hand surgeon for the assessment of tendon, nerve, and muscular damage. Radiographs should be obtained when the bone may have been penetrated or a tooth fragment may be present. Culture and Gram's staining of all infected wounds are essential; anaerobic cultures should be undertaken if abscesses, devitalized tissue, or foul-smelling exudate is present. A small-tipped swab may be used to culture deep punctures or small lacerations. It is also reasonable to culture samples from uninfected wounds due to bites inflicted by animals other than dogs and cats, since the microorganisms causing disease are less predictable in these cases. A white blood cell count should be determined and blood cultured if systemic infection is suspected.

Wound Management Wound closure is controversial in bite injuries. Many authorities prefer not to attempt primary closure of wounds that are or may become infected, preferring to irrigate these wounds copiously, debride devitalized tissue, remove foreign bodies, and approximate the wound edges. Delayed primary closure may be undertaken after the risk of infection is over. Small uninfected wounds may be allowed to close by secondary intention. Puncture wounds due to cat bites should be left unsutured because of the high rate at which they become infected. Facial wounds are usually sutured after thorough cleaning and irrigation because of the importance of a good cosmetic result in this area and because anatomic factors such as an excellent blood supply and the absence of dependent edema lessen the risk of infection.

Antibiotic Therapy

Established Infection Antibiotics should be administered in all established bite-wound infections and should be chosen in light of the most likely potential pathogens, as indicated by the biting species and by Gram's stain and culture results (Table 127-1). For dog and cat bites, antibiotics should be effective against *S. aureus*, *Pasteurella* spp., *C. canimorsus*, streptococci, and oral anaerobes. For human bites, agents with activity against *S. aureus*, *H. influenzae*, andb-lactamase-positive oral anaerobes should be used. The combination of an extended-spectrum penicillin with ab-lactamase inhibitor (amoxicillin/clavulanic acid, ticarcillin/clavulanic acid, ampicillin/sulbactam) appears to

offer the most reliable coverage for these pathogens. Second-generation cephalosporins (cefuroxime, cefoxitin) also offer substantial coverage. The choice of antibiotics in penicillin-allergic patients (particularly those in whom immediate-type hypersensitivity makes the use of cephalosporins hazardous) is more difficult and is based primarily on in vitro sensitivity since data on clinical efficacy are inadequate. The combination of an antibiotic active against gram-positive cocci and anaerobes (such as clindamycin) with trimethoprim-sulfamethoxazole or a fluoroquinolone, which is active against many of the other potential pathogens, would appear reasonable. In vitro data suggest that either trovafloxacin or azithromycin alone provides coverage against most commonly isolated bite-wound pathogens.

Antibiotics are normally given for 10 to 14 days, but the response to therapy must be carefully monitored. Failure to respond should prompt a consideration of diagnostic alternatives and surgical evaluation for possible drainage or debridement. Complications such as osteomyelitis or septic arthritis mandate a longer duration of therapy.

Management of *C. canimorsus* sepsis requires a 2-week course of intravenous penicillin G (2 million units intravenously every 4 h) and supportive measures. Alternative agents for the treatment of *C. canimorsus* infection include cephalosporins and fluoroquinolones. Serious infection with *P. multocida* (e.g., pneumonia, sepsis, or meningitis) should also be treated with intravenous penicillin G. Alternative agents include second- or third-generation cephalosporins or ciprofloxacin.

Bites by venomous snakes may not require antibiotic treatment, but it is often difficult to distinguish signs of infection from tissue damage caused by the envenomation. Thus many authorities continue to recommend treatment directed against the snake's oral flora -- i.e., the administration of broadly active agents such as ceftriaxone (1 to 2 g intravenously every 12 to 24 h) or ampicillin/sulbactam (1.5 to 3.0 g intravenously every 6 h).

Seal finger appears to respond to doxycycline (100 mg twice daily for an interval guided by the response to therapy).

Presumptive or Prophylactic Therapy The use of antibiotics in patients presenting early after bite injury (within 8 h) is controversial. Although symptomatic infection will not yet be manifest in many of these wounds at this point, many early wounds will harbor pathogens, and many will become infected. Studies of the use of prophylactic antibiotics in wound infections are limited and have often included small numbers of cases in which various types of wounds have been managed according to various protocols. A recent meta-analysis of eight randomized trials of prophylactic antibiotics in patients with dog-bite wounds demonstrated a reduction of the rate of infection by approximately 50% with prophylaxis. However, in the absence of sound clinical trials, many clinicians base the decision to treat bite wounds with empirical antibiotics on the species of the biting animal; the location, severity, and extent of the bite wound; and the existence of comorbid conditions in the host. All human- and monkey-bite wounds should be treated presumptively because of the high rate of infection. Most cat-bite wounds, particularly those involving the hand, should be treated. Other factors favoring treatment for bite wounds include severe injury, as in crush wounds; potential bone or joint involvement; involvement of the hands or genital region; host immunocompromise, including that due

to liver disease or splenectomy; and prior mastectomy on the side of an involved upper extremity. When prophylactic antibiotics are administered, they are usually given for 3 to 5 days.

Rabies and Tetanus Prophylaxis Rabies prophylaxis, consisting of both passive administration of rabies immune globulin (with as much of the dose as possible infiltrated in and around the wound) and active immunization with rabies vaccine, should be given in consultation with local and regional public health authorities for many wild-animal (and some domestic-animal) bites and scratches as well as for certain nonbite exposures (Chap. 197). Rabies is endemic in a variety of animals, including dogs and cats in many areas of the world. Many local health authorities require the reporting of all animal bites. A tetanus booster immunization should be given if the patient has undergone primary immunization but has not received a booster dose in the past 5 years. Patients who have not previously completed primary immunization should be immunized and should also receive tetanus immune globulin. Elevation of the site of injury is an important adjunct to antimicrobial therapy. Immobilization of the infected area, especially the hand, is also beneficial.

BURNS

Epidemiology More than 2 million burn injuries are brought to medical attention in the United States each year. While many burn injuries are minor and require little or no intervention, approximately 70,000 persons are hospitalized for these injuries, and 20,000 of this number are burned severely enough to require admission to a specialized burn unit. Scalds, structural fires, and flammable liquids and gases are the major causes of burns, but electrical, chemical, and smoking-related sources are also important. Burns predispose to infection by damaging the protective barrier function of the skin, thus facilitating the entry of pathogenic microorganisms, and by inducing systemic immunosuppression. It is therefore not surprising that infectious complications are the major cause of morbidity and mortality in serious burn injury and that as many as 10,000 patients in the United States die of burn-related infections each year.

Pathophysiology Loss of the cutaneous barrier facilitates entry of the patient's own flora and of organisms from the hospital environment into the burn wound. The wound often contains devitalized or frankly necrotic tissue that quickly becomes contaminated with bacteria. Invasive infection -- localized and/or systemic -- occurs when bacteria penetrate viable tissue, usually below the eschar. Streptococci and staphylococci were the predominant causes of burn-wound infection in the preantibiotic era and remain important pathogens at present. With the advent of antimicrobial agents, *P. aeruginosa* became a major problem in burn-wound management. As antibiotics more effective against *Pseudomonas* have become available, fungi (particularly *Candida albicans*, *Aspergillus* spp., and the agents of mucormycosis) have emerged as increasingly important pathogens in burn-wound patients. Herpes simplex virus infection has also been found in burn wounds, especially on the face.

The frequency of infection parallels the extent and severity of burn injury. Severe burns cause defects in both cellular and humoral immunity that have a major impact on infection. For example, decreases in the number and activity of circulating helper T cells, increases in suppressor T cells, and diminution in levels of immunoglobulin follow

major burns. Neutrophil function has also been shown to be impaired after burns. The increased levels of multiple cytokines detected in burn patients are compatible with the widely held belief that the inflammatory response becomes dysregulated in these individuals. Increased permeability of the gut wall to bacteria and their components, such as endotoxin, also contributes to immune dysregulation and sepsis. Thus, the burn patient is predisposed to infection at remote sites (see below) as well as at the sites of burn injury.

Clinical Manifestations Since clinical indications of wound infection are difficult to interpret, wounds must be monitored carefully for changes that may reflect infection. A margin of erythema frequently surrounds the sites of burns and by itself is not usually indicative of infection. Signs of infection include the conversion of a partial-thickness to a full-thickness burn, color changes (e.g., the appearance of a dark brown or black discoloration of the wound), the new appearance of erythema or violaceous edema in normal tissue at the wound margins, the sudden separation of the eschar from subcutaneous tissues, and the degeneration of the wound with the appearance of a new eschar. The appearance of a green discoloration of the wound or subcutaneous fat or the development of ecthyma gangrenosum at a remote site points to a diagnosis of invasive *P. aeruginosa* infection. Changes in body temperature, hypotension, tachycardia, altered mentation, neutropenia or neutrophilia, thrombocytopenia, and renal failure may result from invasive burn wounds and sepsis. However, because profound alterations in homeostasis occur as a consequence of burns per se and because inflammation without infection is a normal component of these injuries, the assessment of these changes is complicated. Alterations in body temperature, for example, are attributable to thermoregulatory dysfunction; tachycardia and hyperventilation accompany the metabolic changes induced by extensive burn injury and are not necessarily indicative of bacterial sepsis.

Given the difficulty of evaluating burn wounds solely on the basis of clinical observation and laboratory data, wound biopsies are necessary for definitive diagnosis of infection. The timing of these biopsies can be guided by clinical changes, but in some centers burn wounds are routinely biopsied at regular intervals. The biopsy specimen is examined for histologic evidence of bacterial invasion, and quantitative microbiologic cultures are performed. The presence of $>10^5$ viable bacteria per gram of tissue is highly suggestive of invasive infection and of a dramatically increased risk of sepsis. Histopathologic evidence of invasion of viable tissue by microorganisms is a more definitive indicator of infection. A blood culture positive for the same organism seen in large quantities in biopsied tissue is a reliable indicator of burn sepsis. Surface cultures may provide some indication of the microorganisms present in the hospital environment but are not indicative of the etiology of infection.

In addition to infection of the burn wound itself, a number of other infections due to the immunosuppression caused by extensive burns and the manipulations necessary for clinical care put burn patients at risk. Pneumonia, now the most common infectious complication among hospitalized burn patients, is most often nosocomially acquired via the respiratory route; septic pulmonary emboli may also occur. Suppurative thrombophlebitis may complicate the vascular catheterization necessary for fluid and nutritional support in burns. Endocarditis, urinary tract infection, bacterial chondritis (particularly in patients with burned ears), and intraabdominal infection also complicate

serious burn injury.

TREATMENT

The ultimate goal of burn-wound management is closure and healing of the wound. Early surgical excision of burned tissue, with extensive debridement of necrotic tissue and grafting of skin or skin substitutes, greatly decreases the mortality associated with severe burns. In addition, the three widely used topical antimicrobial agents -- silver sulfadiazine cream, mafenide acetate cream, and silver nitrate -- dramatically decrease the bacterial burden of burn wounds and reduce the incidence of burn-wound infection; they are routinely applied to partial- and full-thickness burns. All three agents are broadly active against many bacteria and against some fungi and are useful before bacterial colonization is established. Silver sulfadiazine is often used initially, but its value can be limited by bacterial resistance. Mafenide acetate has broader activity; the cream penetrates eschars and thus can prevent or treat infection beneath the eschars. The foremost disadvantages of this agent are that it can inhibit carbonic anhydrase, resulting in metabolic acidosis, and that it elicits hypersensitivity reactions in up to 7% of patients. This agent is most often used when gram-negative bacteria invade the burn wound and when treatment with silver sulfadiazine fails.

When invasive wound infection is diagnosed, topical therapy should be changed to mafenide acetate. Subeschar clysis (the direct instillation of an antibiotic, often piperacillin, under the eschar into wound tissues) is a useful adjunct to surgical and systemic antimicrobial therapy. Systemic treatment with antibiotics active against the pathogens present in the wound should be instituted. In the absence of culture data, treatment is broad and should cover organisms commonly encountered in the particular burn unit. Usually such coverage is achieved with an antibiotic active against gram-positive pathogens, such as oxacillin (2 g intravenously every 4 h), and with antibiotics active against *P. aeruginosa* and other gram-negative rods, such as mezlocillin (3 g intravenously every 4 h) and gentamicin (5 mg/kg intravenously per day). In the penicillin-allergic patient, vancomycin (1 g intravenously every 12 h) may be substituted for oxacillin (and is efficacious when methicillin-resistant *S. aureus* is present), and ciprofloxacin (400 mg intravenously every 12 h) may be substituted for mezlocillin. Patients with burn wounds frequently have alterations in metabolism and renal clearance mechanisms that mandate the monitoring of serum antibiotic levels; the levels achieved with standard doses are often subtherapeutic.

In general, prophylactic systemic antibiotics have no role in the management of burn wounds (except for minor burns in outpatients) and can in fact lead to colonization with resistant microorganisms. An exception involves cases requiring burn-wound manipulation. Since procedures such as debridement, excision, or grafting frequently result in bacteremia, prophylactic systemic antibiotics are administered at the time of burn-wound manipulation; the particular agents used should be chosen on the basis of data obtained by wound culture or data on the hospital's resident flora. All burn-injury patients should undergo tetanus booster immunization if they have completed primary immunization but have not received a booster dose in the past 5 years. Patients without prior immunization should receive tetanus immune globulin and undergo primary immunization. Infection control measures play a major role in preventing burn-wound infection and limiting the spread of antibiotic-resistant nosocomial pathogens.

128. INFECTIONS OF THE SKIN, MUSCLE, AND SOFT TISSUES - *Dennis L. Stevens*

ANATOMIC RELATIONSHIPS: CLUES TO THE DIAGNOSIS OF SOFT TISSUE INFECTIONS

Protection against infection of the epidermis is dependent on the mechanical barrier afforded by the stratum corneum, since the epidermis itself is devoid of blood vessels (Fig. 128-1). Disruption of this layer by burns or bites (Chap. 127), abrasions, foreign bodies, primary dermatologic disorders (e.g., herpes simplex, varicella, and ecthyma gangrenosum), surgery, or vascular or pressure ulcer allows penetration of bacteria to the deeper structures. Similarly, the hair follicle can serve as a portal either for components of the normal flora (e.g., *Staphylococcus*) or for extrinsic bacteria (e.g., *Pseudomonas* in hot-tub folliculitis). Intracellular infection of the squamous epithelium with vesicle formation may arise from cutaneous inoculation, as in infection with herpes simplex virus (HSV) type 1; from the dermal capillary plexus, as in varicella and infections due to other viruses associated with viremia; or from cutaneous nerve roots, as in herpes zoster. Bacteria infecting the epidermis, such as *Streptococcus pyogenes*, may be translocated laterally to deeper structures via lymphatics, an event that results in the rapid superficial spread of erysipelas. Later, engorgement or obstruction of lymphatics causes flaccid edema of the epidermis, another characteristic of erysipelas.

The rich plexus of capillaries beneath the dermal papillae provides nutrition to the stratum germinativum, and physiologic responses of this plexus produce important clinical signs and symptoms. For example, infective vasculitis of the plexus results in petechiae, Osler's nodes (Fig. 126-CD3), Janeway lesions (Fig. 19-CD2), and palpable purpura, which are important clues to the existence of endocarditis (Chap. 126). In addition, metastatic infection within this plexus can result in cutaneous manifestations of disseminated fungal infection (Chap. 205), gonococcal infection (Chap. 147), *Salmonella* infection (Chap. 156), *Pseudomonas* infection (i.e., ecthyma gangrenosum; Chap. 155), meningococcemia (Chap. 146), and staphylococcal infection (Chap. 139). The plexus also provides access for bacteria to the circulation, thereby facilitating local spread or bacteremia. The postcapillary venules of this plexus are a major site of polymorphonuclear leukocyte sequestration, diapedesis, and chemotaxis to the site of cutaneous infection.

Exaggeration of these physiologic mechanisms by excessive levels of cytokines or bacterial toxins causes leukostasis, venous occlusion, and pitting edema. Edema with purple bullae, ecchymosis, and cutaneous anesthesia suggests loss of vascular integrity and necessitates exploration of the deeper structures for evidence of necrotizing fasciitis or myonecrosis. An early diagnosis requires a high level of suspicion in instances of unexplained fever and of pain and tenderness in the soft tissue, even in the absence of acute cutaneous inflammation.

INFECTIONS ASSOCIATED WITH VESICLES (Table 128-1)

Vesicle formation due to infection is caused by viral proliferation within the epidermis. In varicella and variola, viremia precedes the onset of a diffuse centripetal rash that progresses from macules to vesicles, then to pustules, and finally to scabs over the

course of 1 to 2 weeks. Vesicles of varicella have a "dewdrop" appearance and develop in crops randomly about the trunk, extremities, and face over 3 to 4 days. Herpes zoster occurs in a single dermatome; the appearance of vesicles is preceded by pain for several days. Zoster may occur in persons of any age but is most common among immunosuppressed individuals and elderly patients, whereas most cases of varicella occur in young children. Vesicles due toHSV are found on or around the lips (HSV-1) or genitals (HSV-2) but may appear on the head and neck of young wrestlers (herpes gladiatorum) or on the digits of health care workers (herpetic whitlow). Coxsackievirus A16 characteristically causes vesicles on the hands, feet, and mouth of children. Orf is caused by a DNA virus related to smallpox virus and infects the fingers of individuals who work around goats and sheep. Molluscum contagiosum virus induces flaccid vesicles on the skin of healthy and immunocompromised individuals.

Rickettsialpox begins following mite-bite inoculation of *Rickettsia akari* into the skin. A papule with a central vesicle evolves to form a 1- to 2.5-cm painless crusted black eschar with an erythematous halo and proximal adenopathy. While more common in the northeastern United States and the Ukraine in 1940-1950, rickettsialpox has recently been described in Ohio, Arizona, and Utah. Blistering dactylitis is a painful, vesicular, localized *Staphylococcus aureus* or group A streptococcal infection of the pulps of the distal digits of the hands.

INFECTIONS ASSOCIATED WITH BULLAE (Table 128-1)

Staphylococcal scalded-skin syndrome (SSSS) (Fig. 18-CD5) in neonates is caused by a toxin (exfoliatin) from phage group II *S. aureus*. SSSS must be distinguished from toxic epidermal necrolysis (TEN), which occurs primarily in adults, is drug-induced, and has a higher mortality. Punch biopsy with frozen section is useful in making this distinction since the cleavage plane is the stratum corneum in SSSS (Fig. 128-1) and the stratum germinativum in TEN. Intravenous g-globulin is a promising treatment for TEN. Necrotizing fasciitis and gas gangrene also induce bulla formation (see "Necrotizing Fasciitis," below). Halophilic vibrio infection can be as aggressive and fulminant as necrotizing fasciitis; a helpful clue in its diagnosis is a history of exposure to waters of the Gulf of Mexico or the Atlantic seaboard or (in a patient with cirrhosis) the ingestion of raw seafood. The etiologic organism (*Vibrio vulnificus*) is highly susceptible to tetracycline.

INFECTIONS ASSOCIATED WITH CRUSTED LESIONS (Table 128-1)

Impetigo contagiosa is caused by *S. pyogenes*, and bullous impetigo is due to *S. aureus* (Fig. 128-CD1). Both skin lesions may have an early bullous stage but then appear as thick crusts with a golden-brown color (Fig. 128-CD2). Streptococcal lesions are most common among children 2 to 5 years of age, and epidemics may occur in settings of poor hygiene, particularly among children of lower socioeconomic status in tropical climates. It is important to recognize impetigo contagiosa because of its relationship to poststreptococcal glomerulonephritis. Superficial dermatophyte infection (ringworm) can occur on any skin surface, and skin scrapings with KOH staining are diagnostic. Primary infections with dimorphic fungi such as *Blastomyces dermatitidis* and *Sporothrix schenckii* can initially present as crusted skin lesions resembling ringworm. Disseminated infection with *Coccidioides immitis* can also involve the skin, and biopsy

and culture should be performed on crusted lesions in patients from endemic areas. Crusted nodular lesions caused by *Mycobacterium chelonei* have been described in HIV-seropositive patients. Treatment with clarithromycin looks promising.

FOLLICULITIS (Table 128-1)

Hair follicles serve as a portal for a number of bacteria, though *S. aureus* is the most common cause of localized folliculitis (Fig. 128-CD3). Sebaceous glands empty into hair follicles and ducts and, if blocked, form sebaceous cysts, which may resemble staphylococcal abscesses or may become secondarily infected. Infection of sweat glands (hidradenitis suppurativa) can also mimic infection of hair follicles, particularly in the axillae. Chronic folliculitis is uncommon except in acne vulgaris, where constituents of the normal flora (e.g., *Propionibacterium acnes*) may play a role.

Diffuse folliculitis occurs in two settings. "Hot-tub folliculitis" (Fig. 128-CD4) is caused by *Pseudomonas aeruginosa* in waters that are insufficiently chlorinated and maintained at temperatures between 37 and 40°C. Infection is usually self-limited, though bacteremia and shock have been reported. Swimmer's itch occurs when a skin surface is exposed to water infested with freshwater avian schistosomes. Warm water temperatures and alkaline pH are suitable for mollusks that serve as intermediate hosts between birds and humans. Free-swimming schistosomal cercariae readily penetrate human hair follicles or pores but quickly die and elicit a brisk allergic reaction causing intense itching and erythema.

PAPULAR AND NODULAR LESIONS (Table 128-1)

Raised lesions of the skin occur in many different forms. *Mycobacterium marinum* infections of the skin may present as cellulitis or as raised erythematous nodules. Erythematous papules are early manifestations of cat-scratch disease (primary site of inoculation) and bacillary angiomatosis (*Bartonella henselae*). Raised serpiginous or linear eruptions are characteristic of cutaneous larva migrans, which is caused by burrowing larvae of dog or cat hookworms (*Ancylostoma braziliense*) and which humans acquire through contact with soil that has been contaminated with dog or cat feces. Similar burrowing raised lesions are present in dracunculiasis caused by migration of the adult female nematode *Dracunculus medinensis*. Nodules caused by *Onchocerca volvulus* may range from 1 to 10 cm in diameter and occur largely in persons bitten by *Simulium* flies in Africa. The nodules contain the adult worm encased in fibrous tissue. Migration of microfilariae into the eyes may result in blindness. Verruca peruana is caused by *Bartonella bacilliformis*, which is transmitted to humans by the sandfly *Phlebotomus*. This condition can take the form of single gigantic lesions (several centimeters in diameter) or multiple small lesions (several millimeters in diameter). Numerous subcutaneous nodules may also be present in cysticercosis caused by larvae of *Taenia solium*. Multiple erythematous papules develop in schistosomiasis; each represents a cercarial invasion site. Skin nodules as well as thickened subcutaneous tissue are prominent features of lepromatous leprosy. Large nodules or gummas are features of tertiary syphilis (Fig. 128-CD5), whereas flat papulosquamous lesions are characteristic of secondary syphilis. Human papillomavirus may cause singular warts (verruca vulgaris; Fig. 128-CD6) or multiple warts in the anogenital area (condylomata acuminata).

ULCERS WITH OR WITHOUT ESCHARS (Table 128-1)

Cutaneous anthrax begins as a pruritic papule, which develops within days into an ulcer with surrounding vesicles and edema and then into an enlarging ulcer with a black eschar. Cutaneous anthrax may cause chronic nonhealing ulcers with an overlying dirty-gray membrane, though lesions may also mimic psoriasis, eczema, or impetigo. Ulceroglandular tularemia may have associated ulcerated skin lesions with painful regional adenopathy. Although buboes are the major cutaneous manifestation of plague, in 25% of cases ulcers with eschars, papules, or pustules are also present.

Mycobacterium ulcerans typically causes chronic skin ulcers on the extremities of individuals living in the tropics. *Mycobacterium leprae* may be associated with cutaneous ulcerations in patients with lepromatous leprosy related to Lucio's phenomenon or during reversal reactions. *Mycobacterium tuberculosis* may also cause ulcerations, papules, or erythematous macular lesions of the skin in both normal and immunocompromised patients.

Decubitus ulcers are due to tissue hypoxia secondary to pressure-induced vascular insufficiency and may become secondarily infected with components of the skin and gastrointestinal flora, including anaerobes. Ulcerative lesions on the anterior shins may be due to pyoderma gangrenosum, which must be distinguished from similar lesions of infectious etiology by histologic evaluation of biopsy sites. Ulcerated lesions on the genitals may be either painful (chancroid) or painless (primary syphilis).

ERYSIPELAS (Table 128-1)

Erysipelas is due to *S. pyogenes* and is characterized by an abrupt onset of fiery-red swelling of the face or extremities. The distinctive features of erysipelas are well-defined indurated margins, particularly along the nasolabial fold; rapid progression; and intense pain. Flaccid bullae may develop during the second or third day of illness, but extension to deeper soft tissues is rare. Treatment with penicillin is effective; swelling may progress despite appropriate treatment, though fever, pain, and the intense red color diminish. Desquamation of the involved skin occurs 5 to 10 days into the illness. Infants and elderly adults are most commonly afflicted, and the severity of systemic toxicity varies.

CELLULITIS (Table 128-1)

Cellulitis is an acute inflammatory condition of the skin that is characterized by localized pain, erythema, swelling, and heat. Cellulitis may be caused by indigenous flora colonizing the skin and appendages (e.g., *S. aureus* and *S. pyogenes*) or by a wide variety of exogenous bacteria. Because the exogenous bacteria involved in cellulitis occupy unique niches in nature, a thorough history including epidemiologic data provides important clues to etiology. When there is drainage, an open wound, or an obvious portal of entry, Gram's stain and culture provide a definitive diagnosis. In the absence of these findings, the bacterial etiology of cellulitis is difficult to establish, and in some cases staphylococcal and streptococcal cellulitis may have similar features. Even with needle aspiration of the leading edge or a punch biopsy of the cellulitis tissue itself,

cultures are positive in only 20% of cases. This observation suggests that relatively low numbers of bacteria may cause cellulitis and that the expanding area of erythema within the skin may be a direct effect of extracellular toxins or of the soluble mediators of inflammation elicited by the host.

Bacteria may gain access to the epidermis through cracks in the skin, abrasions, cuts, burns, insect bites, surgical incisions, and intravenous catheters. Cellulitis caused by *S. aureus* spreads from a central localized infection, such as an abscess, folliculitis, or an infected foreign body (e.g., a splinter, a prosthetic device, or an intravenous catheter). In contrast, cellulitis due to *Staphylococcus pyogenes* is a more rapidly spreading, diffuse process frequently associated with lymphangitis and fever. Recurrent streptococcal cellulitis of the lower extremities may be caused by organisms of group A, C, or G in association with chronic venous stasis or with saphenous venectomy for coronary artery bypass surgery. Streptococci also cause recurrent cellulitis among patients with chronic lymphedema resulting from elephantiasis, lymph node dissection, or Milroy's disease. Recurrent staphylococcal cutaneous infections are more common among individuals who have eosinophilia and elevated serum levels of IgE (Job's syndrome) and among nasal carriers of staphylococci. Cellulitis caused by *S. agalactiae* (group B streptococci) occurs primarily in elderly patients and those with diabetes mellitus or peripheral vascular disease. *Haemophilus influenzae* typically causes periorbital cellulitis in children in association with sinusitis, otitis media, or epiglottitis. It is unclear whether this form of cellulitis will (like meningitis) become less common as a result of the impressive efficacy of the *H. influenzae* type b vaccine.

Many other bacteria also cause cellulitis. Fortunately, these organisms occur in such characteristic settings that a good history provides useful clues to the diagnosis. Cellulitis associated with cat bites and, to a lesser degree, with dog bites is commonly caused by *Pasteurella multocida*, though in the latter case *Staphylococcus intermedius* and *Capnocytophaga canimorsus* (formerly DF-2) must also be considered. Sites of cellulitis and abscesses associated with dog bites and human bites also contain a variety of anaerobic organisms, including *Fusobacterium*, *Bacteroides*, aerobic and anaerobic streptococci, and *Eikenella corrodens*. *Pasteurella* is notoriously resistant to dicloxacillin and nafcillin but is sensitive to all other b-lactam antimicrobials as well as to quinolones, tetracycline, and erythromycin. Ampicillin/clavulanate, ampicillin/sulbactam, and cefoxitin are good choices for the treatment of animal or human bite infections. *Aeromonas hydrophila* causes aggressive cellulitis in tissues surrounding lacerations sustained in fresh water (lakes, rivers, and streams). This organism remains sensitive to aminoglycosides, fluoroquinolones, chloramphenicol, trimethoprim-sulfamethoxazole, and third-generation cephalosporins; it is resistant to ampicillin, however.

P. aeruginosa causes three types of soft tissue infection: ecthyma gangrenosum in neutropenic patients, hot-tub folliculitis, and cellulitis following penetrating injury. Most commonly, *P. aeruginosa* is introduced into the deep tissues when a person steps on a nail. Treatment includes surgical inspection and drainage, particularly if the injury also involves bone or joint capsule. Choices for empirical treatment while antimicrobial susceptibility data are awaited include an aminoglycoside, a third-generation cephalosporin (ceftazidime, cefoperazone, or cefotaxime), a semisynthetic penicillin (ticarcillin, mezlocillin, or piperacillin), or a fluoroquinolone (though drugs of the last class are not indicated for the treatment of children <13 years old).

Gram-negative bacillary cellulitis, including that due to *P. aeruginosa*, is most common among hospitalized, immunocompromised hosts. Cultures and sensitivity tests are critically important in this setting because of multidrug resistance (Chap. 155).

The gram-positive aerobic rod *Erysipelothrix rhusiopathiae* is most often associated with fish and domestic swine and causes cellulitis primarily in bone renderers and fishmongers (Fig. 128-CD7). *E. rhusiopathiae* remains susceptible to most b-lactam antibiotics (including penicillin), erythromycin, clindamycin, tetracycline, and cephalosporins but is resistant to sulfonamides, chloramphenicol, and vancomycin. Its resistance to vancomycin, which is unusual among gram-positive bacteria, is of potential clinical significance since this agent is sometimes used in empirical therapy for skin infection. Fish food containing the water flea *Daphnia* is sometimes contaminated with *M. marinum*, which can cause cellulitis or granulomas on skin surfaces exposed to the water in aquariums or injured in swimming pools. Rifampin plus ethambutol has been an effective therapeutic combination in some cases, though no comprehensive studies have been undertaken. In addition, some strains of *M. marinum* are susceptible to tetracycline or to trimethoprim-sulfamethoxazole.

NECROTIZING FASCIITIS (Table 128-1,Fig. 18-CD4)

Necrotizing fasciitis, formerly called streptococcal gangrene, may be associated with group A *Streptococcus* or mixed aerobic-anaerobic bacteria or may occur as part of gas gangrene caused by *Clostridium perfringens*. Early diagnosis may be difficult when pain or unexplained fever is the only presenting manifestation. Swelling then develops and is followed by brawny edema and tenderness. With progression, dark red induration of the epidermis appears along with bullae filled with blue or purple fluid. Later the skin becomes friable and takes on a bluish, maroon, or black color. By this stage, thrombosis of blood vessels in the dermal papillae (Fig. 128-1) is extensive. Extension of infection to the level of the deep fascia causes this tissue to take on a brownish-gray appearance. Rapid spread occurs along fascial planes, through venous channels and lymphatics. Patients in the later stages are toxic and frequently manifest shock and multiorgan failure.

Necrotizing fasciitis caused by mixed aerobic-anaerobic bacteria begins with a breach in the integrity of a mucous membrane barrier, such as the mucosa of the gastrointestinal or genitourinary tract. The portal can be a malignancy, diverticulum, hemorrhoid, anal fissure, or urethral tear. Other predisposing factors include peripheral vascular disease, diabetes mellitus, surgery, and penetrating injury to the abdomen. Leakage into the perineal area results in a syndrome called *Fournier's gangrene*, characterized by massive swelling of the scrotum and penis with extension into the perineum or the abdominal wall and legs.

Necrotizing fasciitis caused by *S. pyogenes* has increased in frequency and severity since 1985. It frequently begins deep at the site of a nonpenetrating minor trauma such as a bruise or a muscle strain. Seeding of the site via transient bacteremia is likely, though most patients deny antecedent streptococcal infection. Alternatively, *S. pyogenes* may reach the deep fascia from a site of cutaneous infection or penetrating trauma. Toxicity is severe, and renal impairment may precede the development of

shock. In 20 to 40% of cases, myositis occurs concomitantly, and, as in gas gangrene (see below), serum creatinine phosphokinase values may be markedly elevated. Necrotizing fasciitis due to mixed aerobic-anaerobic bacteria may be associated with gas in the deep tissue, but gas is not usually present when the cause is *S. pyogenes*. Prompt surgical exploration down to the deep fascia and muscle is essential. Necrotic tissue must be surgically removed, and Gram's staining and culture of excised tissue are useful in establishing whether group A streptococci, mixed aerobic-anaerobic bacteria, or *Clostridium* spp. are present (see "Treatment" below).

MYOSITIS/MYONECROSIS (Table 128-1)

Muscle involvement can occur with virus infection (e.g., influenza virus, dengue virus, or coxsackievirus B) or parasitic invasion (e.g., trichinosis, cysticercosis, or toxoplasmosis). Although myalgia can occur in most of these infections, severe muscle pain is the hallmark of pleurodynia (coxsackie virus B), trichinosis, and bacterial infection. Acute rhabdomyolysis predictably occurs with clostridial and streptococcal myositis but may also be associated with influenza virus, echovirus, coxsackievirus, Epstein-Barr virus, and *Legionella* infection.

Pyomyositis is usually due to *S. aureus*, is common in tropical areas, and generally has no known portal of entry. Infection remains localized, and shock does not develop unless organisms produce toxic shock syndrome toxin 1 or certain enterotoxins and the patient lacks antibodies to the toxin produced by the infecting organisms. In contrast, *S. pyogenes* may induce primary myositis referred to as *streptococcal necrotizing myositis*, which is associated with severe systemic toxicity. Myonecrosis occurs concomitantly with necrotizing fasciitis in about 50% of cases. Both are part of the streptococcal toxic shock syndrome.

Gas gangrene usually follows severe penetrating injuries that result in interruption of the blood supply and introduction of soil into wounds. Such cases of traumatic gangrene are usually caused by *C. perfringens*, *C. septicum*, or *C. histolyticum*. Rarely, latent or recurrent gangrene can occur years after penetrating trauma, most likely owing to dormant spores that reside at the site of previous injury. Spontaneous nontraumatic gangrene among patients with neutropenia, gastrointestinal malignancy, diverticulosis, or recent radiation therapy to the abdomen is caused by several clostridial species, although *C. septicum* is most common. The tolerance of this anaerobe to oxygen probably explains why it can initiate infection spontaneously in normal tissue anywhere in the body.

Synergistic nonclostridial anaerobic myonecrosis, also known as necrotizing cutaneous myositis and synergistic necrotizing cellulitis, is a variant of necrotizing fasciitis caused by mixed aerobic and anaerobic bacteria with the exclusion of clostridial organisms (see "Necrotizing Fasciitis," above).

DIAGNOSIS

This chapter has emphasized the physical appearance and location of lesions within the soft tissues as important diagnostic clues. The temporal progression of the lesions as well as the patient's travel history, animal exposure or bite history, age, underlying

disease status, and lifestyle are also crucial considerations in the formulation of a narrowed differential diagnosis. However, even the astute clinician may find it challenging to diagnose all infections of the soft tissues by history and inspection alone. Soft tissue radiography, computed tomography, and magnetic resonance imaging may be useful in determining the depth of infection and should be performed in patients with rapidly progressing lesions or in those with evidence of systemic inflammatory response syndrome. These tests are particularly valuable for defining a localized abscess or detecting gas in tissue. Unfortunately, they may reveal only soft tissue swelling and thus are not specific for fulminant infections such as necrotizing fasciitis or myonecrosis caused by group A *Streptococcus*, where gas is not found in lesions.

Aspiration of the leading edge or punch biopsy with frozen section may be helpful if the results are positive, but false-negative results occur in approximately 80% of cases. There is some evidence that aspiration alone may be superior to injection and aspiration using normal saline. Frozen sections are especially useful in distinguishingSSSSfrom TEN and are quite valuable in cases of necrotizing fasciitis. Open surgical inspection with debridement as indicated is clearly the best way to determine the extent and severity of infection and to obtain material for Gram's staining and culture. Such an aggressive approach is important and may be lifesaving if undertaken early in the course of fulminant infections where there is evidence of systemic toxicity.

TREATMENT

A full description of the treatment of all the clinical entities described herein is beyond the scope of this chapter. As a guide to the clinician in selecting appropriate treatment, the antimicrobial agents useful in the most common and the most fulminant cutaneous infections are listed inTable 128-2.

Early and aggressive surgical exploration is essential in patients with suspected necrotizing fasciitis, myositis, or gangrene in order to (1) visualize the deep structures, (2) remove necrotic tissue, (3) reduce compartment pressure, and (4) obtain suitable material for Gram's staining and for aerobic and anaerobic cultures. Appropriate empirical antibiotic treatment for mixed aerobic-anaerobic infections could consist of ampicillin/sulbactam, cefoxitin, or the following combination: (1) clindamycin (600 to 900 mg intravenously every 8 h) or metronidazole (750 mg every 6 h) plus (2) ampicillin or ampicillin/sulbactam (2 to 3 g intravenously every 6 h) plus (3) gentamicin (1.0 to 1.5 mg/kg every 8 h). Group A streptococcal and clostridial infection of the fascia and/or muscle carries a mortality rate of 20 to 50% with penicillin treatment. In experimental models of streptococcal and clostridial necrotizing fasciitis/myositis, clindamycin has exhibited markedly superior efficacy, but no comparative trials have been performed in humans. Hyperbaric oxygen treatment may also be useful in gas gangrene due to clostridial species. Antibiotic treatment should be continued until all signs of systemic toxicity have resolved, all devitalized tissue has been removed, and granulation tissue has developed (Chaps. 140,145, and167).

In summary, infections of the skin and soft tissues are diverse in presentation and severity and offer a great challenge to the clinician. This chapter provides an approach to diagnosis and understanding of the pathophysiologic mechanisms involved in these infections. More in-depth information is found in chapters on specific infections.

129. OSTEOMYELITIS - *James H. Maguire*

Osteomyelitis, an infection of bone, is caused most commonly by pyogenic bacteria and mycobacteria. Classification of cases on the basis of the causative agent; the route, duration, and anatomic location of infection; and local and systemic host factors provides a useful framework for evaluating the patient and planning treatment.

PATHOGENESIS AND PATHOLOGY

Microorganisms enter bone by the hematogenous route, by direct introduction from a contiguous focus of infection, or by a penetrating wound. Trauma, ischemia, and foreign bodies enhance the susceptibility of bone to microbial invasion by exposing sites to which bacteria can bind. Phagocytes attempt to contain the infections and, in the process, release enzymes that lyse bone. Pus spreads into vascular channels, raising intraosseous pressure and impairing the flow of blood; as the untreated infection becomes chronic, ischemic necrosis of bone results in the separation of large devascularized fragments (*sequestra*). When pus breaks through the cortex, subperiosteal or soft tissue abscesses form, and the elevated periosteum deposits new bone (the *involucrum*) around the sequestrum. Bacteria escape host defenses by adhering tightly to damaged bone, by entering and persisting within osteoblasts, and by coating themselves and underlying surfaces with a protective polysaccharide-rich biofilm.

Microorganisms, infiltrates of neutrophils, and congested or thrombosed blood vessels are the principal histologic findings of acute osteomyelitis. The distinguishing feature of chronic osteomyelitis is necrotic bone, which is characterized by the absence of living osteocytes. Mononuclear cells predominate in chronic infections, and granulation and fibrous tissues replace bone that has been resorbed by osteoclasts. In the chronic stage, organisms may be too few to be seen.

HEMATOGENOUS OSTEOMYELITIS

Hematogenous infection accounts for ~20% of cases of osteomyelitis and primarily affects children, in whom the long bones are infected, and older adults and intravenous drug users, in whom the spine is the usual site of infection.

Acute Hematogenous Osteomyelitis Infection usually involves a single bone, most commonly the tibia, femur, or humerus. Bacteria settle in the well-perfused metaphysis, where functioning phagocytes are scarce, a network of venous sinusoids slows the flow of blood, and fenestrations in capillaries allow organisms to escape into the extravascular space. Because vascular anatomy changes with age, hematogenous infection of long bones is uncommon during adulthood and, when it occurs, usually involves the diaphysis.

In children, the source of bacteremia is often inapparent, although there may have been recent blunt trauma to the extremity leading to a small intraosseous hematoma or vascular obstruction. On presentation, the child usually appears acutely ill, with high fever, chills, localized pain and tenderness, and leukocytosis. Cutaneous erythema and swelling indicate extension of pus through the cortex. During infancy and after puberty,

infection may spread through the epiphysis into the joint space. In children of other ages (i.e., between infancy and puberty), extension of infection through the cortex results in involvement of joints if the metaphysis is intracapsular. Thus, septic arthritis of the elbow, shoulder, and hip may complicate osteomyelitis of the proximal radius, humerus, and femur, respectively.

Plain radiographs initially show soft tissue swelling, but the first change in bone -- a periosteal reaction -- is not evident until at least 10 days after the onset of infection. Lytic changes can be detected after 2 to 6 weeks, when 50 to 75% of bone density has been lost. Rarely, a well-circumscribed lytic lesion, or *Brodie's abscess*, is seen in a child who has been in pain for several months but has had no fever.

Chronic Hematogenous Osteomyelitis With prompt treatment,<5% of cases of acute hematogenous osteomyelitis progress to chronic osteomyelitis. On average, 10 days are required for the formation of necrotic bone, but plain radiographs are unable to detect sequestra or sclerotic new bone for many weeks.

A protracted clinical course, long periods of quiescence, and recurrent exacerbations are characteristic of chronic osteomyelitis. Sinus tracts between bone and skin may drain purulent material and occasionally pieces of necrotic bone. An increase in drainage, pain, or the erythrocyte sedimentation rate (ESR) signals an exacerbation. Fever is unusual except when obstruction of a sinus tract leads to soft tissue infection. Rare late complications include pathologic fractures, squamous cell carcinoma of the sinus tract, and amyloidosis.

Vertebral Osteomyelitis Organisms reach the well-perfused vertebral body of adults via spinal arteries and quickly spread from the end plate into the disk space and then to the adjacent vertebral body. The infection may originate in the urinary tract, and it does so particularly often among elderly men. Other sources of bacteremia include endocarditis, soft tissue infection, and a contaminated intravenous line; these sources are usually obvious. Diabetes mellitus, hemodialysis, and intravenous drug use carry an increased risk of spinal infection. Penetrating injuries and surgical procedures to the spine may cause nonhematogenous vertebral osteomyelitis or infection localized to the disk.

Most patients with vertebral osteomyelitis report neck or back pain; 15% describe atypical pain in the chest, the abdomen, or an extremity that is due to irritation of nerve roots. Symptoms are localized to the lumbar spine more often than to the thoracic spine (>50% vs. 35% of cases) or the cervical spine in pyogenic infections, but the thoracic spine is involved most commonly in tuberculous spondylitis (Pott's disease). Percussion over the involved vertebra elicits tenderness, and physical examination may reveal spasm of the paraspinal muscles and a limitation of motion. More than 50% of patients experience a subacute illness in which a vague, dull pain gradually intensifies over 2 to 3 months; fever is low grade or absent, and the white blood cell count is normal. An acute presentation with high fever and toxicity is less common and suggests ongoing bacteremia.

Usually, by the time the patient seeks medical attention, theESR is elevated, and plain radiographs show irregular erosions in the end plates of adjacent vertebral bodies and

narrowing of the intervening disk space. This radiographic pattern is virtually diagnostic of bacterial infection because tumors and other diseases of the spine rarely cross the disk space. Computed tomography (CT) or magnetic resonance imaging (MRI) may demonstrate epidural, paraspinal, retropharyngeal, mediastinal, retroperitoneal, or psoas abscesses that originate in the spine. An epidural abscess may evolve suddenly or over several weeks; irreversible paralysis may result from failure to recognize the classic clinical presentation of a spinal epidural abscess: spinal pain progressing to radicular pain and weakness.

Microbiology More than 95% of cases of hematogenous osteomyelitis are caused by a single organism. *Staphylococcus aureus* accounts for 50% of isolates. Other common pathogens include group B streptococci and *Escherichia coli* during the newborn period and group A streptococci and *Haemophilus influenzae* in early childhood. Vertebral osteomyelitis is due to *E. coli* and other enteric bacilli in ~25% of cases. *S. aureus*, *Pseudomonas aeruginosa*, and *Serratia* infections are associated with intravenous drug use in some parts of the United States and may involve the sacroiliac, sternoclavicular, or pubic joints as well as the spine. *Salmonella* spp. and *S. aureus* are the major causes of long-bone osteomyelitis complicating sickle cell anemia and other hemoglobinopathies. Tuberculosis and brucellosis affect the spine more often than other bones. Other common sites of tuberculous osteomyelitis include the small bones of the hands and feet, the metaphyses of long bones, the ribs, and the sternum.

Unusual causes of hematogenous osteomyelitis include disseminated histoplasmosis, coccidioidomycosis, and blastomycosis in endemic areas. Immunocompromised persons on rare occasions develop osteomyelitis due to atypical mycobacteria, *Bartonella henselae*, or *Pneumocystis carinii* or to species of *Candida*, *Cryptococcus*, or *Aspergillus*. Syphilis, yaws, varicella, and vaccinia may involve bone. The etiology of chronic relapsing multifocal osteomyelitis, an inflammatory condition of children that is characterized by recurrent episodes of painful lytic lesions in multiple bones, has not yet been identified.

OSTEOMYELITIS SECONDARY TO A CONTIGUOUS FOCUS OF INFECTION

Clinical Features This broad category of osteomyelitis includes infections introduced by penetrating injuries and surgical procedures and by direct extension of infection from adjacent soft tissues. It accounts for the greatest number of cases of osteomyelitis and occurs most commonly in adults.

Frequently, the diagnosis is not made until the infection has already become chronic. The pain, fever, and inflammatory signs due to acute osteomyelitis may be attributed to the original injury or soft tissue infection. An indolent infection may become apparent only weeks or months later, when a sinus tract develops, a surgical wound breaks down, or a fracture fails to heal. It may be impossible to distinguish radiographic abnormalities due to osteomyelitis from those due to the precipitating condition.

A special type of contiguous-focus osteomyelitis occurs in the setting of peripheral vascular disease and nearly always involves the small bones of the feet of adult diabetic patients. Diabetic neuropathy exposes the foot to frequent trauma and pressure sores, and the patient may be unaware of infection as it spreads into bone. Poor tissue

perfusion impairs normal inflammatory responses and wound healing and creates a milieu that is conducive to anaerobic infections. It is often during the evaluation of a nonhealing ulcer, a swollen toe, or acute cellulitis that a radiograph provides the first evidence of osteomyelitis. If bone is palpable during examination of the base of an ulcer with a blunt surgical probe, osteomyelitis is likely.

Microbiology *S. aureus* is a pathogen in more than half of cases of contiguous-focus osteomyelitis. However, in contrast to hematogenous osteomyelitis, these infections are often polymicrobial and are more likely to involve gram-negative and anaerobic bacteria. Hence a mixture of staphylococci, streptococci, enteric organisms, and anaerobic bacteria may be isolated from a diabetic foot infection or pelvic osteomyelitis underlying a decubitus ulcer. Aerobic and anaerobic bacteria cause osteomyelitis following surgery or soft tissue infection of the oropharynx, paranasal sinuses, gastrointestinal tract, or female genital tract. *S. aureus* is the principal cause of postoperative infections; coagulase-negative staphylococci are common pathogens after implantation of orthopedic appliances; and these organisms as well as gram-negative enteric bacilli, atypical mycobacteria, and *Mycoplasma* may cause sternal osteomyelitis after cardiac surgery. Infection with *P. aeruginosa* is frequently associated with puncture wounds of the foot or with thermal burns, and *Pasteurella multocida* infection commonly follows cat bites (Chap. 127).

DIAGNOSIS

Early diagnosis of acute osteomyelitis is critical because prompt antibiotic therapy may prevent the necrosis of bone. The evaluation usually begins with plain radiographs because of their ready availability, although they frequently show no abnormalities during early infection. TheESR and C-reactive protein levels are elevated in most cases of active osteomyelitis, including those in which constitutional symptoms and leukocytosis are lacking. These findings are not specific to osteomyelitis, however, and the ESR is occasionally normal in early infections. In 95% of cases, the technetium radionuclide scan using ^{99m}Tc diphosphonate is positive within 24 h of the onset of symptoms. Falsely negative scans usually indicate obstruction of blood flow to the bone. Because the uptake of technetium reflects osteoblastic activity and skeletal vascularity, the bone scan cannot differentiate osteomyelitis from fractures, tumors, infarction, or neuropathic osteopathy.^{67}Ga citrate- and^{111}In-labeled leukocyte or immunoglobulin scans, which have greater specificity for inflammation, may help distinguish infectious from noninfectious processes and indicate inflammatory changes within bones that for other reasons are already abnormal on radiography and technetium scanning. Ultrasound can be used to diagnose osteomyelitis by the detection of subperiosteal fluid collections, soft tissue abscesses adjacent to bone, and periosteal thickening and elevation.

MRIis as sensitive as the bone scan for the diagnosis of acute osteomyelitis because it is able to detect changes in the water content of marrow. MRI yields better anatomic resolution of epidural abscesses and other soft tissue processes than CTand is currently the imaging technique of choice for vertebral osteomyelitis (Fig. 129-1).

The role of diagnostic imaging in chronic osteomyelitis is to determine the presence of active infection and delineate the extent of debridement necessary to remove necrotic

bone and abnormal soft tissues. Although plain films accurately reflect chronic changes, theCT scan is more sensitive for the detection of sequestra, sinus tracts, and soft tissue abscesses. Both CT and ultrasound are useful for guiding percutaneous aspiration of subperiosteal and soft tissue fluid collections. Sequential technetium and gallium or indium scans may help determine whether infection is active and may distinguish infection from noninflammatory bone changes; these methods do not, however, provide good anatomic detail.MRIprovides detailed information about the activity and the anatomic extent of infection but does not always distinguish osteomyelitis from healing fractures and tumors. MRI is particularly useful in distinguishing cellulitis from osteomyelitis in the diabetic foot; however, no imaging modality consistently distinguishes infection from neuropathic osteopathy.

Appropriate samples for microbiologic studies should be obtained in all cases of suspected osteomyelitis before the initiation of antimicrobial therapy. Blood cultures are indicated in acute cases and are positive in more than one-third of cases of hematogenous osteomyelitis in children and in 25% of cases of vertebral osteomyelitis in adults. If the clinical picture demands immediate antibiotic therapy or if blood cultures are negative, samples from needle aspiration of pus in bone or soft tissues or from a bone biopsy should be obtained for culture.

The results of culture of specimens obtained by swabbing of a sinus tract or the base of an ulcer correlate poorly with the organisms infecting the bone. For this reason, in cases of chronic osteomyelitis and contiguous-focus osteomyelitis, samples for aerobic and anaerobic culture should be obtained from several sites by percutaneous needle aspiration, percutaneous biopsy, or intraoperative biopsy at the time of debridement. Isolates of coagulase-negative staphylococci and other organisms of low virulence should not automatically be disregarded as contaminants, especially in the presence of prosthetic materials. Special culture media may be necessary for the isolation of mycobacteria, fungi, and less common pathogens. In some cases, histopathologic examination of biopsy specimens may be the only way to make a diagnosis.

TREATMENT

Antibiotic Therapy Antibiotics are administered only after appropriate specimens have been obtained for culture. The antibiotics selected should be bactericidal and, at least initially, should be given intravenously. When necessary, empirical therapy is guided by findings on Gram's staining of a specimen from the bone or abscess or is chosen to cover the most likely pathogens. Empirical therapy in most cases should include high doses of an agent active against *S. aureus* (such as oxacillin, nafcillin, a cephalosporin, or vancomycin) and, if gram-negative organisms are likely to be involved, a third-generation cephalosporin, an aminoglycoside, or a fluoroquinolone.

Specific intravenous therapy is based on the in vitro susceptibility of the organism(s) isolated from bone or blood. Penicillin G (3 to 4 million units every 4 h) is the drug of choice for the treatment of infections due to penicillin-sensitive staphylococci and streptococci; nafcillin or oxacillin (2 g every 4 h) is preferred for penicillin-resistant, methicillin-sensitive staphylococci. Cefazolin (1 to 2 g every 8 h) or vancomycin [15 mg/kg (up to 1 g) every 12 h] is an alternative for persons allergic to penicillins. Infections due to methicillin-resistant staphylococci are treated with vancomycin.

Regimens for infections due to susceptible gram-negative rods include ampicillin (2 g every 4 h), cefazolin, a second-generation cephalosporin such as cefuroxime (1.5 g every 8 h), or a fluoroquinolone such as ciprofloxacin (400 mg every 12 h) or levofloxacin (500 mg every 24 h). Initial therapy for osteomyelitis due to *P. aeruginosa* or *Enterobacter* spp. should not consist of ab-lactam antibiotic alone because of the potential for these organisms to develop resistance during therapy. Appropriate intravenous therapies for *P. aeruginosa* infections include tobramycin (1.7 mg/kg every 8 h, or 5 to 7 mg/kg every 24 h) and a broad-spectrumb-lactam compound such as ticarcillin (3 g every 4 h), ceftazidime (1 to 2 g every 8 h), or aztreonam (1 to 2 g every 8 h); a fluoroquinolone may be substituted for one of the latter. *Enterobacter* infections can be treated with a fluoroquinolone alone or with combinations of a broad-spectrum b-lactam antibiotic and gentamicin in the same doses as tobramycin. Serum levels of aminoglycosides should be monitored closely to avoid toxicity.

The duration of therapy is typically 4 to 6 weeks; at-home intravenous administration of antibiotics or oral therapy is appropriate for motivated and medically stable patients. Antibiotics that require infrequent dosing, such as ceftriaxone and vancomycin, facilitate home therapy. Children with acute hematogenous osteomyelitis routinely receive oral antibiotics after 5 to 10 days of parenteral therapy if signs of active infection have resolved; such treatment has been as successful as standard parenteral therapy. The doses of oral penicillins or cephalosporins required for the treatment of osteomyelitis are several times higher than the doses of these drugs given for common infections. Adults may not tolerate these high doses as well as children, and, except in the case of the fluoroquinolones, few data support the use of oral antibiotics by adults. For treatment of osteomyelitis due to Enterobacteriaceae, oral administration of an agent such as ciprofloxacin (750 mg every 12 h) or levofloxacin (500 mg every 24 h) has been as successful as intravenous administration of b-lactam antibiotics. Caution should be exercised in the use of fluoroquinolones as the sole agents for treatment of infection due to *S. aureus* or *P. aeruginosa* because resistance may develop during therapy. Addition of rifampin to a quinolone has yielded encouraging results in infections due to *S. aureus*, but further studies are necessary to confirm these findings. Oral administration of clindamycin (300 to 450 mg every 6 h) or metronidazole (500 mg every 8 h) results in high drug levels in serum and can take the place of intravenous regimens for the treatment of *Bacteroides* infections. Oral clindamycin has produced good results in therapy for osteomyelitis due to *S. aureus*, especially in children. There are few data to support the routine use of the serum minimal bactericidal concentration (MBC) other than to document adherence to treatment.

Acute Osteomyelitis Early treatment of acute hematogenous osteomyelitis of childhood with 4 to 6 weeks of an appropriate antibiotic is usually successful; treatment for<3 weeks has resulted in a 10-fold greater rate of failure. Surgical intervention in childhood cases is indicated for intraosseous or subperiosteal abscesses, concomitant septic arthritis, and failure of the acute signs of infection to improve in 24 to 48 h. Acute hematogenous osteomyelitis of bones other than the spine in adults often requires surgical debridement.

Vertebral Osteomyelitis A 4- to 6-week course of treatment with an appropriate antibiotic is usually sufficient to cure vertebral osteomyelitis. Failure of theESR to drop by two-thirds or more of its pretreatment level is an indication for longer treatment.

Surgery is seldom necessary, even in cases of many months' duration, except in instances of spinal instability, new or progressive neurologic deficits, large soft tissue abscesses that cannot be drained percutaneously, or a failure of medical treatment. Patients should maintain bed rest until back pain has declined to the point at which ambulation is possible. Body casts are no longer used. Spontaneous fusion of involved vertebrae occurs in the majority of cases after successful treatment.

Contiguous-Focus Osteomyelitis Even when diagnosed early, contiguous-focus osteomyelitis usually requires surgery in addition to 4 to 6 weeks of appropriate antibiotic therapy because of underlying soft tissue infection or damage to bone from an injury or surgery. A 2-week course of antibiotics following thorough debridement and soft tissue coverage has yielded excellent results in treatment of superficial osteomyelitis involving only the outer cortex of bone.

Chronic Osteomyelitis The risks and benefits of aggressive therapy for chronic osteomyelitis should be weighed before any attempt is made to eradicate the infection. Some patients with extensive disease prefer to live with their infections rather than undergo multiple surgical procedures, take prolonged courses of antimicrobial therapy, and face the risk of loss of an extremity. Such persons often benefit from intermittent courses of oral antibiotics to suppress acute exacerbations.

Once the decision has been made to treat chronic osteomyelitis aggressively, the patient's nutritional and metabolic status should be optimized to expedite healing of soft tissues and bone. Antibiotic administration should be started several days before surgery to reduce inflammation if the etiology of the infection is known preoperatively. If not, antibiotic therapy should be withheld until surgical debridement. An empirical antibiotic regimen is started intraoperatively after culture specimens are obtained. A 4- to 6-week course of appropriate antibiotic therapy is given postoperatively on the basis of the susceptibility pattern of organisms isolated from the bone. The benefit of prolonged oral antibiotic therapy after 4 to 6 weeks of parenteral therapy remains unproven. There is insufficient information to recommend the routine use of hyperbaric oxygen to enhance the killing of microorganisms by phagocytes or of instillation pumps and antibiotic-impregnated methacrylate beads to deliver high levels of antibiotics to the bone.

The success of therapy for chronic osteomyelitis rests largely on the complete surgical removal of necrotic bone and abnormal soft tissues. Modern imaging techniques allow accurate preoperative delineation of tissues to be debrided, but it remains difficult for the surgeon to determine intraoperatively whether all necrotic and infected tissue has been removed. In the past, the inability to repair large defects in bone and soft tissue limited the extent of debridement. Muscle flaps and skin grafts are now used routinely to cover large soft tissue defects and fill dead space, and bone grafts and vascularized bone transfer may restore a seriously compromised bone to a functional state.

In infections of recent fractures, internal fixators are often left in place, and the infection is controlled by limited debridement and suppressive antibiotic therapy. Definitive surgical/antimicrobial therapy is delayed until after bony union of the fracture is achieved. If there is nonunion of the fracture or loosening of the fixator, the appliance should be removed, the bone debrided, and an external fixator or a new internal fixator

applied.

Osteomyelitis of the small bones of the feet in persons with vascular disease also requires surgical treatment. The effectiveness of the surgery is limited by the blood supply to the site and the body's ability to heal the wound. Revascularization of the extremity is indicated if the vascular disease involves large arteries. In cases of decreased perfusion due to small-vessel disease, foot-sparing surgery may fail, and the best option is suppressive therapy or amputation. The duration of antibiotic therapy depends on the surgical procedure performed. When the infected bone is removed entirely but residual infection of soft tissues remains, antibiotic therapy should be given for 2 weeks; if amputation eliminates infected bone and soft tissue, standard surgical prophylaxis is given; otherwise, postoperative antibiotics must be given for 4 to 6 weeks.

130. INTRAABDOMINAL INFECTIONS AND ABSCESSES - *Dori F. Zaleznik*, *Dennis L. Kasper*

Intraperitoneal infections generally arise because a normal anatomic barrier is disrupted. This disruption may occur when the appendix, a diverticulum, or an ulcer ruptures; when the bowel wall is weakened by ischemia, tumor, or inflammation (e.g., in inflammatory bowel disease); or with adjacent inflammatory processes, such as pancreatitis or pelvic inflammatory disease, in which enzymes (in the former case) or organisms (in the latter) may leak into the peritoneal cavity. Whatever the inciting event, once inflammation develops and organisms usually contained within the bowel or another organ enter the normally sterile peritoneal space, a predictable series of events takes place. Intraabdominal infections occur in two stages: peritonitis and -- if it goes untreated -- abscess formation. The types of microorganisms predominating in each stage of infection are responsible for the pathogenesis of disease.

PERITONITIS

The peritoneal cavity is large but is divided into compartments. The upper and lower peritoneal cavities are divided by the transverse mesocolon; the greater omentum extends from the transverse mesocolon and from the lower pole of the stomach to line the lower peritoneal cavity. The pancreas, duodenum, and ascending and descending colon are located in the anterior retroperitoneal space; the kidneys, ureters, and adrenals are found in the posterior retroperitoneal space. The other organs, including liver, stomach, gallbladder, spleen, jejunum, ileum, transverse and sigmoid colon, cecum, and appendix, are found within the peritoneal cavity itself. Normally the cavity is lined with a serous membrane that can serve as a conduit for fluids -- a property utilized in peritoneal dialysis. A small amount of fluid, sufficient to allow movement of organs, is normally present in the peritoneal space. This fluid is serous, with a protein content (consisting mainly of albumin) of<30 g/L and fewer than 300 white blood cells (WBCs, generally mononuclear cells) per microliter. In the presence of infection, some of these compartments collect fluid or pus more often than others. These compartments include the pelvis (the lowest portion), the subphrenic spaces on the right and left sides, and Morrison's pouch, which is a posterosuperior extension of the subhepatic spaces and is the lowest part of the paravertebral groove when a patient is recumbent. The falciform ligament separating the right and left subphrenic spaces appears to act as a barrier to the spread of infection; consequently, it is unusual to find bilateral subphrenic collections.

SPONTANEOUS BACTERIAL PERITONITIS

Peritonitis is either primary (without an apparent source of contamination) or secondary. The types of organisms found and the clinical presentation of these two processes are different. In adults, primary or spontaneous bacterial peritonitis (SBP) occurs most commonly in conjunction with cirrhosis of the liver (frequently the result of alcoholism). It virtually always develops in patients with ascites. Nevertheless, it is not a common event, occurring in£10% of cirrhotic patients. The cause of SBP has not been established definitively but is believed to involve hematogenous spread of organisms in a patient in whom a diseased liver and altered portal circulation result in a defect in the usual filtration function. Organisms are able to multiply in ascites, a good medium for

growth. The proteins of the complement cascade have been found in peritoneal fluid, with lower levels in cirrhotic patients than in patients with ascites of other etiologies. The opsonic and phagocytic properties of neutrophils are decreased in patients with advanced liver disease.

The presentation ofSBPdiffers from that of secondary peritonitis. The most common manifestation is fever, which is reported in as many as 80% of patients. Ascites is found but virtually always predates infection. Abdominal pain, an acute onset of symptoms, and peritoneal irritation detected during physical examination can be helpful diagnostically, but the absence of any of these findings does not exclude this often-subtle diagnosis. It is vital to sample the peritoneal fluid of any cirrhotic patient with ascites and fever. The finding of>300 polymorphonuclear leukocytes (PMNs) per microliter is diagnostic for SBP, according to Conn. The microbiology of SBP is also distinctive. While enteric gram-negative bacilli such as *Escherichia coli* are most commonly encountered, gram-positive organisms such as streptococci, enterococci, or even pneumococci are sometimes found. In SBP, a single organism is typically isolated; anaerobes are found less frequently in SBP than in secondary peritonitis, in which a mixed flora including anaerobes is the rule. In fact, if SBP is suspected and multiple organisms including anaerobes are recovered from the peritoneal fluid, the diagnosis must be reconsidered and a source of secondary peritonitis sought.

The diagnosis ofSBP is not easy. It depends on the exclusion of a primary intraabdominal source of infection. Contrast-enhanced computed tomography (CT) is very useful in identifying an intraabdominal source for infection. It may be difficult to recover organisms from cultures of peritoneal fluid, presumably because the burden of organisms is low. However, the yield can be improved if 10 mL of peritoneal fluid is placed directly into a blood culture bottle. Bacteremia frequently accompanies SBP; therefore, blood should be cultured simultaneously. No specific radiographic studies are helpful in the diagnosis of SBP. A plain film of the abdomen would be expected to show ascites. Chest and abdominal radiography should be performed in patients with abdominal pain to exclude free air, which signals a perforation.

TREATMENT

Treatment for SBPis directed at the isolate from blood or peritoneal fluid. Gram's staining of peritoneal fluid often gives negative results in primary peritonitis; therefore, until culture results become available, empirical therapy should cover gram-negative aerobic bacilli and gram-positive cocci. Ampicillin plus gentamicin is a reasonable initial regimen. Third-generation cephalosporins, carbapenems, or broad-spectrum penicillin/b-lactamase inhibitor combinations are also options. Empirical coverage for anaerobes is not necessary. After the infecting organism is identified, therapy should be narrowed to target that specific pathogen. Patients with SBP usually respond within 72 h to appropriate antibiotic therapy.

SECONDARY PERITONITIS

Secondary peritonitis develops when bacteria contaminate the peritoneum as a result of spillage from an intraabdominal viscus. The organisms found almost always constitute a mixed flora in which facultative gram-negative bacilli and anaerobes predominate,

especially when the contaminating source is colonic. Early in the course of infection, when the host response is directed toward containment of the infection, exudate containing fibrin andPMNs is found. Early death in this setting is attributable to gram-negative bacillary sepsis and to potent endotoxins circulating in the bloodstream (Chap. 124). Gram-negative bacilli, particularly *E. coli*, are common bloodstream isolates, but *Bacteroides fragilis* bacteremia occurs as well. The severity of abdominal pain and the clinical course depend on the inciting process. The species of organisms isolated from the peritoneum also vary with the source of the initial process and the normal flora present at that site. Peritonitis can result primarily from chemical irritation or bacterial contamination. For example, as long as the patient is not achlorhydric, a ruptured gastric ulcer will release low-pH gastric contents that will serve as a chemical irritant. The normal flora of the stomach comprises the same organisms found in the oropharynx (Chap. 167) but in lower numbers. The surfaces of teeth contain ~10^7aerobic and 10^7anaerobic organisms per milliliter of saliva; the normally acidic stomach contains an equal ratio of aerobic and anaerobic species, but in concentrations more in the range of 10^5/mL. After meals, when gastric acidity is highest, this number may fall to 10^3/mL. Thus, the bacterial burden in a ruptured gastric ulcer -- or even a duodenal ulcer -- is negligible compared with that in a ruptured appendix. The normal flora of the colon below the ligament of Treitz contains ~10^{11}anaerobic organisms per gram of feces but only 10^8aerobes per gram; therefore, anaerobic species account for 99% of the bacteria. Leakage of colonic contents (pH 7 to 8) does not cause significant chemical peritonitis, but infection is intense because of the heavy bacterial load.

Depending on the inciting event, local symptoms may initially be found in secondary peritonitis -- for example, epigastric pain from a ruptured gastric ulcer. In appendicitis (Chap. 291), the initial presenting symptoms are often vague, with periumbilical discomfort and nausea followed in a number of hours by pain more localized to the right lower quadrant. Unusual locations of the appendix (including a retrocecal position) can complicate this presentation further. Once infection has spread to the peritoneal cavity, however, pain increases, particularly with infection involving the parietal peritoneum, which is innervated extensively. Patients usually lie motionless, often with knees drawn up to avoid stretching the nerve fibers of the peritoneal cavity. Coughing and sneezing, which increase pressure within the peritoneal cavity, are associated with sharp pain. There may or may not be pain localized to the infected or diseased organ from which secondary peritonitis has arisen. Patients with secondary peritonitis generally have abnormal findings on abdominal examination, with marked voluntary and involuntary guarding of the anterior abdominal musculature. Later findings include tenderness, especially rebound tenderness. In addition, there may be localized findings in the area of the inciting event. In general, patients are febrile, with marked leukocytosis and a left shift of theWBCs to earlier granulocyte forms.

While recovery of organisms from peritoneal fluid is easier in secondary than in primary peritonitis, a tap of the abdomen is rarely the procedure of choice in secondary peritonitis. An exception is in cases involving trauma, where the possibility of a hemoperitoneum may need to be excluded early.

TREATMENT

Treatment for secondary peritonitis includes early administration of antibiotics aimed

particularly at aerobic gram-negative bacilli and anaerobes (see below) as well as etiologic studies. Secondary peritonitis usually requires both surgical intervention to address the inciting process and antibiotic administration to treat early bacteremia, to decrease the incidence of abscess formation and wound infection, and to prevent more distant spread of infection. InSBP in adults, surgery is rarely indicated. In secondary peritonitis, surgery may be life-saving.

PERITONITIS IN PATIENTS UNDERGOING CAPD

A third type of peritonitis arises in patients who are undergoing continuous ambulatory peritoneal dialysis (CAPD). Unlike primary and secondary peritonitis, which are caused by endogenous bacteria, peritonitis in CAPD patients usually involves skin organisms. The pathogenesis of infection is similar to that of intravascular-device infection, in which skin organisms migrate along the catheter, which both serves as an entry point and exerts the effects of a foreign body. Exit-site or tunnel infection may or may not accompany CAPD peritonitis. Like primary peritonitis, CAPD peritonitis is usually caused by a single organism. Peritonitis is, in fact, the most common reason for discontinuation of CAPD. Improvements in equipment design, especially that of the Y-set connector, have resulted in a decrease from one case of peritonitis per 9 months of CAPD to one case per 15 months.

The clinical presentation ofCAPDperitonitis resembles that of secondary peritonitis in that diffuse pain and peritoneal signs are common. The dialysate is usually cloudy and contains>100WBCs per microliter, >50% of which are neutrophils. The most common etiologic organism is coagulase-negative *Staphylococcus*, which accounts for ~30% of cases. *S. aureus* causes ~10% of cases, is more commonly identified among patients who are nasal carriers of the organism, and is the most frequent pathogen in those with an overt exit-site infection. Gram-negative bacilli and fungi such as *Candida* species are also found. Vancomycin-resistant enterococci (VRE) and vancomycin-intermediate *S. aureus* (VISA) have been reported to produce peritonitis in CAPD patients. The finding of more than one organism in dialysate culture should prompt a search for a cause of secondary peritonitis. As with primary peritonitis, culture of dialysate fluid in blood culture bottles improves the yield.

TREATMENT

Empirical therapy forCAPDperitonitis should be directed at coagulase-negative *Staphylococcus*, *S. aureus*, and gram-negative bacilli until the results of cultures are available. Since the advent ofVRE andVISA, recommended treatment has changed from vancomycin and an aminoglycoside to a first-generation cephalosporin such as cefazolin and an aminoglycoside, which can be administered together in the same bag. A loading dose of cefazolin (500 mg/L) is administered intraperitoneally, with a maintenance dose of 125 mg/L in each bag. Ototoxicity is a significant concern in patients receiving aminoglycosides; some data suggest that administration of a single daily dose lessens this risk. Thus, gentamicin is usually administered at a dose of 20 mg/L once a day. If methicillin-resistant *S. aureus* is a relatively common isolate in a community, vancomycin may still be a reasonable first choice for empirical therapy, especially in a toxic-appearing patient or a patient with an overt exit-site infection. The dose (2 g) is allowed to remain in the peritoneal cavity for 6 h. The clinical response to

an empirical treatment regimen should be rapid; if the patient has not responded after 48 h of treatment, catheter removal should be considered.

INTRAPERITONEAL ABSCESSES

Abscess formation is common in untreated peritonitis if overt gram-negative sepsis either does not develop or develops but is not fatal. In experimental models of abscess formation, mixed aerobic and anaerobic organisms have been implanted intraperitoneally. Without therapy directed at anaerobes, animals develop intraabdominal abscesses. As in humans, these experimental abscesses may stud the peritoneal cavity, lie within the omentum or mesentery, or even develop on the surface of or within viscera such as the liver.

PATHOGENESIS AND IMMUNITY

There is often disagreement about whether an abscess represents a disease state or a host response. In a sense, it represents both: While an abscess is an infection in which viable infecting organisms andPMNs are contained in a fibrous capsule, it is also a process by which the host confines microbes to a limited space, thereby preventing further spread of infection. Experimental work has helped to define both the host cells and the bacterial virulence factors responsible -- most notably, in the case of *B. fragilis*. This organism, although accounting for only 0.5% of the normal colonic flora, is the anaerobe most frequently isolated from intraabdominal infections and is the most common anaerobic bloodstream isolate. On clinical grounds, therefore, *B. fragilis* appears to be uniquely virulent. Moreover, *B. fragilis* causes abscesses in animal models of intraabdominal infection, whereas most other *Bacteroides* species must act synergistically with a facultative organism to induce abscess formation.

Of the several virulence factors identified in *B. fragilis*, one is critical -- the capsular polysaccharide complex (CPC) found on the bacterial surface. The CPC comprises several distinct surface polysaccharides. Structural analysis of the polysaccharides in the CPC has shown an unusual motif of oppositely charged sugars. Polysaccharides having these *zwitterionic* characteristics evoke a host response in the peritoneal cavity that localizes bacteria into abscesses. *B. fragilis* and the CPC have been found to adhere to primary mesothelial cells in vitro; this adherence, in turn, stimulates the production of tumor necrosis factora (TNF-a) and intercellular adhesion molecule 1 (ICAM-1) by peritoneal macrophages. Mice treated with antibodies to TNF-a or ICAM-1 did not develop abscesses in the mouse peritonitis model. Although abscesses characteristically containPMNs, the process of abscess induction depends on the stimulation of T lymphocytes by these unique polysaccharides. Experimentally, the essential role of T cells in initiating abscess formation has been proven following blockage of the CD28-B7 costimulatory pathway. The alternative pathways of complement and fibrinogen also participate in abscess formation.

While antibodies to theCPC are not critical in immunity to abscesses, they enhance bloodstream clearance of *B. fragilis*. When administered subcutaneously, *B. fragilis* surface polysaccharide A (PS A) has immunomodulatory characteristics and stimulates T cells via an interleukin-2-dependent mechanism to inhibit the host response of abscess formation to intraperitoneal challenge with *B. fragilis*. Treatment of

experimental animals with PS A or other zwitterionic molecules reduces abscess development and can be administered after bacterial contamination of the peritoneal cavity.

CLINICAL PRESENTATION

Most intraperitoneal abscesses result from fecal spillage from a colonic source, such as an inflamed appendix. Of all intraabdominal abscesses, 74% are intraperitoneal or retroperitoneal and are not visceral. Abscesses can also arise from a number of other processes. They usually form within weeks of the development of peritonitis and may be found in a variety of locations, from omentum to mesentery, pelvis to psoas muscles, and subphrenic space to a visceral organ such as the liver, where they may develop either on the surface of the organ or within it. Periappendiceal and diverticular abscesses have traditionally been frequent. Diverticular abscesses are least likely to rupture. Infections of the female genital tract and pancreatitis are also among the more common causative events. When abscesses occur in the female genital tract -- either as a primary infection (e.g., tuboovarian abscess) or as an infection extending into the pelvic cavity or peritoneum -- *B. fragilis* figures prominently among the organisms isolated. *B. fragilis* is not found in large numbers in the normal vaginal flora. It is encountered less commonly in pelvic inflammatory disease and endometritis, for example, without an associated abscess. In pancreatitis with leakage of damaging pancreatic enzymes, inflammation is prominent. Therefore, clinical findings such as fever, leukocytosis, and even abdominal pain do not distinguish pancreatitis itself from complications such as pancreatic pseudocyst, pancreatic abscess (Chap. 304), or intraabdominal collections of pus. Especially in cases of necrotizing pancreatitis, in which the incidence of local pancreatic infection may be as high as 30%, needle aspiration underCTguidance is performed as often as once a week to sample fluid for culture. Many centers prescribe prophylactic antibiotics to prevent infection in patients with necrotizing pancreatitis. Imipenem is the most frequently used drug for this purpose since it achieves high tissue levels in the pancreas, although it is not unique in this regard. If infected fluid is removed during needle aspiration, most experts agree that surgery is superior to percutaneous drainage.

The psoas muscle of the anterior back is another location in which abscesses are encountered. These abscesses may arise from a presumed hematogenous source, by contiguous spread from an intraabdominal or pelvic process, or by contiguous spread from nearby bony structures such as vertebral bodies. Associated osteomyelitis due to spread from bone to muscle or from muscle to bone is common in psoas abscesses. When Pott's disease was common, *Mycobacterium tuberculosis* was a frequent cause of psoas abscess. Currently in the United States, the usual isolates from psoas abscesses are either *S. aureus* or a mixture of enteric organisms including aerobic gram-negative bacilli. *S. aureus* is most likely to be isolated when a psoas abscess arises from hematogenous spread or a contiguous focus of osteomyelitis; a mixed enteric flora is most likely when the abscess has an intraabdominal or pelvic source.

DIAGNOSIS

A variety of scanning procedures have considerably facilitated the diagnosis of intraabdominal abscesses. AbdominalCTprobably has the highest yield, although

ultrasonography is particularly useful for the right upper quadrant, kidneys, and pelvis. Both indium-labeledWBCs and gallium tend to localize in abscesses and may be useful in finding a collection. Since gallium is taken up in the bowel, indium-labeled WBCs may have a slightly greater yield for abscesses near the bowel. Neither indium-labeled WBC nor gallium scans serve as a basis for a definitive diagnosis, however; both need to be followed by other, more specific studies, such as CT, if an area of possible abnormality is identified. Abscesses contiguous with or contained within outpouchings of bowel are particularly difficult to diagnose with scanning procedures. Occasionally, a barium enema may detect a diverticular abscess not diagnosed by other procedures, although barium should not be injected if a free perforation is suspected. If one study is negative, a second study sometimes reveals a collection. On occasion, exploratory laparotomy still must be undertaken if an abscess is strongly suspected on clinical grounds, although this procedure has been less commonly used since the advent of CT.

TREATMENT

An algorithm for the management of patients with intraabdominal abcesses is presented in Fig. 130-1. The treatment of intraabdominal infections involves the determination of the initial focus of infection, the administration of broad-spectrum antibiotics targeted at organisms involved in the associated infection, and the performance of a drainage procedure if one or more definitive abscesses have formed already. It cannot be overemphasized that antimicrobial therapy, in general, is adjunctive to drainage and/or surgical correction of an underlying lesion or process in intraabdominal abscesses (Fig. 130-CD1). Unlike the intraabdominal abscesses precipitated by most infections, for which drainage of some kind is generally required, abscesses associated with diverticulitis usually wall off locally after rupture of a diverticulum, so that surgical intervention is not routinely required.

A number of antimicrobial agents exhibit excellent activity against aerobic gram-negative bacilli. Since mortality in intraabdominal sepsis is linked to gram-negative bacteremia, empirical therapy for intraabdominal infection always needs to include adequate coverage of gram-negative aerobic and facultative organisms. Aminoglycosides and second- and third-generation cephalosporins are the agents most widely tested and used in intraabdominal processes. Newer antibiotics, such as aztreonam, imipenem, ticarcillin/clavulanic acid, piperacillin/tazobactam, and quinolones (e.g., ciprofloxacin), cover these organisms as well, although at a higher cost. Second-generation cephalosporins, such as cefoxitin or cefotetan, are not as uniformly active as the other agents against all of the aerobic gram-negative species. Aztreonam, ciprofloxacin, aminoglycosides, and most of the third-generation cephalosporins are not active against anaerobes; for the treatment of intraabdominal infections, these drugs need to be used in combination with another antibiotic. Since a number of antibiotics highly effective against anaerobes are available, third-generation cephalosporins generally should not be considered for use against the anaerobic bacteria involved in intraabdominal sepsis.

The most active and cost-effective antibiotic for anaerobic coverage currently is metronidazole (Chap. 167). Only rare isolates of *B. fragilis* have been reported to be resistant to this drug. In a study of 3177 anaerobic isolates from eight centers in the United States over a 5-year period, no strains resistant to metronidazole were

documented among *B. fragilis* isolates, and resistance to imipenem, ampicillin/sulbactam, and piperacillin/tazobactam was exceedingly rare. In contrast, resistance to cefotetan, ceftizoxime, and clindamycin increased during this interval, and resistance to cefoxitin was measurable but unchanged during the study. Despite increasing reports of in vitro resistance of *B. fragilis* to a number of agents, clinical failures are still limited to case reports; therefore, the clinical significance of antimicrobial resistance in anaerobes is uncertain. One report describes a bloodstream isolate of *B. fragilis* with resistance to metronidazole and with reduced susceptibility to imipenem and amoxicillin/clavulanic acid that became resistant to both of the latter two drugs after treatment of the patient with imipenem. Among newer agents, imipenem, ticarcillin/clavulanic acid, piperacillin/tazobactam, meropenem, and ampicillin/sulbactam are highly active against anaerobes. Chloramphenicol, which exhibits strong activity against *B. fragilis* in vitro, nevertheless should probably not be considered a first-line drug for use against anaerobes, since failures of treatment have been documented in both experimental and clinical intraabdominal infections. Neither metronidazole nor clindamycin covers aerobic gram-negative bacilli; thus, these drugs must be combined with other agents for use in this setting. Metronidazole is also less active against gram-positive than against gram-negative anaerobic species.

VISCERAL ABSCESSES

Liver Abscesses The liver is the organ most subject to the development of abscesses. Altemeier and associates studied 540 intraabdominal abscesses over a 12-year period. Of these abscesses 26% were visceral. Liver abscesses made up 13% of the total number of abscesses, or 48% of all visceral abscesses. Liver abscesses may be solitary or multiple (Fig. 130-CD2); they may arise from hematogenous spread of bacteria or from local spread from contiguous sites of infection within the peritoneal cavity. In the past, appendicitis with rupture and subsequent spread of infection was the most common route for the development of a liver abscess. Currently, associated disease of the biliary tract is most often the etiology. Suppurative pylephlebitis (suppurative thrombosis of the portal vein), usually arising from infection in the pelvis but sometimes from infection elsewhere in the peritoneal cavity, is another common source for bacterial seeding of the liver.

Fever is the most common presenting sign of liver abscess. Some patients, particularly those with active associated disease of the biliary tract, have symptoms and signs localized to the right upper quadrant, including pain, guarding, punch tenderness, and even rebound tenderness. Nonspecific symptoms, such as chills, anorexia, weight loss, nausea, and vomiting, may also develop. Only 50% of patients with liver abscesses, however, have hepatomegaly, right-upper-quadrant tenderness, or jaundice; thus, half of patients have no symptoms or signs that would direct attention to the liver. Fever of unknown origin (FUO) may be the only presenting manifestation of liver abscess, especially in the elderly. Diagnostic studies of the abdomen, especially the right upper quadrant, should be a part of any FUO workup. The single most reliable laboratory finding is an elevated serum concentration of alkaline phosphatase, which is documented in 70% of patients with liver abscesses. Other tests of liver function may yield normal results, but 50% of patients have elevated serum levels of bilirubin, and 48% have elevated concentrations of aspartate aminotransferase. Other associated laboratory findings include leukocytosis in 77% of patients, anemia (usually

normochromic, normocytic) in 50%, and hypoalbuminemia in 33%. Concomitant bacteremia is found in one-third of patients. A liver abscess is sometimes suggested by chest radiography, especially if a new elevation of the right hemidiaphragm is seen; other suggestive findings include a right basilar infiltrate and a right pleural effusion.

Imaging studies are the most reliable methods for diagnosing liver abscesses. These studies include ultrasonography,CT, indium-labeledWBC or gallium scans, and even magnetic resonance imaging. In an occasional case, more than one such study may be required. Organisms recovered from liver abscesses vary with the etiology. In liver infection arising from the biliary tree, enteric gram-negative aerobic bacilli and enterococci are common isolates. Unless previous surgery has been performed, anaerobes are not generally involved in liver abscesses arising from biliary infections. In contrast, in liver abscesses arising from pelvic and other intraperitoneal sources, a mixed flora including aerobic and anaerobic species (especially *B. fragilis*) is common. With hematogenous spread of infection, usually only a single organism is encountered; this species may be *S. aureus* or a streptococcal species such as *S. milleri.*

Liver abscesses may also be caused by *Candida* species; such abscesses usually follow fungemia in patients receiving chemotherapy for cancer and often present when neutrophils return after a period of neutropenia. Amebic liver abscesses are not an uncommon problem (Chap. 213). Amebic serologic testing gives positive results in >95% of cases; thus, a negative result helps to exclude this diagnosis.

TREATMENT

While drainage -- either percutaneous (with a pigtail catheter kept in place) or surgical -- remains the mainstay of therapy for intraabdominal abscesses (including liver abscesses), there is growing interest in medical management alone for pyogenic liver abscesses. The drugs used in empirical broad-spectrum antibiotic therapy include the same ones used in intraabdominal sepsis. Usually, a diagnostic aspirate of abscess contents should be obtained before the initiation of empirical therapy, with antibiotic choices adjusted when the results of Gram's staining and culture become available. Cases treated without definitive drainage generally require longer courses of antibiotic therapy. When percutaneous drainage was compared with open surgical drainage, the average length of hospital stay for the former was almost twice that for the latter, although both the time required for fever to resolve and mortality were the same for the two procedures. Mortality was appreciable despite treatment, averaging 15%. Several factors may predict the failure of percutaneous drainage and therefore may favor primary surgical intervention. These factors include the presence of multiple, sizable abscesses; viscous abscess contents that tend to plug the catheter; associated disease (e.g., disease of the biliary tract) that requires surgery; or the lack of a clinical response to percutaneous drainage in 4 to 7 days.

Treatment of candidal liver abscesses usually entails lengthy administration of amphotericin B, although reports have described successful maintenance therapy with fluconazole after an initial course of amphotericin (Chap. 205).

Splenic Abscesses Splenic abscesses are much less common than liver abscesses. In fact, no splenic abscesses were observed in Altemeier's series of 540 intraabdominal

abscesses. The incidence of splenic abscesses has ranged from 0.14 to 0.7% in various autopsy series. The clinical setting and the organisms isolated usually differ from those for liver abscesses. The degree of clinical suspicion for splenic abscess needs to be high, as this condition is frequently fatal if left untreated. Even in the most recently published series, diagnosis was made only at autopsy in 37% of cases. While splenic abscesses may arise occasionally from contiguous spread of infection or from direct trauma to the spleen, hematogenous spread of infection is the usual mode of development. Bacterial endocarditis is the most common associated infection. Splenic abscesses can develop in patients who have received extensive immunosuppressive therapy (particularly those with malignancy involving the spleen) and in patients with hemoglobinopathies or other hematologic disorders (especially sickle cell anemia).

While ~50% of patients with splenic abscesses have abdominal pain, the pain is localized to the left upper quadrant in only half of these cases. Splenomegaly is found in ~50% of cases. Fever and leukocytosis are generally present; the development of fever preceded diagnosis by an average of 20 days in one series. Left-sided chest findings may include abnormalities to auscultation, and chest radiographic findings may include an infiltrate or a left-sided pleural effusion. When splenic abscesses are being considered in a differential diagnosis,CT scan of the abdomen has been the most sensitive diagnostic tool. Ultrasonography can yield the diagnosis, but cases have been missed with this modality. Liver-spleen scan or gallium scan may also be useful. Streptococcal species are the most common bacterial isolates from splenic abscesses, and *S. aureus* is the next most common; presumably these prevalences reflect the bacterial cause of the associated endocarditis. An increase in the frequency of isolation of gram-negative aerobic organisms from splenic abscesses has been reported; these organisms often derive from a urinary tract focus, with associated bacteremia, or from another intraabdominal source. *Salmonella* species are seen fairly commonly, especially in patients with sickle cell hemoglobinopathy. Anaerobic species accounted for only 5% of isolates in the largest collected series, but the reporting of a number of "sterile abscesses" may indicate that optimal techniques for the isolation of anaerobes were not employed.

TREATMENT

Because of the high mortality figures reported for splenic abscesses, the treatment of choice is splenectomy with adjunctive antibiotics. However, percutaneous drainage has been successful. The most important factor in successful treatment of splenic abscesses is early consideration of the diagnosis.

Perinephric and Renal Abscesses Perinephric and renal abscesses are not common: The former accounted for only ~0.02% of hospital admissions and the latter for ~0.2% in Altemeier's series of 540 intraabdominal abscesses. While liver abscesses generally arise from contiguous foci of infection or track from other intraabdominal sources and splenic abscesses usually arise from hematogenous spread (e.g., spread from bacterial endocarditis), perinephric and renal abscesses have a different pathogenesis. Before antibiotics became available, most renal and perinephric abscesses were hematogenous in origin, with *S. aureus* most commonly recovered. Now, in contrast,>75% of perinephric and renal abscesses arise from an initial urinary tract infection. Infection ascends from the bladder to the kidney, with pyelonephritis occurring

first. Bacteria may directly invade the renal parenchyma from medulla to cortex. Local vascular channels within the kidney may also facilitate the transport of organisms. Areas of abscess developing within the parenchyma may rupture into the perinephric space. The kidneys and adrenal glands are surrounded by a layer of perirenal fat that, in turn, is surrounded by Gerota's fascia, which extends superiorly to the diaphragm and inferiorly to the pelvic fat. When abscesses extend into the perinephric space, tracking may occur through Gerota's fascia into the psoas or transversalis muscles, into the anterior peritoneal cavity, superiorly to the subdiaphragmatic space, or inferiorly to the pelvis. Of the several risk factors that have been associated with the development of perinephric abscesses, the most important is the presence of concomitant nephrolithiasis producing local obstruction to urinary flow. Of patients with perinephric abscess, 20 to 60% have renal stones. In addition, other structural abnormalities of the urinary tract, a history of urologic surgery, trauma, and diabetes mellitus have all been identified as risk factors.

The organisms most frequently encountered in perinephric and renal abscesses are *E. coli*, *Proteus* species, and *Klebsiella* species. *E. coli*, the aerobic species most commonly found in colonic flora, seems to have unique virulence properties in the urinary tract, including factors promoting adherence to uroepithelial cells. The urease of *Proteus* species splits urea, thereby creating a more alkaline and hospitable environment for bacterial proliferation. *Proteus* species are frequently found in association with large struvite stones caused by the precipitation of magnesium ammonium sulfate in an alkaline environment. These stones serve as a nidus for recurrent urinary tract infection. While a single bacterial species is usually recovered from a perinephric or renal abscess, multiple species may also be found. If a urine culture is not contaminated with periurethral flora and is found to contain more than one organism, a perinephric abscess or renal abscess should be considered in the differential diagnosis. Urine cultures may also be polymicrobial in cases of bladder diverticulum.

Candida species should be considered in the etiology of renal abscesses. This fungus may spread to the kidney via the hematogenous route or by ascension from the bladder. The hallmark of the latter route of infection is ureteral obstruction with large fungal balls.

The presentation of perinephric and renal abscesses is quite nonspecific. Flank pain and abdominal pain are common. At least 50% of patients are febrile. Pain may be referred to the groin or leg, particularly with extension of infection. The diagnosis of perinephric abscess, like that of splenic abscess, is frequently delayed, and mortality in some series is appreciable, although lower than in the past. Perinephric or renal abscess should be most seriously considered when a patient presents with symptoms and signs of pyelonephritis and remains febrile after 4 or 5 days, by which time the fever should have resolved. Moreover, when a urine culture yields a polymicrobial flora, when a patient is known to have renal stone disease, or when fever and pyuria coexist with a sterile urine culture, the diagnosis of perinephric or renal abscess should be entertained.

Renal ultrasonography and abdominalCT are the most useful diagnostic modalities. If a renal abscess or perinephric abscess is diagnosed, nephrolithiasis should be excluded, especially when a high urinary pH suggests the presence of a urea-splitting organism.

TREATMENT

Treatment for perinephric or renal abscesses, like that for other intraabdominal abscesses, includes drainage of pus and antibiotic therapy directed at the organism(s) recovered. For perinephric abscesses, percutaneous drainage is usually successful.

131. ACUTE INFECTIOUS DIARRHEAL DISEASES AND BACTERIAL FOOD POISONING - *Joan R. Butterton*, *Stephen B. Calderwood*

Ranging from mild annoyances during vacations to devastating dehydrating illnesses that can kill within hours, acute gastrointestinal illnesses rank second only to acute upper respiratory illnesses as the most common diseases worldwide. In children <5 years old, attack rates range from 2 to 3 illnesses per child per year in developed countries to as high as 10 to 18 illnesses per child per year in developing countries. In Asia, Africa, and Latin America, acute diarrheal illnesses are not only a leading cause of morbidity in children -- with an estimated 1 billion cases per year -- but also the major cause of mortality, being responsible for 4 to 6 million deaths per year, or a sobering total of 12,600 deaths per day. In some areas, more than 50% of childhood deaths are directly attributable to acute diarrheal illnesses. In addition, by contributing to malnutrition and thereby reducing resistance to other infectious agents, gastrointestinal illnesses may be indirect factors in a far greater burden of disease.

The wide range of clinical manifestations of acute gastrointestinal illnesses is matched by the wide variety of infectious agents involved, including viruses, bacteria, and parasitic pathogens (Table 131-1). This chapter will discuss factors that enable gastrointestinal pathogens to cause disease, will review host defense mechanisms, and will delineate an approach to the evaluation and treatment of patients presenting with acute diarrhea. Individual organisms causing acute gastrointestinal illnesses are discussed in detail in subsequent chapters.

PATHOGENIC MECHANISMS

Enteric pathogens have developed a variety of tactics to overcome host defenses. Understanding the virulence factors employed by these organisms is important in the diagnosis and treatment of clinical disease.

Inoculum Size The number of microorganisms that must be ingested to cause disease varies considerably from species to species. For *Shigella*, enterohemorrhagic *Escherichia coli*, *Giardia lamblia*, or *Entamoeba*, as few as 10 to 100 bacteria or cysts can produce infection, while 10^5 to 10^8 *Vibrio cholerae* organisms must be ingested orally to cause disease. The infective dose of *Salmonella* varies widely, depending on the species, host, and food vehicle. The ability of organisms to overcome host defenses has important implications for transmission; *Shigella*, enterohemorrhagic *E. coli*, *Entamoeba*, and *Giardia* can spread by person-to-person contact, whereas under some circumstances *Salmonella* may have to grow in food for several hours before reaching an effective infectious dose.

Adherence Many organisms must adhere to the gastrointestinal mucosa as an initial step in the pathogenic process; thus, organisms that can compete with the normal bowel flora and colonize the mucosa have an important advantage in causing disease. Specific cell-surface proteins involved in attachment of bacteria to intestinal cells are important virulence determinants. *V. cholerae*, for example, adheres to the brush border of small-intestinal enterocytes via specific surface adhesins, including the toxin-coregulated pilus and other accessory colonization factors. Enterotoxigenic *E. coli* produces an adherence protein called *colonization factor antigen* that is necessary for

colonization of the upper small intestine by the organism prior to the production of enterotoxin. Enteropathogenic and enterohemorrhagic strains of *E. coli* produce virulence determinants that allow these organisms to attach to and efface the brush border of the intestinal epithelium.

Toxin Production The production of one or more exotoxins is important in the pathogenesis of numerous enteric organisms. Such toxins include *enterotoxins*, which cause watery diarrhea by acting directly on secretory mechanisms in the intestinal mucosa; *cytotoxins*, which cause destruction of mucosal cells and associated inflammatory diarrhea; and *neurotoxins*, which act directly on the central or peripheral nervous system. Some exotoxins act by more than one mechanism; *Shigella dysenteriae* type 1, for example, produces an exotoxin that has both enterotoxic and cytotoxic activities.

The prototypical enterotoxin is cholera toxin, a heterodimeric protein composed of one A and five B subunits. The A subunit contains the enzymatic activity of the toxin, while the B subunit pentamer binds holotoxin to the enterocyte surface receptor, the ganglioside G_{M1}. After the binding of holotoxin, a fragment of the A subunit is translocated across the eukaryotic cell membrane into the cytoplasm, where it catalyzes the ADP-ribosylation of a GTP-binding protein and causes persistent activation of adenylate cyclase. The end result is an increase of cyclic AMP in the intestinal mucosa, which increases Cl^- secretion and decreases Na^+absorption, leading to loss of fluid and the production of diarrhea.

Enterotoxigenic strains of *E. coli* may produce a protein called *heat-labile enterotoxin* (LT) that is similar to cholera toxin and causes secretory diarrhea by the same mechanism. Alternatively, enterotoxigenic strains of *E. coli* may produce *heat-stable enterotoxin* (ST), one form of which causes diarrhea by activation of guanylate cyclase and elevation of intracellular cyclic GMP. Some enterotoxigenic strains produce both LT and ST.

Bacterial cytotoxins, in contrast, destroy intestinal mucosal cells and produce the syndrome of dysentery, with bloody stools containing inflammatory cells. Enteric pathogens that produce such cytotoxins include *S. dysenteriae* type 1, *Vibrio parahaemolyticus*, and *Clostridium difficile*. Shiga toxin-producing strains of *E. coli*, most commonly serotype O157:H7 in the United States, produce potent cytotoxins that are highly related to the Shiga toxin of *S. dysenteriae* type 1. Such strains of *E. coli* have been associated with outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome.

Neurotoxins usually are produced by the responsible organism outside the host and therefore cause symptoms soon after ingestion. Included are the staphylococcal and *Bacillus cereus* toxins, which act on the central nervous system to produce vomiting.

Invasion Dysentery may result not only from the production of cytotoxins but also from bacterial invasion and destruction of intestinal mucosal cells. Infections due to *Shigella* and enteroinvasive *E. coli*, for example, are characterized by the organisms' invasion of mucosal epithelial cells, intraepithelial multiplication, and subsequent spread to adjacent cells. *Salmonella*, on the other hand, causes inflammatory diarrhea by invasion of the bowel mucosa but generally is not associated with the destruction of enterocytes or the

full clinical syndrome of dysentery. *Salmonella typhi* and *Yersinia enterocolitica* can penetrate intact intestinal mucosa, multiply intracellularly in Peyer's patches and intestinal lymph nodes, and then disseminate through the bloodstream to cause enteric fever, a syndrome characterized by fever, headache, relative bradycardia, abdominal pain, splenomegaly, and leukopenia.

HOST DEFENSES

Given the enormous number of microorganisms ingested with every meal, the normal host must possess effective defense mechanisms to combat a constant influx of potential enteric pathogens. Studies of infections in patients with alterations in these defenses have led to a greater understanding of the variety of ways in which the normal host can protect itself against disease.

Normal Flora The large numbers of bacteria that normally inhabit the intestine act as an important host defense by preventing colonization by potential enteric pathogens. Persons with fewer intestinal bacteria, such as infants who have not yet developed normal enteric colonization or patients receiving antibiotics, are at significantly greater risk of developing infections with enteric pathogens. The composition of the intestinal flora is as important as the number of organisms present. More than 99% of the normal colonic flora is made up of anaerobic bacteria, and the acidic pH and volatile fatty acids produced by these organisms appear to be critical elements in resistance to colonization.

Gastric Acid The acidic pH of the stomach is an important barrier to enteric pathogens, and an increased frequency of infections due to *Salmonella*, *G. lamblia*, and a variety of helminths has been reported among patients who have undergone gastric surgery or are achlorhydric for some other reason. Neutralization of gastric acid with antacids or H_2blockers -- common among hospitalized patients -- similarly increases the risk of enteric colonization. Some microorganisms, however, can survive the extreme acidity of the gastric environment; rotavirus, for example, is highly stable to acidity.

Intestinal Motility Normal peristalsis is the major mechanism for clearance of bacteria from the proximal small intestine, although gastric acidity and secreted immunoglobulins also play a role in limiting the number of organisms present. When intestinal motility is impaired -- for example, by treatment with opiates or other antimotility drugs, anatomic abnormalities (diverticula, fistulas, or afferent-loop stasis following surgery), or hypomotility states (as in diabetes mellitus or scleroderma) -- the frequency of bacterial overgrowth and infection of the small bowel with enteric pathogens is much increased. Some patients in whom *Shigella* infection is treated with diphenoxylate hydrochloride with atropine (Lomotil) experience prolonged fever and shedding of organisms, while patients treated with opiates for mild *Salmonella* gastroenteritis have a higher frequency of bacteremia than those not treated with opiates.

Immunity Both cellular immune responses and antibody production play important roles in protecting susceptible hosts from enteric infections. The wide spectrum of viral, bacterial, parasitic, and fungal gastrointestinal infections in patients with AIDS highlights the significance of cell-mediated immunity in protecting the normal host from these pathogens. Humoral immunity is also important and consists of systemic IgG and IgM

as well as secretory IgA. Growing evidence supports the concept of a mucosal immune system for secretory IgA in which binding of bacterial antigens to the luminal surface of M cells in the distal small bowel and subsequent presentation of the antigens to subepithelial lymphoid tissue lead to the proliferation of sensitized lymphocytes. These lymphocytes circulate and populate all of the mucosal tissues of the body as IgA-secreting plasma cells.

Approach to the Patient

The approach to the patient with possible infectious diarrhea or bacterial food poisoning is shown inFig. 131-1.

History The answers to questions with high discriminating value can quickly narrow the range of potential causes of diarrhea and help determine whether treatment is needed. Important elements of the narrative history are detailed inFig. 131-1.

Physical Examination The examination of patients for signs of dehydration provides essential information about the severity of the diarrheal illness and the need for rapid therapy. Mild dehydration is indicated by thirst, dry mouth, decreased axillary sweat, decreased urine output, and slight weight loss. Signs of moderate dehydration include an orthostatic fall in blood pressure, skin tenting, and sunken eyes (or, in infants, a sunken fontanelle). Signs of severe dehydration range from hypotension and tachycardia to confusion and frank shock.

Diagnostic Approach After the severity of illness is assessed, the most important distinction that the clinician must make is between *inflammatory* and *noninflammatory* disease. Using the history and epidemiologic features of the case as guides in making this distinction, the clinician can rapidly evaluate the need for further efforts to define a specific etiology and for therapeutic intervention. Examination of a stool sample is an important supplement to the narrative history (Fig. 131-CD1). Grossly bloody or mucoid stool suggests an inflammatory process, but all stools should be examined for fecal leukocytes; the latter task is accomplished by the preparation of a thin smear of the stool on a glass slide, the addition of a drop of methylene blue, and examination of the wet mount. Causes of acute infectious diarrhea, categorized as inflammatory and noninflammatory, are listed inTable 131-1.

EPIDEMIOLOGY

Travel History Of the 12 to 20 million people who travel from temperate industrialized countries to tropical regions of Asia, Africa, and Central and South America each year, 20 to 50% experience a sudden onset of abdominal cramps, anorexia, and watery diarrhea; thus *traveler's diarrhea* is the most common travel-related illness (Chap. 123). The time of onset is usually 3 days to 2 weeks after the traveler's arrival in a tropical area; most cases begin within the first 3 to 5 days. The illness is generally self-limited, lasting 1 to 5 days. The high rate of diarrhea among travelers to underdeveloped areas is related to the ingestion of contaminated food or water.

The organisms that cause traveler's diarrhea vary considerably with location. In all areas, enterotoxigenic *E. coli* is the most common isolate from persons with the classic

secretory traveler's diarrhea syndrome; the proportion of cases accounted for by this organism ranges from a high of approximately 50% in Latin America to a low of 15% in Asia. *Shigella*, *Salmonella*, and *Campylobacter* spp. are classically considered to cause more invasive dysenteric disease than enterotoxigenic *E. coli*, but clinical differentiation of infections attributable to these organisms can be difficult. *Shigella*, *Salmonella*, and *Campylobacter* are isolated in 1 to 15% of cases, with different organisms being more common in different locations. *Vibrio* spp. are most common in Asia, although *V. cholerae* O1 reached epidemic proportions in parts of Central and South America in 1991 and remains a significant source of concern to travelers to these regions. Epidemic *V. cholerae* O139 Bengal has spread throughout India and Southeast Asia since 1992. Less frequently isolated bacteria are *Aeromonas hydrophila* and *Plesiomonas shigelloides*, which are more common among travelers to Thailand. Parasitic causes of traveler's diarrhea include *Entamoeba histolytica*, which is responsible for up to 5% of cases in Mexico and Thailand, and *G. lamblia*, which has been associated with contaminated freshwater supplies in many areas of the world. *Giardia* is found in association with zoonotic reservoirs in the northern United States and poses a risk to hikers and campers who drink from freshwater streams. A striking association of *Giardia* with contaminated water supplies has likewise been noted in Russia. *Cryptosporidium* has been recognized as a problem in travelers to the former Soviet Republics, Mexico, and Africa and has caused large-scale urban outbreaks of infection in the United States. Disease due to *Cyclospora* and microsporidia has recently been recognized. Viruses such as rotavirus and Norwalk-like viruses have been isolated from as many as 10 to 40% of visitors to areas of Latin America, Asia, and Africa who develop traveler's diarrhea.

Location Day-care centers are sites of particularly high attack rates of enteric infections. Rotavirus is most common among children <2 years old, with attack rates of 75 to 100% among those exposed. *G. lamblia* is more common among older children, with somewhat lower attack rates. Other common organisms, often spread by fecal-oral contact, are *Shigella*, *Campylobacter jejuni*, and *Cryptosporidium*. A characteristic feature of infection in day-care centers is the high rate of secondary cases among family members.

Similarly, hospitals are sites for concentrations of enteric infections. In medical intensive-care units and pediatric wards, diarrhea is among the most common nosocomial infections. *C. difficile* is the predominant cause of nosocomial diarrhea among adults in the United States; viral pathogens, especially rotavirus, can spread rapidly in pediatric wards. Enteropathogenic *E. coli* has been associated with outbreaks of diarrhea in nurseries for newborns. One-third of elderly patients in chronic-care institutions develop a significant diarrheal illness each year. Surveillance stool cultures suggest that 25% of the residents of these institutions harbor cytotoxin-producing *C. difficile*, which causes more than half of all cases of diarrhea in this population. Antimicrobial therapy can predispose to pseudomembranous colitis by altering the normal colonic flora and allowing the multiplication of *C. difficile*.

Age Most of the morbidity and mortality from enteric pathogens involves children<5 years of age. Breast-fed infants are protected from contaminated food and water and derive some protection from maternal antibodies, but their risk of infection rises dramatically when they begin to eat solid foods. Infants and younger children are more

likely than adults to develop rotaviral disease, while older children and adults are more commonly infected with Norwalk-like viruses. Other organisms with higher attack rates among children than among adults include enterotoxigenic, enteropathogenic, and enterohemorrhagic *E. coli*; *C. jejuni*; and *G. lamblia*. In children, the incidence of *Salmonella* infections is highest among infants<1 year of age, while the attack rate for *Shigella* infections is greatest among children aged 6 months to 4 years.

Bacterial Food Poisoning If the history and the stool examination indicate a noninflammatory etiology of diarrhea and there is evidence of a common-source outbreak, questions concerning the ingestion of specific foods and the time of onset of the diarrhea after a meal can provide clues to the bacterial cause of the illness. Potential causes of bacterial food poisoning are shown inTable 131-2.

Bacterial disease caused by an enterotoxin elaborated outside the host, such as that due to *Staphylococcus aureus* or *B. cereus*, has the shortest incubation period (1 to 6 h) and generally lasts <12 h. Most cases of staphylococcal food poisoning are caused by contamination from infected human carriers. Staphylococci can multiply at a wide range of temperatures; thus, if food is left to cool slowly and remains at room temperature after cooking, the organisms will have the opportunity to form enterotoxin. Outbreaks following picnics where potato salad, mayonnaise, and cream pastries have been served offer classic examples of staphylococcal food poisoning. Diarrhea, nausea, vomiting, and abdominal cramping are common, while fever is less so.

B. cereus can produce either a syndrome with a short incubation period -- the *emetic* form, mediated by a staphylococcal type of enterotoxin -- or one with a longer incubation period (8 to 16 h) -- the *diarrheal* form, caused by an enterotoxin resembling *E. coli*LT, in which diarrhea and abdominal cramps are characteristic but vomiting is uncommon. The emetic form of *B. cereus* food poisoning is associated with contaminated fried rice; the organism is common in uncooked rice, and its heat-resistant spores survive boiling. If cooked rice is not refrigerated, the spores can germinate and produce toxin. Frying before serving may not destroy the preformed, heat-stable toxin.

Food poisoning due to *C. perfringens* also has a slightly longer incubation period (8 to 14 h) and results from the survival of heat-resistant spores in inadequately cooked meat, poultry, or legumes. After ingestion, toxin is produced in the intestinal tract, causing moderately severe abdominal cramps and diarrhea; vomiting is rare, as is fever. The illness is self-limited, rarely lasting for more than 24 h.

Not all food poisoning has a bacterial cause. Diagnostic confusion can result from diarrhea caused by nonbacterial agents of short-incubation food poisoning, including capsaicin, which is found in hot peppers, and a variety of toxins found in fish and shellfish (Chap. 397).

LABORATORY EVALUATION

Many cases of noninflammatory diarrhea are self-limited or can be treated empirically, and in these instances the clinician may not need to determine a specific etiology. Potentially pathogenic *E. coli* cannot be distinguished from normal fecal flora by routine culture. Special tests to detectLT andST are not available in most clinical laboratories. In

situations in which cholera is a concern, stool should be cultured on thiosulfate-citrate-bile salts-sucrose (TCBS) agar. A latex agglutination test has made the rapid detection of rotavirus in stool practical for many laboratories, while reverse transcriptase polymerase chain reaction and specific antigen enzyme immunoassays have been developed for the identification of Norwalk-like viruses. At least three stool specimens should be examined for *Giardia* cysts or stained for *Cryptosporidium* if the level of clinical suspicion regarding the involvement of these organisms is high.

All patients with fever and evidence of inflammatory disease acquired outside the hospital should have stool cultured for *Salmonella*, *Shigella*, and *Campylobacter*. *Salmonella* and *Shigella* can be selected on MacConkey's agar as non-lactose-fermenting (colorless) colonies or can be grown on *Salmonella-Shigella* agar or in selenite enrichment broth, both of which inhibit most organisms except these pathogens. Evaluation of nosocomial diarrhea should initially focus on *C. difficile*; stool culture for other pathogens in this setting has an extremely low yield and is not cost-effective. Pathogenic strains of *C. difficile* generally produce two toxins, A and B. Toxin B can be detected with a cytotoxin assay; if the toxin is present, a monolayer culture of fibroblasts will show cytopathic effects within 6 to 24 h. Rapid enzyme immunoassays and latex agglutination tests for both toxin A and toxin B have recently been developed (Chap. 145). Isolation of *C. jejuni* requires inoculation of fresh stool onto selective growth medium and incubation at 42°C in a microaerophilic atmosphere. In many laboratories in the United States, *E. coli* O157:H7 is among the most common pathogens isolated from visible bloody stools. Strains of this enterohemorrhagic serotype can be identified in specialized laboratories by serotyping but also can be identified presumptively as lactose-fermenting, indole-positive colonies of sorbitol nonfermenters (white colonies) on sorbitol MacConkey plates. Fresh stools should be examined for amebic cysts and trophozoites.

TREATMENT

In many cases, a specific diagnosis is not necessary or not available to guide treatment. The clinician can proceed with the information obtained from the history, stool examination, and evaluation of the severity of dehydration. Empirical regimens for the treatment of traveler's diarrhea are listed inTable 131-3.

The mainstay of treatment is adequate rehydration. The treatment of cholera and other dehydrating diarrheal diseases was revolutionized by the promotion of oral rehydration solutions, the efficacy of which depends on the fact that glucose-facilitated absorption of sodium and water in the small intestine remains intact in the presence of cholera toxin. The use of oral rehydration solutions has reduced mortality due to cholera from>50% (in untreated cases) to<1%. The World Health Organization recommends a solution containing 3.5 g sodium chloride, 2.5 g sodium bicarbonate, 1.5 g potassium chloride, and 20 g glucose (or 40 g sucrose) per liter of water. Patients who are severely dehydrated or in whom vomiting precludes the use of oral therapy should receive intravenous solutions such as Ringer's lactate.

Although most secretory forms of traveler's diarrhea -- usually due to enterotoxigenic *E. coli* -- can be treated effectively with rehydration, bismuth subsalicylate, or antiperistaltic agents, antimicrobial agents can shorten the duration of illness from between 3 and 4

days to between 24 and 36 h.

PROPHYLAXIS

Improvements in hygiene to limit fecal-oral spread of enteric pathogens will be necessary if the prevalence of diarrheal diseases is to be significantly reduced in developing countries. Travelers can reduce their risk of diarrhea by eating only hot, freshly cooked food; by avoiding raw vegetables, salads, and unpeeled fruit; and by drinking only boiled or treated water and avoiding ice. In one cross-sectional epidemiologic survey, fewer than 3% of all European and North American travelers to Jamaica adhered to prescribed dietary restrictions, and travel health advice had no impact on the incidence of traveler's diarrhea; overall, the diarrhea attack rate among these travelers was 23.6%, with classic traveler's diarrhea in 11.7%.

Bismuth subsalicylate is an inexpensive agent for the prophylaxis of traveler's diarrhea; it is taken at a dosage of 2 tablets (525 mg) four times a day. Treatment appears to be effective and safe for up to 3 weeks. Prophylactic antimicrobial agents, although effective, are not generally recommended for the prevention of traveler's diarrhea, except when travelers are immunosuppressed or have other underlying illnesses that place them at high risk for morbidity from gastrointestinal infection. The risk of side effects and the possibility of developing an infection with a drug-resistant organism or with more harmful, invasive bacteria make it more reasonable to institute a short course of treatment once symptoms have developed.

The possibility of exerting a major impact on the worldwide morbidity and mortality associated with diarrheal diseases has led to intense efforts to develop effective vaccines against the common bacterial and viral enteric pathogens. Recent research has shown promising advances in the development of vaccines against rotavirus, *Shigella*, *V. cholerae*, *S. typhi*, and enterotoxigenic *E. coli*.

132. SEXUALLY TRANSMITTED DISEASES: OVERVIEW AND CLINICAL APPROACH - *King K. Holmes*

In all societies, sexually transmitted diseases (STDs) rank among the most common of all infectious diseases, with over 30 infections now classified as predominantly sexually transmitted or as frequently sexually transmissible (Table 132-1). The many new sexually transmitted pathogens recognized and characterized since 1980 include HIV types 1 and 2, human T cell lymphotropic virus (HTLV) types I and II, many genital types of human papillomavirus (HPV), *Mycoplasma genitalium*, two species of *Mobiluncus* (associated with bacterial vaginosis), two species of *Helicobacter* (initially associated with proctocolitis in homosexual men and later, during the AIDS era, with bacteremia, dermatitis, and fever among immunosuppressed individuals), and the Kaposi's sarcoma-associated herpesvirus (human herpesvirus type 8, or HHV-8).

In developing countries, with three-quarters of the world's population and 90% of the world'sSTDs, such factors as population growth (especially in adolescent and young-adult age groups), rural-to-urban migration, wars, and poverty create exceptional vulnerability to disease resulting from risky sexual behaviors. This situation leads to the spread of STD, with the emergence of new pathogens and new variants of old pathogens. During the 1990s, in China, Russia, the states of the former Soviet Union, and South Africa, internal social structures changed rapidly as borders opened to the West, unleashing enormous new epidemics of HIV infection and other STDs. HIV has become the leading cause of death in some developing countries, andHPV and hepatitis B virus (HBV) remain important causes of cervical and hepatocellular carcinoma, respectively -- two of the commonest malignancies in the developing world. Sexually transmitted herpes simplex virus (HSV) infections now cause most genital ulcer disease throughout the world and an increasing proportion of cases of genital herpes in developing countries with generalized HIV epidemics, where the positive feedback loop between HSV and HIV transmission is a growing, intractable problem. Globally, the agents of curable STDs -- gonorrhea, chlamydial infections, syphilis, chancroid, and trichomoniasis -- caused ~350 million new infections annually in the mid-1990s. Bacterial vaginosis (arguably acquired sexually) occurs in up to 50% of women of reproductive age in developing countries. Thus, there are probably close to 1 billion cases of these curable infections annually, all six of which are associated with increased risk of HIV transmission or acquisition.

In the industrialized countries, fear of HIV infection since the mid- 1980s, coupled with widespread behavioral interventions and better- organized systems of care for the curableSTDs, have helped curb the transmission of the latter diseases. Nonetheless, viral STDs, such as genital herpes andHPVinfection, had not obviously decreased in incidence at the turn of the millennium, and infection with HIV remains a leading cause of death in persons 25 to 44 years of age in the United States, as in developing countries, despite the advent of potent antiretroviral therapy.

Although rates of the bacterialSTDshave fallen in all industrialized countries over the past 20 years, foci of hyperendemic transmission persist in the southeastern United States and in most large U.S. cities. Rates of gonorrhea and syphilis remain higher in the United States than in any other Western industrialized country. The reemergence of syphilis and gonorrhea epidemics in Russia and the former Soviet states has created

similar foci for reintroduction of these STDs into western Europe. The remarkable return of high rates of gonorrhea and syphilis among homosexual and bisexual men in many parts of the United States reflects increased risk-taking since the advent of potent antiretroviral therapy and may portend resurgent transmission of HIV in this group.

CLASSIFICATION AND EPIDEMIOLOGY

Sexually transmitted infection (STI) may or may not result in disease (STD). Some prefer the term *reproductive tract infection* to destigmatize the diagnosis and treatment of STIs and to encompass conditions such as bacterial vaginosis, whose designation as an STD is debated.

CertainSTDs(such as syphilis, gonorrhea, HIV infection, hepatitis B, and chancroid) are most concentrated within "core populations" having high rates of partner change, concurrent partners, or "dense" sexual networks -- for example, prostitutes and their clients and persons involved in the use of illicit drugs, particularly crack cocaine. Poor access to or low motivation for obtaining early treatment also fosters spread of the curable STIs. In most of the United States, groups most vulnerable to STDs, including HIV infection, consist predominantly of young unmarried individuals of low socioeconomic status who often reside within crowded urban neighborhoods, although some rural areas (e.g., in the southeastern United States) also have high rates of STIs. Other STDs are distributed more evenly in society. For example, chlamydial infections can persist for many months, often asymptomatically, and can propagate widely in populations that do not share all of the characteristics of core groups described above. Similarly, genitalHPVinfections and genital herpes persist and spread efficiently in relatively low-risk populations.

In general, the product of three factors determines the initial rate of spread of anySTIwithin a population: rate of exposure, efficiency of transmission per exposure, and duration of infectivity of those infected. Efforts to prevent and control STIs attempt to decrease the duration of infectivity (through early diagnosis and curative or suppressive treatment), to decrease the efficiency of transmission (e.g., through promotion of condom use and safer sexual practices), and to decrease the rate of exposure of susceptibles to infected persons (e.g., through provision of information, health education, and counseling and efforts to change the norms of sexual behavior).

MANAGEMENT OF COMMON STD SYNDROMES

Although other chapters discuss management of specificSTIs, delineating treatment based on diagnosis of a specific infection, most patients are actually managed (at least initially) on the basis of presenting symptoms and signs and associated risk factors, even in industrialized countries.Table 132-2 lists some of the most common clinicalSTDsyndromes and their microbial etiologies. Strategies for their management are outlined below. Chaps. 191 and309address the management of infections with human retroviruses.

RISK ASSESSMENT

Routine patient care begins with risk assessment (e.g., for heart disease, cancer). An

overall risk assessment interview should include STD/HIV in primary care, urgent care, and emergency care settings as well as in specialty clinics providing adolescent, prenatal, and family planning services. STD/HIV risk assessment guides interpretation of symptoms that could reflect an STD; decisions on screening or prophylactic/preventive treatment; risk reduction counseling and intervention (e.g., hepatitis B vaccination); and notification of partners of patients with known infections. Consideration of routine demographic data (e.g., gender, age, marital status, area of residence) is a simple first step in STD/HIV risk assessment. For example, national guidelines recommend routine screening of sexually active females £25 years of age for *C. trachomatis* infection. Table 132-3 provides a set of 10 STD/HIV risk assessment questions that clinicians can pose verbally or that health care systems can adapt (with yes/no responses) into a routine self-administered questionnaire for use in clinics. The initial framing statement gives permission to discuss taboo topics.

Risk assessment is followed by clinical assessment (elicitation of information on specific current symptoms and signs of STDs). Confirmatory diagnostic tests (for those with symptoms or signs) or screening tests (for those without symptoms or signs) may involve microscopic examination, culture, antigen detection tests, genetic probe or amplification tests, or serology. Initial syndrome-based treatment should cover the most likely causes. For certain syndromes, results of rapid tests can narrow the spectrum of this initial therapy (e.g., wet mount of vaginal fluid for women with vaginal discharge, Gram's stain of urethral discharge for men with urethral discharge, rapid plasma reagin test for genital ulcer). After the institution of treatment, STD management proceeds to the "4 C's" of prevention and control: *c*ontact tracing (see "Prevention and Control of STDs," below), ensuring *c*ompliance with therapy, and *c*ounseling on risk reduction, including *c*ondom promotion and provision.

URETHRITIS IN MEN

The incidence of reported gonococcal urethritis (Fig. 145-CD1) in the United States has fallen to the lowest level since reporting began, while that of nongonococcal urethritis (NGU) remains high -- a pattern typical of all industrialized countries. Until recently, *Chlamydia trachomatis* caused ~30 to 40% of NGU cases, but the proportion of cases due to this organism may have declined in some populations served by effective chlamydial control programs.HSV and *Trichomonas vaginalis* each cause a small proportion of NGU cases in the United States. Case-control studies have also implicated *Ureaplasma urealyticum* and *M. genitalium* as probable causes of many *Chlamydia*-negative cases, and coliform bacteria can cause urethritis in men who practice insertive anal intercourse. The initial diagnosis of urethritis in men currently includes specific tests only for *Neisseria gonorrhoeae* and *C. trachomatis*. Table 132-4 summarizes the steps in management of sexually active men with symptoms of urethral discharge and/or dysuria.

1. *Establish the presence of urethritis*. If proximal-to-distal "milking" of the urethra does not express a purulent or mucopurulent discharge, even after the patient has not voided for several hours or preferably overnight, the centrifuged sediment of the first 20 to 30 mL of voided urine can be examined for inflammatory cells, either by microscopy or by the leukocyte esterase test. In urethral gonococcal or chlamydial infection, a Gram's-stained smear of overt discharge or of an anterior urethral specimen obtained

by passage of a small urethrogenital swab 2 to 3 cm into the urethra usually reveals ³5 neutrophils per 1000´ field in areas containing cells; in gonococcal infection, such a smear also usually reveals gram-negative intracellular diplococci. Patients with symptoms who lack objective evidence of urethritis may have functional rather than organic problems and generally do not benefit from repeated courses of antibiotics.

2. *Evaluate for complications or alternative diagnoses*. A brief history and examination will exclude epididymitis and systemic complications, such as disseminated gonococcal infection and Reiter's syndrome. Although digital examination of the prostate gland seldom contributes to the evaluation of sexually active young men with urethritis, men with dysuria who lack evidence of urethritis as well as sexually inactive men with urethritis should undergo prostate palpation, urinalysis, and urine culture to exclude bacterial prostatitis and cystitis.

3. *Evaluate for gonococcal and chlamydial infection*. An absence of typical gram-negative diplococci on Gram's-stained smear of urethral exudate containing inflammatory cells warrants a preliminary diagnosis ofNGU and should lead to testing of the urethral specimen for *C. trachomatis*. Culture or DNA detection tests for *N. gonorrhoeae* may be positive when Gram's staining is negative; certain strains of *N. gonorrhoeae* reportedly can result in negative urethral Gram's stains in up to 30% of cases of urethritis. Results of tests for gonococcal and chlamydial infection predict the patient's prognosis (with greater risk for recurrent NGU if neither chlamydiae nor gonococci are found than if either is detected) and can guide both the counseling given to the patient and the management of the patient's sexual partner(s).

4. *Treat urethritis*.

TREATMENT

In practice, if Gram's stain does not reveal gonococci, urethritis is treated with a regimen effective forNGU, such as azithromycin (1.0 g orally in a single dose). If gonococci are demonstrated by Gram's stain or if no diagnostic tests are performed to definitively exclude gonorrhea, treatment should also include a single-dose regimen for gonorrhea (Chap. 147). Sexual partners should be tested for gonorrhea and chlamydial infection and should receive the same regimen given to the male index case.

EPIDIDYMITIS

Acute epididymitis, almost always unilateral, must be differentiated from testicular torsion, tumor, and trauma. Torsion, a surgical emergency, usually occurs in the second or third decade of life and produces a sudden onset of pain, elevation of the testicle within the scrotal sac, rotation of the epididymis from a posterior to an anterior position, and absence of blood flow on Doppler examination or^{99m}Tc scan. Persistence of symptoms after a course of therapy for epididymitis suggests the possibility of testicular tumor. In sexually active men under age 35, acute epididymitis is caused most frequently by *C. trachomatis* and less commonly by *N. gonorrhoeae* and is usually associated with overt or subclinical urethritis. Acute epididymitis in older men or following urinary tract instrumentation is usually caused by urinary pathogens. Similarly, epididymitis in men who have practiced insertive rectal intercourse is often caused by

Enterobacteriaceae. These men usually have no urethritis but do have bacteriuria.

TREATMENT

Ofloxacin (300 mg orally bid for 10 days) is an optimal agent for syndrome-based treatment of epididymitis because of its effectiveness against *N. gonorrhoeae*, *C. trachomatis*, and Enterobacteriaceae. Alternatively, ceftriaxone (250 mg intramuscularly) followed by doxycycline (100 mg orally bid for 10 days) is effective for epididymitis caused by *N. gonorrhoeae* or *C. trachomatis*.

URETHRITIS AND THE URETHRAL SYNDROME IN WOMEN

C. trachomatis, *N. gonorrhoeae*, and occasionallyHSVcause symptomatic urethritis -- known as the urethral syndrome in women -- characterized by "internal" dysuria (usually without urinary urgency or frequency) and pyuria, with *Escherichia coli* or other uropathogens not present in urine at counts of£10^2/mL. In contrast, the dysuria associated with vulvar herpes or vulvovaginal candidiasis (and perhaps with trichomoniasis) is often described as "external," being caused by painful contact of urine with the inflamed or ulcerated labia or introitus. Acute onset, association with urinary urgency or frequency, hematuria, or suprapubic bladder tenderness suggests bacterial cystitis. Among women with symptoms of acute bacterial cystitis, costovertebral pain and tenderness or fever suggests acute pyelonephritis. The management of bacterial urinary tract infection (UTI) is discussed inChap. 280.

Signs of vulvovaginitis, coupled with symptoms of external dysuria, suggest vulvar infection (e.g., withHSV or *Candida albicans*). Among dysuric women without signs of vulvovaginitis, bacterialUTI must be differentiated from the urethral syndrome by assessment of risk, evaluation of the pattern of symptoms and signs, and specific microbiologic testing. AnSTDetiology of the urethral syndrome is suggested by young age, more than one current sexual partner or a new partner within the past month, or coexisting mucopurulent cervicitis (MPC; see below). The finding of a single urinary pathogen, such as *E. coli* or *Staphylococcus saprophyticus*, at a concentration of^3$10^2$/mL in a properly collected specimen of midstream urine from a dysuric woman with pyuria indicates probable bacterial UTI, whereas pyuria with<10^2conventional uropathogens per milliliter of urine ("sterile" pyuria) suggests acute urethral syndrome due to *C. trachomatis* or *N. gonorrhoeae*. Gonorrhea and chlamydial infection should be sought by specific tests. Among women with sterile pyuria caused by chlamydial infection, treatment with doxycycline (100 mg bid for 7 days) alleviates dysuria.

VULVOVAGINAL INFECTIONS

Abnormal Vaginal Discharge If directly questioned during routine health checkups, many women acknowledge having nonspecific symptoms of vaginal discharge that do not correlate with objective signs of inflammation or with actual infection. However, unsolicited reporting of abnormal vaginal discharge does suggest bacterial vaginosis or trichomoniasis. Specifically, an abnormally increased amount, an abnormal odor, and an abnormal yellow color of the discharge are associated with one or both of these conditions. Cervical infection with *N. gonorrhoeae* or *C. trachomatis* does not appear to cause an increased amount or abnormal odor of discharge, but cervicitis, like

trichomoniasis, can include the production of an increased number of neutrophils in vaginal fluid, resulting in a yellow color. Vulvar conditions such as genital herpes or vulvovaginal candidiasis can cause vulvar pruritus, burning, irritation, or lesions as well as external dysuria (as urine passes over the inflamed vulva) or vulvar dyspareunia.

Certain vulvovaginal infections may have serious sequelae. Trichomoniasis, bacterial vaginosis, and vulvovaginal candidiasis have all been associated with increased risk of acquisition of HIV infection. Vaginal trichomoniasis and bacterial vaginosis early in pregnancy independently predict premature onset of labor. Bacterial vaginosis can also lead to anaerobic bacterial infection of the endometrium and salpinges. Vaginitis may be an early and prominent feature of toxic shock syndrome, and recurrent or chronic vulvovaginal candidiasis develops with increased frequency among women with systemic illnesses, such as diabetes mellitus or HIV-related immunosuppression (although only a very small proportion of women with recurrent vulvovaginal candidiasis in the United States actually have a serious predisposing illness).

Thus vulvovaginal symptoms or signs warrant careful evaluation, including pelvic examination, simple rapid diagnostic tests, and appropriate therapy specific for the anatomic site and type of infection. Unfortunately, a recent survey in the United States indicated that clinicians seldom perform the tests required to establish the cause of such symptoms. The diagnosis and treatment of the three most common types of vaginal infection are summarized inTable 132-5.

Inspection of the vulva and perineum may reveal tender genital ulcerations (typically due to HSVinfection, occasionally to chancroid) or fissures (typically due to vulvovaginal candidiasis) or discharge visible at the introitus before insertion of a speculum (suggestive of bacterial vaginosis or trichomoniasis). Speculum examination permits the clinician to discern whether the discharge in fact looks abnormal and whether any abnormal discharge in the vagina emanates from the cervical os (mucoid and, if abnormal, yellow) or from the vagina (not mucoid, since the vaginal epithelium does not produce mucus). Symptoms or signs of abnormal vaginal discharge should prompt testing of vaginal fluid for pH, odor when mixed with 10% KOH, and microscopic features when mixed with saline and with 10% KOH. Additional objective laboratory tests useful for establishing the cause of abnormal vaginal discharge include Gram's staining to detect alterations in the vaginal flora; new card and dipstick tests for bacterial vaginosis, as described below; and a new DNA probe test purported to detect *T. vaginalis* and *C. albicans* as well as the increased concentrations of *Gardnerella vaginalis* associated with bacterial vaginosis.

TREATMENT

Patterns of treatment for vaginal discharge vary widely. In developing countries, where clinics or pharmacies often dispense treatment based on symptoms alone without examination or testing, oral treatment with metronidazole, either as a 2-g single dose or as a 7-day regimen, provides reasonable coverage against both trichomoniasis and bacterial vaginosis, the usual causes of symptoms of vaginal discharge; metronidazole treatment of sex partners would prevent reinfection of women with trichomoniasis even if it does not help prevent the recurrence of bacterial vaginosis. Guidelines promulgated during the 1990s by the World Health Organization suggested treatment for cervical

infection and for vulvovaginal candidiasis in women with symptoms of abnormal vaginal discharge; in retrospect, these recommendations were faulty, since these conditions seldom produce such symptoms.

In industrialized countries, clinicians treating symptoms and signs of abnormal vaginal discharge should at least differentiate between bacterial vaginosis and trichomoniasis, because optimal management of patients and partners differs for these two conditions, as discussed briefly below.

Vaginal Trichomoniasis (See also Chap. 218) Symptomatic trichomoniasis characteristically produces a profuse, yellow, purulent, homogeneous vaginal discharge and vulvar irritation, often with visible inflammation of the vaginal and vulvar epithelium and petechial lesions on the cervix (the so-called strawberry cervix, usually evident only by colposcopy). The pH of vaginal fluid usually rises to ^{3}5.0. In women with typical symptoms and signs of trichomoniasis, microscopic examination of vaginal discharge mixed with saline reveals motile trichomonads in at least 80% of culture-positive cases. However, in the absence of symptoms or signs, culture is often required for detection of the organism. Treatment of asymptomatic as well as symptomatic cases reduces rates of transmission and prevents later development of symptoms.

TREATMENT

Only nitroimidazoles consistently cure trichomoniasis. Tinidazole and ornidazole have longer half-lives than metronidazole but do not give better results than a single 2-g oral dose of metronidazole, the treatment of choice. Treatment of male sexual partners -- often facilitated by dispensing metronidazole to the female patient to give to her partner(s), with a warning about avoiding the concurrent use of alcohol -- reduces both the risk of reinfection and the reservoir of infection. Treatment with 0.75% metronidazole gel intravaginally, although effective for bacterial vaginosis, is not reliable for vaginal trichomoniasis. Systemic use of metronidazole is not recommended during the first trimester of pregnancy but is considered safe thereafter.

Bacterial Vaginosis This syndrome (formerly termed *nonspecific vaginitis*, *Haemophilus vaginitis*, *anaerobic vaginitis*, or *Gardnerella-associated vaginal discharge*) is characterized by symptoms of vaginal malodor and a slightly to moderately increased white discharge, which appears homogeneous, is low in viscosity, and smoothly coats the vaginal mucosa. Risk factors include multiple sexual partners and recent intercourse with a new partner, but antibiotic treatment of male partners has not reduced the rate of recurrence among affected women.

The vaginal fluid of women with bacterial vaginosis is characterized by markedly increased prevalences and concentrations of *G. vaginalis*, *Mycoplasma hominis*, and several anaerobic bacteria [e.g., *Mobiluncus* spp., *Prevotella* spp. (formerly *Bacteroides* spp.), and some *Peptostreptococcus* spp.]. The vaginal fluid usually lacks hydrogen peroxide-producing *Lactobacillus* spp., which constitute most of the normal vaginal flora and perhaps help protect against certain cervical and vaginal infections. Vaginal douching, use of intravaginal nonoxynol-9 spermicide, and new sexual partners can all result in loss of vaginal colonization by hydrogen peroxide-producing lactobacilli.

Bacterial vaginosis is conventionally diagnosed clinically with the *Amsel criteria*, which include any three of the following four clinical abnormalities: (1) objective signs of increased white homogeneous vaginal discharge; (2) a vaginal discharge pH of >4.5; (3) liberation of a distinct fishy odor (attributable to volatile amines such as trimethylamine) immediately after vaginal secretions are mixed with a 10% solution of KOH; and (4) microscopic demonstration of "clue cells" (vaginal epithelial cells coated with coccobacillary organisms giving them a granular appearance and indistinct borders; Fig. 132-1) on a wet mount prepared by mixing vaginal secretions with normal saline in a ratio of ~1:1. A new card test now facilitates screening of vaginal fluid for pH >4.5 and trimethylamine, and a new dipstick test detects proline aminopeptidase, an enzyme associated with this syndrome.

Alternatively, the microbiology laboratory can determine the *Nugent score* by examining a Gram-stained smear of vaginal discharge. A score of 7 to 10, based on reduced numbers or the absence of large gram-positive rods (lactobacilli) and the presence of small gram-negative or variable rods (*Gardnerella* and anaerobic rods) and of curved gram-negative or variable rods (*Mobiluncus*), has high sensitivity and specificity for the diagnosis of bacterial vaginosis. Attempts to isolate *G. vaginalis*, genital mycoplasmas, or anaerobic bacteria do not aid in the diagnosis of bacterial vaginosis because these organisms occur (albeit in much lower concentrations) in the vaginal flora of many women without the syndrome.

TREATMENT

The standard dosage of metronidazole for the treatment of bacterial vaginosis is 500 mg orally bid for 7 days. Alternatively, the single 2-g oral dose of metronidazole recommended for trichomoniasis produces short-term rates of recurrence of bacterial vaginosis somewhat higher than those obtained with the 7-day regimen. Intravaginal treatment with 2% clindamycin cream [one full applicator (5 g containing 100 mg of clindamycin phosphate) each night for 7 nights] or with 0.75% metronidazole gel [one full applicator (5 g containing 37.5 mg of metronidazole) twice daily for 5 days] is also effective and does not elicit systemic adverse reactions. Nonetheless, long-term recurrence (i.e., after several months) is distressingly common after either oral or intravaginal treatment. Treatment of male partners with metronidazole does not prevent recurrence of bacterial vaginosis, even though new sexual partners have been implicated as a risk factor for recurrence.

No controlled data support the use of currently available vaginal or oral preparations of lactobacilli for the treatment or prevention of recurrence of bacterial vaginosis. Clinical trials are evaluating prevention of recurrence by repeated intravaginal inoculation of a vaginal *Lactobacillus* species that produces hydrogen peroxide and adheres to vaginal epithelium.

Vulvovaginal Pruritus, Burning, or Irritation Vulvovaginal candidiasis produces vulvar pruritus, burning, or irritation, generally without symptoms of increased vaginal discharge or malodor. Genital herpes can produce similar symptoms, with lesions sometimes difficult to distinguish from the fissures caused by candidiasis. Signs of vulvovaginal candidiasis include vulvar erythema, edema, fissures, and tenderness. With candidiasis, a white scanty vaginal discharge sometimes takes the form of white

thrushlike plaques or cottage cheese- like curds adhering loosely to the vaginal mucosa. *C. albicans* accounts for nearly all cases of symptomatic vulvovaginal candidiasis, which probably arise from endogenous strains of *C. albicans* that have colonized the vagina or the intestinal tract.

The diagnosis of vulvovaginal candidiasis usually involves the demonstration of pseudohyphae or hyphae by microscopic examination of vaginal fluid mixed with saline or 10% KOH or subjected to Gram's staining. Microscopic examination is less sensitive than culture but correlates better with symptoms.

TREATMENT

Symptoms and signs of vulvovaginal candidiasis warrant treatment, usually intravaginal administration of any of several imidazole antibiotics (e.g., miconazole or clotrimazole) for 3 to 7 days. Over-the-counter marketing of such preparations has reduced the cost of care and made treatment more convenient for many women with recurrent yeast vulvovaginitis. However, most women who purchase these preparations do not have vulvovaginal candidiasis, while many do have other vaginal infections that require different treatment. Therefore, only women with classic symptoms of vulvar pruritus and a history of previous episodes of yeast vulvovaginitis documented by an experienced clinician should self-treat. Single-dose oral treatment with fluconazole (150 mg) is also effective and is preferred by many patients. Prolonged or periodic oral therapy may benefit women with severe or frequently recurrent vulvovaginal candidiasis and those who do not respond to intravaginal or single-dose oral therapy. Such patients probably should be evaluated for diabetes and HIV infection, although such systemic illnesses seldom explain recurrent vulvovaginal candidiasis. Treatment of sexual partners is not routinely indicated.

Other Causes of Vaginal Discharge or Vaginitis In the ulcerative vaginitis associated with staphylococcal toxic shock syndrome, *Staphylococcus aureus* should be promptly identified in vaginal fluid by Gram's stain and by culture. In desquamative inflammatory vaginitis, smears of vaginal fluid reveal neutrophils, massive vaginal epithelial cell exfoliation with increased numbers of parabasal cells, and gram-positive cocci; this syndrome responds to treatment with 2% clindamycin cream. Additional causes of vaginitis and vulvovaginal symptoms in women include retained foreign bodies (e.g., tampons), cervical caps, vaginal spermicides, vaginal antiseptic preparations or douches, vaginal epithelial atrophy in postmenopausal women or in the postpartum period during prolonged breast-feeding, allergic reactions to latex condoms, vaginal aphthae associated with HIV infection or Behcet's syndrome, and vestibulitis (a poorly understood syndrome).

MUCOPURULENT CERVICITIS

MPCrefers to inflammation of the columnar epithelium and subepithelium of the endocervix and of any contiguous columnar epithelium that lies exposed in an ectopic position on the exocervix. MPC in women represents the "silent partner" of urethritis in men, being equally common and often caused by the same agents (*N. gonorrhoeae* or *C. trachomatis*) but more difficult to recognize. As the most common manifestation of these serious bacterial infections in women, MPC can be a harbinger or sign of pelvic

inflammatory disease (PID) and -- in pregnant women -- can lead to obstetric complications. More than half of all cases of this syndrome in the United States today remain idiopathic.

The diagnosis ofMPCrests on the detection of yellow mucopurulent discharge from the cervical os or of increased numbers of polymorphonuclear leukocytes in Gram-stained or Papanicolaou-stained smears of endocervical mucus. MPC due to *C. trachomatis* can also produce edematous cervical ectopy (see below) and endocervical bleeding upon gentle swabbing. Unlike the endocervicitis produced by gonococcal or chlamydial infection, cervicitis caused byHSVproduces ulcerative lesions on the stratified squamous epithelium of the exocervix as well as on the columnar epithelium. Yellow cervical mucus on a white swab removed from the endocervix indicates the presence of polymorphonuclear leukocytes. The mucus should be rolled thinly on a slide for Gram's staining. The presence of ³20 polymorphonuclear cells per 1000´ microscopic field within strands of cervical mucus not contaminated by vaginal squamous epithelial cells or vaginal bacteria indicates endocervicitis (Fig. 132-2). Detection of intracellular gram-negative diplococci in carefully collected endocervical mucus is quite specific but£50% sensitive for gonorrhea. Therefore, specific and sensitive tests for *N. gonorrhoeae* as well as *C. trachomatis* are also indicated in evaluation of MPC.

TREATMENT

Although the above criteria forMPC are neither highly specific nor highly predictive of gonococcal or chlamydial infection in many settings, current guidelines of the Centers for Disease Control and Prevention call for consideration of empirical treatment for MPC, pending test results, "for a patient who has suspected gonorrhea or chlamydial infection, if the prevalences of these infections are high in the patient population, and the patient might be difficult to locate after treatment." In this situation, therapy should include a single-dose regimen effective for gonorrhea plus treatment for chlamydial infection, as outlined inTable 132-4 for treatment of urethritis. In settings where gonorrhea is much less common than chlamydial infection, initial therapy for chlamydial infection alone suffices. The etiology and potential benefit of treatment of endocervicitis not associated with gonorrhea or chlamydial infection remain undefined. Sexual partner(s) of a woman with MPC should be examined and given a regimen similar to that chosen for the woman unless results of tests for gonorrhea or chlamydial infection in either partner warrant different therapy or no therapy.

CERVICAL ECTOPY

Cervical ectopy, often mislabeled "cervical erosion," is easily confused with infectious endocervicitis. Ectopy represents the presence of the one-cell-thick columnar epithelium extending from the endocervix out onto the visible ectocervix. In ectopy, the cervical os may contain clear or slightly cloudy mucus but usually not yellow mucopus. Colposcopy shows intact epithelium. Normally found during adolescence and early adulthood, ectopy gradually recedes through the second and third decades of life, as squamous metaplasia replaces the ectopic columnar epithelium. Oral contraceptive use favors the persistence or reappearance of ectopy, while smoking apparently accelerates squamous metaplasia. Cauterization for the elimination of ectopy is not warranted. Ectopy may render the cervix more susceptible to infection with *N. gonorrhoeae*, *C.*

trachomatis, or HIV by exposing a larger area of susceptible columnar epithelium on the exocervix.

PELVIC INFLAMMATORY DISEASE SeeChap. 133.

ULCERATIVE GENITAL LESIONS

Genital ulceration reflects a set of importantSTIs, most of which also sharply increase the risk of sexual acquisition and shedding of HIV. Accurate diagnosis, treatment, and prevention of these infections are high priorities. In a study of genital ulcers carried out in 1996 in 10 of the U.S. cities with the highest rates of primary syphilis, polymerase chain reaction (PCR) testing of ulcer specimens demonstratedHSV in 62% of patients, *Treponema pallidum* in 13%, and *Haemophilus ducreyi* in 12 to 20%.

In Asia and Africa, chancroid (Fig. 132-CD1)was once considered the most common type of genital ulcer, followed by primary syphilis and then genital herpes. With increased efforts to control chancroid and syphilis, together with more frequent recurrences or persistence of genital herpes attributable to the growing numbers of immunosuppressed persons with HIV infection,PCRtesting of genital ulcers now clearly implicates genital herpes as the most common cause of genital ulceration in some developing countries. Lymphogranuloma venereum (LGV) (Fig. 132-CD2) and donovanosis (granuloma inguinale;Fig. 132-CD3) continue to cause genital ulceration in developing countries but rarely occur today in North America or Europe. Other causes of genital ulcer include (1) candidiasis and traumatized genital warts -- both readily recognized; (2) lesions due to genital involvement of more widespread dermatoses; and (3) cutaneous manifestations of systemic diseases, such as genital mucosal ulceration in Stevens-Johnson syndrome.

Although most genital ulcerations cannot be diagnosed confidently on clinical grounds alone, clinical findings plus epidemiologic considerations (Table 132-6) can usually guide initial management (Table 132-7) pending results of further tests. Clinicians should order a rapid serologic test for syphilis in all cases of genital ulcer and a dark-field, direct immunofluorescence, orPCR test for *T. pallidum* from all lesions except those highly characteristic of infection withHSV(i.e., those with herpetic vesicles).

Typical vesicles or pustules or a cluster of painful ulcers preceded by vesiculopustular lesions suggests genital herpes. These typical clinical presentations make detection of the virus optional; however, many patients want confirmation of the diagnosis, and differentiation ofHSV-1 from HSV-2 has prognostic implications, since the latter causes more frequent recurrences.

Painless, nontender, indurated ulcers with firm, nontender inguinal adenopathy suggest primary syphilis. If the results of dark-field examination and a rapid serologic test for syphilis are initially negative and the patient will comply with follow-up and sexual abstinence, the performance of two more dark-field examinations on successive days before treatment is begun will improve the sensitivity of diagnosis of syphilis, as will repeated serologic testing for syphilis 1 or 2 weeks later.

"Atypical" or clinically trivial ulcers may be more common manifestations of genital

herpes than classic vesiculopustular lesions. Specific tests forHSV in the lesions are therefore indicated (Chap. 182). Type-specific serologic tests for serum antibody to HSV-2, now commercially available, may give negative results, especially when patients present early with the initial episode of genital herpes or when HSV-1 is the cause of genital herpes (as in 15 to 30% of cases today). Furthermore, a positive test for HSV-2 antibody does not prove that the current lesions are herpetic, since nearly one-fourth of the general population of the United States becomes seropositive for HSV-2 during early adulthood. Nonetheless, a positive HSV-2 serology does enable the clinician to tell the patient that he or she has had genital herpes, should learn to recognize symptoms, should avoid sex during recurrences, and should consider use of condoms at other times.

Demonstration of *H. ducreyi* by culture (or byPCRtest, when available) is most useful when ulcers are painful and purulent, especially when inguinal lymphadenopathy with fluctuance or overlying erythema is noted; if chancroid is prevalent in the community; or if the patient has recently had a sexual exposure in a chancroid-endemic area (e.g., a developing country or certain North American cities). Enlarged, fluctuant lymph nodes should be aspirated for culture or PCR tests to detect *H. ducreyi* as well as for Gram's staining and culture to rule out the presence of other pyogenic bacteria.

When genital ulcers persist beyond the natural history of initial episodes of herpes (2 to 3 weeks) or of chancroid or syphilis (up to 6 weeks) and do not resolve with syndrome-based antimicrobial therapy, then -- in addition to the usual tests for herpes, syphilis, and chancroid -- biopsy is indicated to exclude donovanosis, carcinoma, and other nonvenereal dermatoses. HIV serology should also be undertaken, since chronic, persistent genital herpes is common in AIDS.

Immediate syndrome-based treatment for acute genital ulcerations (after collection of all necessary diagnostic specimens) is often appropriate. Patients with typical initial or recurrent episodes of genital or anorectal herpes can benefit from prompt oral antiviral therapy (Chap. 182). The patient with nonvesicular ulcerative lesions who may not return for follow-up or may continue sexual activity should receive initial treatment for syphilis, together with empirical therapy for chancroid if exposed in an area where chancroid occurs or if regional lymph node suppuration is evident. In resource-poor settings lacking ready access to diagnostic tests, this approach to syndromic treatment for syphilis and chancroid has helped bring these two diseases under better control. Finally, empirical antimicrobial therapy may be indicated if ulcers persist and the diagnosis remains unclear after a week of observation despite attempts to diagnose herpes, syphilis, and chancroid.

PROCTITIS, PROCTOCOLITIS, ENTEROCOLITIS, AND ENTERITIS

Sexually acquired proctitis, with inflammation limited to the rectal mucosa, results from direct rectal inoculation of typicalSTDpathogens. In contrast, inflammation extending from the rectum to the colon (proctocolitis), involving both the small and the large bowel (enterocolitis), or involving the small bowel alone (enteritis) can result from ingestion of typical intestinal pathogens through oral-anal exposure during sexual contact. Anorectal pain and mucopurulent, bloody rectal discharge suggest proctitis or protocolitis. Proctitis commonly produces tenesmus (causing frequent attempts to defecate, but not true

diarrhea) and constipation, whereas proctocolitis and enterocolitis more often cause true diarrhea. In all three conditions, anoscopy usually shows mucosal exudate and easily induced mucosal bleeding (i.e., a positive "wipe test"), sometimes with petechiae or mucosal ulcers. Exudate should be sampled for Gram's staining and other microbiologic studies. Sigmoidoscopy or colonoscopy shows inflammation limited to the rectum in proctitis or disease extending at least into the sigmoid colon in proctocolitis.

The AIDS era has brought an extraordinary shift in the clinical and etiologic spectrum of intestinal infections among homosexual men. The number of cases of the acute intestinalSTIsdescribed above has fallen as high-risk sexual behaviors have become less common in this group. At the same time, the number of AIDS-related opportunistic intestinal infections has risen rapidly, many associated with chronic or recurrent symptoms. Acquisition of *N. gonorrhoeae*,HSV, or *C. trachomatis* during receptive anorectal intercourse causes most cases of infectious proctitis. Primary and secondary syphilis can also produce anal or anorectal lesions, with or without symptoms. Gonococcal or chlamydial proctitis typically involves the most distal rectal mucosa and the anal crypts and is clinically mild, without systemic manifestations. In contrast, primary proctitis due to HSV and proctocolitis due to the strains of *C. trachomatis* that causeLGVusually produce severe anorectal pain and often cause fever. Perianal ulcers and inguinal lymphadenopathy, most commonly due to HSV, can also occur in LGV or syphilis. Sacral nerve root radiculopathies, usually presenting as urinary retention, laxity of the anal sphincter, or constipation, may complicate primary herpetic proctitis. In LGV, rectal biopsy typically shows crypt abscesses, granulomas, and giant cells -- findings resembling those in Crohn's disease; such findings should always prompt rectal culture and serology for LGV, which is a curable infection. Syphilis can also produce rectal granulomas, usually in association with infiltration by plasma cells or other mononuclear cells.

Diarrhea and abdominal bloating or cramping pain without anorectal symptoms and with normal findings on anoscopy and sigmoidoscopy occur with inflammation of the small intestine (enteritis) or with proximal colitis. In homosexual men without HIV infection, enteritis is often attributable to *Giardia lamblia*. Sexually acquired proctocolitis is most often due to *Campylobacter* or *Shigella* spp.

PREVENTION AND CONTROL OF STDS

Although rates of all curableSTDsfell in the United States throughout the 1990s, all other industrialized countries of comparable economic development have made greater progress. For example, Sweden has virtually eliminated the transmission of gonorrhea, syphilis, and chancroid and has achieved very low rates of HIV transmission. Elimination of syphilis as an endemic disease is now a national goal in the United States, but stronger efforts toward prevention and control of all STDs are necessary.

Prevention and control ofSTDsrequire (1) reduction of the average rate of sexual exposure through alteration of behaviors and behavioral norms among both susceptible and infected persons in all population groups; (2) reduction of the efficiency of transmission through the promotion of safer sexual practices, the use of condoms during casual or commercial sex, hepatitis B immunization, and many other approaches (e.g., early detection and treatment of otherSTIs to reduce the efficiency of sexual

transmission of HIV); and (3) shortening of the duration of infectivity of STDs through early detection and curative or suppressive treatment of patients and their sexual partners.

Primary care physicians usually do not screen for illicit drug use or sexual risk behaviors, even when typical patients have classic presentations for HIV infection or anotherSTD. In fact, clinicians often focus only on detection and treatment of curable STDs to reduce the duration of infectivity. They generally have relatively little training or experience in risk assessment, counseling on risk reduction, tracing and treatment of sexual contacts, or condom promotion. Financial and time constraints imposed by managed-care practice patterns may further curtail screening and prevention services. As outlined inFig. 132-3, the efforts of clinicians simply to detect and treat STDs depend in part on societal efforts to teach young people how to recognize symptoms of STDs; to motivate those with symptoms to seek care promptly; and to make such care accessible, affordable, and acceptable, especially to the young indigent patients most likely to acquire an STD.

Since many infected individuals develop no symptoms or fail to recognize and report symptoms, clinicians should routinely perform anSTI risk assessment for teenagers and young adults as a selective screen. U.S. Preventive Services Task Force Guidelines recommend screening sexually active females£25 years of age for *C. trachomatis* whenever they present for health care (at least once a year); older women should be tested if they have more than one sexual partner, have begun a new sexual relationship since the previous test, or have anotherSTDdiagnosed. In the United States, widespread selective screening of young women for cervical *C. trachomatis* infection in some regions has been associated with a 50 to 60% drop in prevalence, and such screening also protects the individual woman fromPID. Sensitive urine-based genetic amplification tests permit expansion of screening to men and teenage boys and to women in settings where a pelvic examination is not planned or is impractical.

Although gonorrhea is now substantially less common than chlamydial infection in industrialized countries, screening tests for *N. gonorrhoeae* are still appropriate for women and teenage girls attendingSTDclinics and for sexually active teens and young women from areas of high gonorrhea prevalence. Routine screening of asymptomatic men for urethral gonorrhea has a very low yield in the primary care setting. However, genetic amplification tests that combine screening for *N. gonorrhoeae* and *C. trachomatis* in a single low-cost assay may facilitate the prevention and control of both infections in populations at high risk.

All patients with newly detectedSTIs or at high risk for STIs according to routine risk assessment as well as all pregnant women should be encouraged to undergo serologic testing for syphilis and HIV infection, with appropriate HIV counseling before and after testing. Several randomized trials have shown that *risk reduction counseling* of patients with STDs significantly lowers subsequent risk of acquiring an STD. Preimmunization serologic testing for antibody toHBV is indicated for unvaccinated persons who are known to be at high risk, such as homosexually active men and injection drug users. In most young persons, however, it is more cost-effective to vaccinate against HBV without serologic screening.

Partner notification is the process of identifying and informing partners of infected patients of possible exposure to anSTI and of examining, testing, and treating partners as appropriate. In a recently summarized series of 22 reports concerning partner notification during the 1990s, index patients with gonorrhea or chlamydial infection named a mean of 0.75 to 1.6 partners, of whom one-fourth to one- third were infected; those with syphilis named 1.8 to 6.3 partners, with one-third to one-half infected; and those with HIV infection named 0.76 to 5.31 partners, with up to one-fourth infected. Persons who transmit infection or who have recently been infected and are still in the incubation period usually have no symptoms or only mild symptoms and seek medical attention only when notified of their exposure. Therefore, the clinician must encourage patients to participate in partner notification, ensure that exposed persons are notified, and guarantee confidentiality to all involved. In the United States, local health departments will usually offer assistance in partner notification, treatment, and/or counseling. It seems both feasible and most useful to notify those partners exposed within the patient's likely period of infectiousness, which is often considered the preceding 1 month for gonorrhea, 1 to 2 months for chlamydial infection, and up to 3 months for early syphilis.

Persons with a new-onsetSTDalways have a *source* contact who gave them the infection; in addition, they may have a *secondary* (*spread* or *exposed*) contact with whom they had sex after becoming infected. The identification and treatment of these two types of contacts have different objectives. Treatment of the source contact (often a casual contact) benefits the community by preventing further transmission; treatment of the recently exposed secondary contact (typically a spouse or another steady sexual partner) prevents both the development of serious complications (such asPID) in the partner and reinfection of the index patient.

In summary, clinicians and public health agencies share responsibility for the prevention and control ofSTDs. In the managed-care era, the role of primary care clinicians has become increasingly important in prevention as well as in diagnosis and treatment.

133. PELVIC INFLAMMATORY DISEASE - *King K. Holmes*, *Robert C. Brunham*

DEFINITION

The term *pelvic inflammatory disease* (PID) usually refers to infection that ascends from the cervix or vagina to involve the endometrium and/or fallopian tubes. Infection can extend beyond the reproductive tract to cause pelvic peritonitis, generalized peritonitis, perihepatitis, or pelvic abscess. In rare instances, infection extends secondarily to the pelvic organs from adjacent foci of inflammation (e.g., sites of appendicitis, regional ileitis, or diverticulitis), as a result of hematogenous dissemination (e.g., of tuberculosis), or as a rare complication of certain tropical diseases (e.g., schistosomiasis). Intrauterine infection can be primary (spontaneously occurring and usually sexually transmitted) or secondary to invasive intrauterine surgical procedures (e.g., dilatation and curettage, termination of pregnancy, insertion of an intrauterine device, or hysterosalpingography) or to parturition. Endometritis or endomyometritis is particularly common following delivery by emergency cesarean section when antibiotic prophylaxis is not used.

PIDis uncommon during pregnancy itself. The uterotubal junction is closed as early as the seventh week of pregnancy, and the chorioamnion becomes approximated to the endocervical os, sealing off the intrauterine cavity, at the twelfth to fifteenth week of gestation. As a consequence, ascending intrauterine infection prior to the twelfth week of gestation may be associated (as either cause or effect) with endometritis and spontaneous abortion, while ascending infection after the twelfth week may be associated with chorioamnionitis.

Spontaneously occurringPID can be of the chronic or the acute type. Chronic PID due to *Mycobacterium tuberculosis* has become uncommon in industrialized countries. However, subacute or chronic PID caused by persistent or repeated infection with *Chlamydia trachomatis* is thought to be common.

Although the clinical diagnosis ofPID is imprecise, the use of endometrial biopsy together with laparoscopy provides objective evidence of a continuum progressing from cervicitis alone to endometritis, to salpingitis, and to peritonitis. In this chapter, *PID* is used to refer to the clinical syndrome that includes these conditions, while the term *salpingitis* is restricted to cases of visually or histopathologically confirmed inflammation of the fallopian tubes. The distinction between endometritis and salpingitis may be important, because long-term sequelae are much more common after salpingitis. These sequelae include infertility due to bilateral tubal occlusion, peritubal adhesions, ectopic pregnancy due to tubal damage without occlusion, chronic pelvic pain, and recurrent PID.

ETIOLOGY

The etiology ofPID has varied greatly among studies for reasons related to the selection of patients, the prevalence of sexually transmitted disease (STD) pathogens at the time and place of the study, and methodology. As is summarized inTable 133-1, the agents most often implicated in acute PID include those that are primary causes of cervicitis (*Neisseria gonorrhoeae* and *C. trachomatis*) and those that can be regarded as components of an altered vaginal flora.

During the 1980s, *N. gonorrhoeae* and/or *C. trachomatis* was found in 65% of women with a clinical diagnosis ofPID at San Francisco General Hospital and in 85% of patients with proven salpingitis and endometritis in Seattle; in both studies, gonorrhea was nearly twice as common as chlamydial infection and dual infection was common. However, in Western Europe and parts of the United States, as gonococcal infection has come under much better control, endocervical gonococcal infection has been found in a declining proportion of women with PID, and the microbial etiology cannot be defined in a substantial proportion of cases. In general, PID is most often associated with gonorrhea where there is a high incidence of gonorrhea -- e.g., in developing countries and in indigent, inner-city populations in the United States. In several studies of women with PID, up to two-thirds of women with endocervical cultures positive for *N. gonorrhoeae* have also had endometrial, peritoneal, or tubal cultures positive for this organism. Similarly, studies of women with proven PID have shown that *C. trachomatis* can be demonstrated by culture or immunofluorescent staining in the endometrium or tubes of the majority of those who have endocervical chlamydial infection.

Anaerobic and facultative anaerobic organisms (especially *Prevotella* species, peptostreptococci, *Escherichia coli*, and group B streptococci) and genital mycoplasmas have been isolated from specimens obtained at laparoscopy from the peritoneal fluid or fallopian tubes in a varying proportion -- typically one-fourth to one-third -- of women withPIDstudied in the United States. These vaginal organisms can be found in association with chlamydial or gonococcal infection as well as in the absence of such infection. The importance of vaginal organisms in salpingitis has probably been overestimated in some studies in which specimens were obtained for cultures by culdocentesis or endometrial aspiration, procedures in which contamination of the aspirated specimen by vaginal flora is possible. However, specimens obtained by laparoscopy from some patients with PID have also contained anaerobic and facultative species. A compilation of seven studies of the microbial etiology of PID showed that 5 to 78% of patients had anaerobes and facultative bacteria isolated from the upper genital tract. It is extremely difficult to determine the exact microbial etiology of an individual case of PID because of the frequency of mixed infection, the difficulty in sampling the fallopian tube itself, and the complexity of the microbiologic techniques required to detect the various fastidious pathogens involved. This situation has implications for the approach to empirical antimicrobial treatment of PID.

In general, first episodes of acutePID are particularly likely to be caused by *N. gonorrhoeae* and/or *C. trachomatis*. These sexually transmitted pathogens are implicated somewhat less often in recurrent bouts of acute PID, in episodes occurring in women with intrauterine devices (IUDs), in episodes precipitated by invasive intrauterine diagnostic or therapeutic procedures (which are often associated with ascending infection caused by endogenous vaginal flora), and perhaps in HIV-associated PID.

EPIDEMIOLOGY

It has been estimated that about 850,000 cases ofPIDoccurred in the United States each year during the mid-1970s. PID is not a reportable disease in the United States; surveillance of physicians in private practice and of hospital discharges suggests that the incidence of PID increased from the mid-1960s through the mid-1970s and may

then have decreased. Hospitalization for acute PID declined steadily from 1982 through 1997, and initial visits to physicians' offices for PID have been declining since the mid-1980s. Furthermore, the number of hospitalizations for ectopic pregnancy in the United States fell by about two-thirds from 1989 to 1997.

AcutePID is almost exclusively a disease of sexually active women. Important risk factors include a history of salpingitis or of recent vaginal douching; the use of anIUD, particularly the Dalkon shield, has also been a risk factor. In most studies, the relative risk of PID among IUD users is higher in nulliparous than in parous women and is greatest during the first few months after IUD insertion. The increased risk of PID among IUD users is evident mainly among those with multiple sex partners. In contrast, women using oral contraceptives appear to be at decreased risk of PID. Barrier methods of contraception also make PID less likely by reducing the risk of chlamydial and gonococcal infection. Tubal sterilization reduces (but does not completely eliminate) the risk of salpingitis by preventing intraluminal spread of infection into the tubes.

PATHOGENESIS

Factors cited as possibly contributing to the upward spread of gonococci and chlamydiae from the endocervix to the endometrium and endosalpinx include estrogen-dominated (thin) cervical mucus, attachment to sperm that migrate upward into the tubes, use of anIUD, vaginal douching, menstruation, and subendometrial myometrial contractions, which move particulate matter from the cervix to the fundus of the uterus between days 5 and 14 of the menstrual cycle. It is important that the onset of symptoms of *N. gonorrhoeae*-associated and *C. trachomatis*-associatedPIDoften occurs during or soon after the menstrual period. In fallopian tube organ cultures in vitro, gonococci attach to the surface of the secretory columnar cells (but not the ciliated cells) of the endosalpinx. Gonococcal pili and perhaps other surface proteins are important in this attachment. Gonococci are then taken into the secretory cells by endocytosis. They pass through the cells -- and perhaps between cells -- and are extruded through the base of the cell into the submucosal connective tissue. Ciliary motion ceases, and then ciliated cells, although not directly invaded by gonococci, are sloughed from the mucosa -- a factor that may render the tubes more susceptible to superinfection by other organisms. It is uncertain whether this loss of ciliated cells is irreversible in vivo. Gonococcal endotoxin and peptidoglycan as well as certain cytokines (such as tumor necrosis factora) appear to be responsible for these cytotoxic effects.

C. trachomatis also infects the columnar cells of the fallopian tube but produces little damage in tubal organ cultures, perhaps because the host response is more important than directly toxic effects of bacterial products in the pathogenesis of chlamydial salpingitis. *Chlamydia*-infected epithelial cells secrete a number of proinflammatory cytokines, which are chemotactic for neutrophils and mononuclear cells. Routine endometrial biopsies from women with chlamydial mucopurulent cervicitis (MPC) show endometritis in approximately one-half of cases. Endometritis detected in this way is sometimes but not always associated with symptoms of severe abdominal pain, presentation during days 1 through 7 of the menstrual cycle, signs of uterine tenderness, and an erythrocyte sedimentation rate (ESR) of ³20 mm/h. Adnexal tenderness, cervical motion tenderness, and rebound tenderness as well as leukocytosis and elevated C-reactive protein levels are all more common in women with

laparoscopic evidence of salpingitis than in those with endometritis alone. Chlamydial inclusions are demonstrable by direct immunofluorescence in columnar epithelial cells of the endometrium and endosalpinx. The endometrial biopsies usually show neutrophils infiltrating the epithelium and plasma cells infiltrating the stroma, findings also seen in gonococcal endometritis but not in the uninfected endometrium. Experimental inoculation of the fallopian tubes of lower primates with *C. trachomatis* has shown that repeated exposure to *C. trachomatis* leads to the greatest degree of tissue inflammation and damage; this finding suggests that immunopathology also underlies the pathogenesis of chlamydial disease.

The pathogenesis ofPIDattributable to mycoplasmas or other vaginal anaerobic or facultative organisms is less well studied. It is possible that other vaginal organisms implicated in PID often cause tubal infection in women whose tubes have already been damaged by a primary sexually transmitted pathogen (i.e., *N. gonorrhoeae* or *C. trachomatis*). The vaginal organisms implicated in PID are found in the vagina most often and in greatest concentration in bacterial vaginosis, and there is epidemiologic evidence that bacterial vaginosis itself is a predisposing factor for PID (just as poor oral hygiene is a risk factor for aspiration pneumonia).

Certain other iatrogenic factors, such as dilatation and curettage or cesarean section, can increase the risk ofPID in women with endocervical gonococcal or chlamydial infection. Evidence indicates that among women undergoing cesarean section, the presence of bacterial vaginosis increases the risk of postpartum endometritis.

CLINICAL MANIFESTATIONS

Tuberculous Salpingitis Unlike nontuberculous salpingitis, genital tuberculosis often occurs in older women, many of whom are postmenopausal. Presenting symptoms include abnormal vaginal bleeding, pain (including dysmenorrhea), and infertility. Bimanual pelvic examination may be normal, though about one-quarter of these women have had adnexal masses. Endometrial biopsy shows tuberculous granulomas and provides optimal specimens for culture.

Nontuberculous Salpingitis Symptoms of nontuberculous salpingitis classically evolve from a yellow or malodorous vaginal discharge caused byMPCand/or bacterial vaginosis to midline abdominal pain and abnormal vaginal bleeding caused by endometritis and then to bilateral lower abdominal and pelvic pain caused by salpingitis, with nausea and vomiting and increased abdominal tenderness caused by peritonitis. Some patients have diffuse abdominal pain caused by generalized peritonitis or pleuritic right upper quadrant pain caused by perihepatitis. The pattern in which symptoms evolve varies from patient to patient and is also related to the etiology of thePID.

The onset ofIUD-associatedPID is typically gradual and may be preceded by the malodorous vaginal discharge characteristic of bacterial vaginosis. The onset of gonococcal PID may be more acute than that of chlamydial PID, and PID of either etiology usually presents during the first half of the menstrual cycle.

The abdominal pain in nontuberculous salpingitis is usually described as dull or aching. In some cases, pain is lacking or is atypical, and active inflammatory changes are found

in the course of an unrelated evaluation or procedure, such as a tubal ligation or a laparoscopic evaluation for infertility. Abnormal uterine bleeding precedes or coincides with the onset of pain in ~40% of women withPID, symptoms of urethritis (dysuria) occur in 20%, and symptoms of proctitis (anorectal pain, tenesmus, and rectal discharge or bleeding) are occasionally seen in women with gonococcal or chlamydial infection.

Speculum examination shows evidence of MPC(yellow endocervical discharge, easily induced endocervical bleeding) in the majority of women with gonococcal or chlamydialPID. Cervical motion tenderness is produced by stretching of the adnexal attachments on the side toward which the cervix is pushed. Bimanual examination reveals uterine fundal tenderness due to endometritis and abnormal adnexal tenderness due to salpingitis that is usually, but not necessarily, bilateral. Adnexal swelling is palpable in about one-half of women with acute salpingitis, but evaluation of the adnexae in a patient with marked tenderness -- even by an experienced examiner -- is not reliable. The initial temperature is >38°C in only about one-third of patients with acute salpingitis; thus fever is not required for the diagnosis. Laboratory findings include elevation of theESR in 75% of patients with acute salpingitis and elevation of the peripheral white blood cell count in up to 60%.

Certain clinical manifestations of acutePID have been correlated with microbial etiology. For example, the onset of salpingitis is related to menses in women with gonococcal or chlamydial infection. Women with *N. gonorrhoeae*- or *C. trachomatis*-associated salpingitis are significantly younger than women with salpingitis of other etiologies. In a Swedish study, women with *Chlamydia*-associated salpingitis had more indolent disease, with mild symptoms of significantly longer duration and less fever, than women with gonorrhea-associated salpingitis. Women with polymicrobial PID more often have tubal or pelvic abscess formation. It is suspected that, for all recognized cases of symptomatic acute chlamydial salpingitis, there is a comparable number of unrecognized cases of indolent or mildly symptomatic chlamydial salpingitis. Furthermore, it is thought that subclinical chronic or recurrent chlamydial salpingitis may be a major cause of female infertility.

Perihepatitis and Periappendicitis Symptoms of perihepatitis, including pleuritic upper abdominal pain and tenderness (usually localized to the right upper quadrant), develop in 3 to 10% of women with acutePID. The onset of symptoms of perihepatitis takes place during or after the onset of symptoms of PID and may overshadow lower abdominal symptoms, thereby leading to a mistaken diagnosis of cholecystitis. In perhaps 5% of cases of acute salpingitis, early laparoscopy reveals inflammation ranging from edema and erythema of the liver capsule to exudate with fibrinous adhesions between the visceral and parietal peritoneum. When treatment is delayed and laparoscopy is performed late, dense "violin-string" adhesions are seen over the liver; chronic exertional or positional right upper quadrant pain ensues when traction is placed on the adhesions. Although perihepatitis, also known as the *Fitz-Hugh-Curtis syndrome*, was for many years specifically attributed to gonococcal PID, most cases are now attributed to chlamydial salpingitis. In patients with chlamydial salpingitis, serum titers of microimmunofluorescent antibody to *C. trachomatis* are typically much higher when perihepatitis is present than when it is absent, and it has been suggested that repeated chlamydial infections are responsible for perihepatitis.

Physical findings include right upper quadrant tenderness and usually include adnexal tenderness and cervicitis, even in patients whose symptoms are not suggestive of salpingitis. Liver function tests are nearly always normal, since inflammation is largely limited to the liver capsule and usually spares the parenchyma. Ultrasonography of the right upper quadrant is normal. The presence ofMPC and pelvic tenderness in a young woman with subacute pleuritic right upper quadrant pain and normal ultrasonography of the gallbladder points to a diagnosis of perihepatitis.

Periappendicitis (appendiceal serositis without involvement of the intestinal mucosa) has been found in ~5% of patients undergoing appendectomy for suspected appendicitis and can occur as a complication of gonococcal or chlamydial salpingitis.

Influence of HIV Infection HIV infection with immunosuppression increases the risk of repeated gonococcal and chlamydial infections among repeatedly exposed female sex workers, presumably by attenuating the immune response to repeated infection. Further, among women who acquire gonococcal or chlamydial infection of the cervix, HIV infection with immunosuppression increases the likelihood of developing clinical manifestations of salpingitis. Finally, among women with salpingitis, HIV infection is associated with increased severity of salpingitis and with tuboovarian abscess requiring hospitalization and surgical drainage. However, among African women with confirmedPID, those with HIV infection appear less likely to have gonorrhea or chlamydial infection than those without HIV infection, a difference suggesting that other etiologies are especially important in the immunosuppressed patient. Nonetheless, among women with HIV infection and salpingitis, the clinical reponse to conventional antimicrobial therapy (coupled with drainage of tuboovarian abscess, when found) has been satisfactory.

DIAGNOSIS

Early diagnosis and initiation of therapy are essential to minimize tubal scarring. A reanalysis of Westrom's cohort of Swedish women with proven salpingitis showed that those who delayed seeking care were three times more likely than those who sought care promptly to experience subsequent infertility or ectopic pregnancy. Appropriate treatment must not be withheld from patients who have an equivocal diagnosis; it is better to err on the side of overdiagnosis and overtreatment. On the other hand, it is essential to differentiate between salpingitis and other pelvic pathology, particularly surgical emergencies such as appendicitis and ectopic pregnancy.

No readily available clinical finding or laboratory test, short of laparoscopy, definitively identifies salpingitis, and routine laparoscopy to confirm suspected salpingitis is generally impractical. Most patients with acutePID have lower abdominal pain of <3 weeks' duration, pelvic tenderness on bimanual pelvic examination, and evidence of lower genital tract infection (e.g.,MPC). Approximately 60% of such patients have salpingitis at laparoscopy. Among the patients with these findings, a rectal temperature>38°C, a palpable adnexal mass, and elevation of theESR over 15 mm/h also raise the probability of salpingitis, which has been found at laparoscopy in 68% of patients with one of these additional findings, 90% of patients with two, and 96% of patients with three. However, only 17% of all patients with laparoscopy-confirmed salpingitis have had all three additional findings.

MPCis probably responsible for the presence of neutrophils in vaginal fluid inPID. In a woman with pelvic pain and tenderness, demonstration of an increased number of neutrophils (30 per 1000´ microscopic field in strands of cervical mucus) increases the predictive value of a clinical diagnosis of acute PID.

Several clinical features other than the presence of cervicitis also favor the diagnosis of acutePID. These include onset with menses, history of recent abnormal menstrual bleeding, presence of anIUD, history of salpingitis, and sexual exposure to a male with urethritis. Detection of polymorphonuclear leukocytes in pelvic peritoneal fluid aspirated by culdocentesis supports a diagnosis of suspected salpingitis. Urethritis or proctitis may occur in chlamydial or gonococcal infection but may also represent a urinary tract source or an intestinal source, respectively. Appendicitis or another disorder of the gut is favored by the early onset of anorexia, nausea, or vomiting; the onset of pain later than day 14 of the menstrual cycle; or unilateral pain limited to the right or left lower quadrant. All women in whom the diagnosis of PID is being considered should be evaluated for ectopic pregnancy. The more sensitive serum assays for humanb-chorionic gonadotropin are usually positive when ectopic pregnancy is the diagnosis. Ultrasonography and magnetic resonance imaging (MRI) can be useful for the identification of tuboovarian or pelvic abscess. MRI or intravaginal ultrasound assessment of the tubes has been reported to show increased tubal diameter, intratubal fluid, or tubal wall thickening in cases of salpingitis.

Laparoscopy is the most specific method for diagnosis of acute salpingitis. Although laparoscopic findings may be normal if inflammation is limited to the endosalpinx or the endometrium, patients with suspectedPID who have a normal laparoscopy have a better prognosis (with no sequelae at all or fewer sequelae) than patients who have abnormal laparoscopic findings. The primary and uncontested value of laparoscopy in women with lower abdominal pain is for the exclusion of other surgical problems. Some of the most common or serious problems that may be confused with salpingitis (e.g., acute appendicitis, ectopic pregnancy, corpus luteum bleeding, ovarian tumor) are unilateral. Unilateral pain or pelvic mass, though not incompatible with PID, is a strong indication for laparoscopy unless the clinical picture warrants laparotomy instead. Atypical clinical findings, such as the absence of lower genital tract infection, a missed menstrual period, a positive pregnancy test, or failure to respond to appropriate therapy, are other frequent indications for laparoscopy.

Laparoscopic criteria used for the diagnosis of salpingitis include (1) erythema of the fallopian tube, (2) edema of the fallopian tube, and (3) seropurulent exudate or fresh, easily lysed adhesions at the fimbriated end or on the serosal surface of a fallopian tube.

Endometrial biopsy is relatively sensitive and specific for the diagnosis of endometritis when the endometrial changes described above are found, and the presence of endometritis correlates well with the presence of salpingitis. Endometritis is found in at least three-fourths of women with laparoscopically confirmed salpingitis and is not found in women withoutPID.

The etiologic diagnosis ofPID can be further studied by culture or other testing of

specimens obtained by endocervical swab, endometrial aspiration, or culdocentesis or by laparoscopy or laparotomy. Endocervical swab specimens should be examined by Gram's staining for neutrophils and gram-negative diplococci and by culture or DNA amplification test for *N. gonorrhoeae*. Compared with culture, the sensitivity of Gram's staining is ~60% and the specificity is >95%. The endocervical swab specimen should also be tested for *C. trachomatis* by culture or amplification assays for chlamydial DNA or RNA. Although detection of either *N. gonorrhoeae* or *C. trachomatis* in the endocervix does not prove that either agent is also present in the upper genital tract, this finding strongly supports the diagnosis of PID. The clinical diagnosis of PID made by expert gynecologists is confirmed by laparoscopy or endometrial biopsy in only ~60% of patients but in ~90% of those who also have cultures positive for *N. gonorrhoeae* or *C. trachomatis*. There is no evidence that the isolation of anaerobes or facultative aerobes from the cervix or vagina correlates with the presence of these organisms in the upper genital tract in acute PID, but this point has not been well studied. In one study, the isolation of *Haemophilus influenzae* from the endocervix was highly correlated with this organism's recovery from the fallopian tube in cases of salpingitis. Despite the risk of contamination of endometrial specimens with components of the vaginal flora, one study showed a 2.6-fold increase in the rate of recovery of anaerobic gram-negative rods (especially *Prevotella*, black-pigmented rods, and *Fusobacterium*) by endometrial biopsy in women with endometritis compared with control women. When laparoscopy is performed, material can be obtained directly from the cul-de-sac or the fimbriated opening of the tube or by tubal aspiration if pyosalpinx is present. Such specimens should be cultured for anaerobic and facultative pathogens as well as for *N. gonorrhoeae* and *C. trachomatis*.

TREATMENT

Women with PIDcan be treated as either outpatients or inpatients. Over the past decade, the costs of PID treatment have declined considerably because of the increased management of patients in the ambulatory setting, with use of highly active, well-absorbed antimicrobial agents. Nonetheless, hospitalization may be necessary and should be considered when (1) the diagnosis is uncertain and surgical emergencies such as appendicitis and ectopic pregnancy cannot be excluded, (2) pelvic abscess is suspected, (3) severe illness or nausea and vomiting preclude outpatient management, (4) the patient has HIV infection, (5) the patient is assessed as unable to follow or tolerate an outpatient regimen, or (6) the patient has failed to respond to outpatient therapy. If outpatient treatment is embarked on, clinical follow-up after 48 to 72 h of antibiotic treatment should be arranged. Treatment should cover *N. gonorrhoeae*, *C. trachomatis*, gram-negative facultative bacteria (especially *E. coli* and *H. influenzae*), vaginal anaerobes, and group B streptococci. Several antimicrobial combinations do provide a broad spectrum of activity against the major pathogens in vitro, but many have not been adequately evaluated for clinical efficacy in PID (Table 133-2).

Examples of Combination Regimens with Broad Activity Against Major Pathogens in PID Recommended combination regimens for ambulatory or parenteral management of PID are presented in Table 133-3.

Women managed as outpatients should receive a combined regimen with broad activity, such as ceftriaxone [250 mg intramuscularly (IM)] followed by doxycycline (100 mg by

mouth, twice a day for 14 days). Metronidazole (500 mg by mouth twice daily) can be added, if tolerated, to enhance activity against anaerobes. Alternatively, ofloxacin (400 mg twice daily) plus metronidazole (500 mg twice daily), both continued for 14 days, provide good coverage of the major pathogens.

The following two parenteral regimens have given nearly identical results in a multicenter randomized trial:

1. Doxycycline [100 mg twice a day, given intravenously (IV) or orally] plus cefotetan (2.0 g IV every 12 h) or cefoxitin (2.0 g IV every 6 h). These drugs should be continued by the IV route for at least 48 h after the patient's condition improves, then followed with doxycycline (100 mg by mouth, twice a day) to complete 14 days of therapy.

2. Clindamycin (900 mg IV every 8 h) plus gentamicin (2.0 mg/kg IV or IM followed by 1.5 mg/kg every 8 h) in patients with normal renal function. Once-daily dosing of gentamicin (with combination of the total daily dose into a single daily dose) has not been evaluated inPID but has been efficacious in other serious infections and could be substituted. Treatment with these drugs should be continued for at least 48 h after the patient's condition improves, then followed with doxycycline (100 mg orally twice a day) or with clindamycin (450 mg orally four times a day) to complete 14 days of therapy. In cases with tuboovarian abscess, many experts use oral clindamycin rather than doxycycline for continued therapy to provide better coverage for anaerobic infection.

Management of Sexual Partners Sexual partners of patients with acutePID -- particularly those who have been partners within the 1 to 2 months before the onset of symptoms of PID -- should be examined forSTDs and promptly treated with a regimen effective against uncomplicated gonococcal and chlamydial infection. An important point is that³50% of the sexual partners of women with gonococcal and/or chlamydial PID have subclinical urethral infection and may be unaware of their infection status. Treatment of PID should be considered inadequate until sexual partners have been properly evaluated and treated.

Follow-Up Hospitalized patients should show substantial clinical improvement within 3 to 5 days. Women treated as outpatients should be clinically reevaluated within 72 h. A follow-up telephone survey of women seen in an emergency room and given a prescription for 10 days of oral doxycycline forPIDfound that 28% never filled the prescription and 41% stopped taking medication early (after an average of 4.1 days), often because of persistent symptoms, lack of symptoms, or side effects. Women not responding favorably to ambulatory therapy should be hospitalized. After completion of treatment, tests for persistent or recurrent infection with *N. gonorrhoeae* or *C. trachomatis* should be performed if symptoms persist or recur or if the patient has not complied with therapy or has been reexposed to an untreated sex partner.

Removal of anIUD Although a beneficial impact of IUD removal on the response of acute salpingitis to antimicrobial therapy and on the risk of recurrent salpingitis has not been proven, removal of the IUD 2 or 3 days after the initiation of antimicrobial therapy seems reasonable. When an IUD is removed, contraceptive counseling is essential.

Surgery Surgery is necessary for the treatment of salpingitis only in the face of

life-threatening infection (such as rupture or threatened rupture of a tuboovarian abscess) or for drainage of an abscess. Ultrasonography andMRI are useful for diagnosing and monitoring pelvic abscesses. Conservative surgical procedures are usually sufficient. Pelvic abscesses can often be drained by posterior colpotomy, and peritoneal lavage can be used if there is generalized peritonitis.

PROGNOSIS

Among 900 women who underwent long-term follow-up for a mean period of 8 years after successful treatment of an acute episode ofPID with various regimens in Sweden, late sequelae included infertility due to bilateral tubal occlusion, ectopic pregnancy due to tubal scarring without occlusion, chronic pelvic pain, and recurrent salpingitis. Chronic pain lasting>6 months was seen in 18% of patients, and infertility due to tubal occlusion in 17%; 4% of the pregnancies that did occur were ectopic, representing approximately a sixfold increase over the expected rate of ectopic pregnancies. The rate of infertility after salpingitis was found to be related to the age of the patient, the duration of symptoms when treatment was started, the severity of salpingitis (as determined by laparoscopy) at the time of diagnosis, and the number of episodes of salpingitis. The postsalpingitis risk of infertility due to tubal occlusion among sexually active women not using contraceptives was 14% at 15 to 24 years of age and 26% at 25 to 34 years of age; the risk for women of all ages combined was 11% after one episode of salpingitis, 23% after two episodes, and 54% after three or more episodes. Women with chlamydial salpingitis who developed more severe inflammatory damage to the reproductive tract had significantly increased titers of antibody to the chlamydial heat-shock protein HSP60, as did women with infertility or ectopic pregnancy following chlamydial salpingitis. The risk of infertility after treated gonococcal salpingitis appeared lower than that after chlamydial salpingitis or polymicrobial PID. A study of outcomes of PID at the University of Washington found a sevenfold increase in the risk of ectopic pregnancy and an eightfold increase in the rate of hysterectomy after PID.

In several countries, a striking relationship has also been found between infertility due to tubal occlusion and the prevalence and titer of antibody to *C. trachomatis*. Recurrent salpingitis has been seen in ~15 to 25% of women treated for salpingitis in various studies.

PREVENTION

Prevention of PIDdepends first on the effective control of gonococcal and chlamydial infection in the general population. Effective methods include the promotion of changes in sexual behavior and the use of barrier contraceptives together with ensuring ready access to modern methods of diagnosis of these infections and effective treatment of sex partners to control further spread. The decline in popularity of the IUD, particularly among nulliparous women, has undoubtedly helped to reduce the incidence of PID. It is also possible, but not proven, that the use of oral contraceptives and the declining proportion of women who have practiced vaginal douching since the link between douching and PID became known have contributed to lower rates of PID. A randomized controlled trial designed to determine whether selective screening for chlamydial infection reduced the risk of subsequent PID showed that women randomized to undergo screening had a 56% lower rate of PID over the following year than did women

receiving the usual care without screening. This report strongly supports risk-based screening for *Chlamydia* as a highly effective way to reduce the incidence of PID and the prevalence of post-PID sequelae.

The complications and sequelae of salpingitis are minimized by early diagnosis and prompt effective treatment. It seems logical, but is unproven, that broad-spectrum therapy effective against all of the common causes ofPIDoffers the best outcome. Although few methodologically sound clinical trials (especially with prolonged follow-up) have been conducted, one meta-analysis showed a benefit of providing good coverage against anaerobes. One placebo-controlled study showed that concurrent anti-inflammatory therapy with prednisolone hastened the reduction of acute inflammatory changes but did not improve the end results, as measured by fertility, hysterosalpingographic findings, or chronic pain. The potential value of anti-inflammatory therapy remains to be evaluated adequately.

SECTION 3 -CLINICAL SYNDROMES: NOSOCOMIAL INFECTIONS

134. INFECTION CONTROL IN THE HOSPITAL - *Robert A. Weinstein*

The costs of nosocomial (hospital-acquired) infections are great. It is estimated that nosocomial infections cost $4.5 billion and contribute to 88,000 deaths annually. Although infection-control and hospital epidemiology activities have been the subjects of increasing scientific study over the past 30 years, efforts to lower infection risks have been continually challenged by the growing numbers of immunocompromised patients, antibiotic-resistant bacteria, fungal and viral superinfections, and invasive devices and procedures. Four international decennial conferences on infection control, organized by the Centers for Disease Control and Prevention (CDC), have clearly documented these formidable trends. This chapter reviews the basic surveillance and prevention activities that have been developed to deal with these problems and that form the foundation for current hospital epidemiology programs.

ORGANIZATION AND RESPONSIBILITIES OF INFECTION-CONTROL PROGRAMS

The standards of the Joint Commission on Accreditation of Healthcare Organizations require all accredited hospitals to have an active program for surveillance, prevention, and control of nosocomial infections; a multidisciplinary infection-control committee usually oversees the program. The agents of the committee are the chairperson, who is preferably an infectious disease physician, and the infection-control practitioners, who are usually trained in nursing or medical technology and in epidemiology and public health. Education of physicians in infection control and hospital epidemiology is required in infectious disease fellowship programs and is available in courses provided by professional societies, primarily the Society for Healthcare Epidemiology of America.

In the 1970s, theCDC's extensive Study on the Efficacy of Nosocomial Infection Control found that nosocomial infection rates fell by 32% in hospitals that established programs with organized surveillance and control activities; a trained, effectual infection-control physician; and one infection-control practitioner per 250 beds. In contrast, rates in hospitals without effective programs increased by 18%. Since that study, the responsibilities and roles of hospital epidemiology programs have expanded in several directions. Diagnosis-related reimbursement has led hospital administrators to place increased emphasis on cost containment and on documentation of the cost-effectiveness of infection control. The quality-improvement movements and the Joint Commission have redirected infection-control attention, in part, beyond the mere writing of policies and procedures to improvement of the actual processes and optimization of outcomes. In a few hospitals, epidemiology programs have taken on additional pharmacoepidemiologic and antibiotic-use review responsibilities. Finally, all programs must now respond to increasing governmental regulation of hospital waste and to standards mandated by the Occupational Safety and Health Administration for protecting health care workers from occupational exposure to bloodborne pathogens and tuberculosis.

SURVEILLANCE

Traditionally, infection-control practitioners survey inpatients for nosocomial infections

(defined as those neither present nor incubating at the time of admission). Surveillance involves a review of microbiology laboratory results, "shoe-leather" epidemiology on the nursing wards, application of standardized definitions of infection, ongoing dialogue with hospital workers, and common sense. Some innovative infection-control programs have taken advantage of the increased use of computerized pharmacy, microbiology, and other databases in hospitals to create algorithm-driven surveillance activities.

Most hospitals aim surveillance at infections that (1) are associated with a high level of morbidity, e.g., intensive care unit (ICU)-related infections and nosocomial pneumonia; (2) are costly, e.g., cardiac surgical wound infections; (3) are difficult to treat, e.g., infections due to antibiotic-resistant bacteria; (4) pose recurring epidemic problems, e.g., *Clostridium difficile*-related diarrhea; and (5) are potentially preventable, e.g., vascular access-related infections. Quality-assurance activities in infection control have led to increased surveillance of the compliance of personnel with infection-control policies (e.g., monitoring of actual adherence to hand-washing recommendations).

The results of surveillance are expressed as rates; for example, 5 to 10% of patients develop nosocomial infections. Although such overall statistics are often requested of hospitals by administrators or surveyors, they have little value unless qualified by site of infection, by patient population, and by exposure to risk factors. Meaningful denominators for infection rates include the number of patients exposed to a specific risk (e.g., rates of pneumonia among patients using mechanical ventilators) and the number of intervention days (e.g., rates of pneumonia per 1000 patient-days on a ventilator).

Temporal trends in rates should be reviewed, and rates should be compared with regional and national norms. However, even comparison rates generated by theCDC's ongoing National Nosocomial Infections Surveillance System, which collects data from more than 270 hospitals that use standardized definitions of nosocomial infections, have not been validated independently and represent a nonrandom sample of hospitals. Interhospital comparisons are easily confounded by the wide range in risk factors and in severity of underlying illnesses; unless rates are adjusted for these factors, comparisons may be misleading. Unfortunately, systems for making such adjustments either are rudimentary or have not been well validated.

The ongoing analysis of an individual hospital's infection rates helps to determine whether control efforts are succeeding and where increased education and control measures should be focused. Knowledge of infection rates is also useful in discussions with the hospital administration regarding areas to which additional resources should be directed.

PREVENTION AND CONTROL MEASURES

Epidemiologic Basis and General Measures Nosocomial infections follow basic epidemiologic patterns that can help to direct prevention and control measures. Nosocomial pathogens have reservoirs, are transmitted by predictable routes, and require susceptible hosts. Reservoirs and sources exist in the inanimate environment (e.g., tap water contaminated with *Legionella*) and in the animate environment (e.g., infected or colonized health care workers, patients, and hospital visitors). The mode of

transmission most often is either cross-infection (e.g., indirect spread of pathogens from one patient to another on the inadequately washed hands of hospital personnel) or autoinoculation (e.g., aspiration of oropharyngeal flora into the lung along an endotracheal tube). Occasionally, pathogens (e.g., group A streptococci and many respiratory viruses) are spread indirectly from person to person via infectious droplets released by coughing or sneezing. Much less common -- but often devastating in terms of epidemic risk -- is true airborne spread of droplet nuclei (as in nosocomial chickenpox) or common-source spread by contaminated materials (e.g., iodophors contaminated with *Pseudomonas*). Factors that increase host susceptibility include underlying conditions and the many medical-surgical interventions and procedures that bypass or compromise normal host defenses.

Through its program, the hospital's infection-control committee must determine the general and specific measures used to control infections and must review and recommend specific antiseptics and disinfectants for hospital use. Given the prominence of cross-infection, hand washing is the single most important preventive measure in hospitals. Many studies have examined the antimicrobial activity of a wide variety of antiseptic-containing hand-washing agents. The use of such medicated agents is important before invasive procedures and possibly in ICU settings. In light of the poor general compliance with hand-washing recommendations, the importance of using any hand cleanser between patient contacts cannot be overemphasized (Table 134-1).

The fact that 25 to 50% of nosocomial infections are due to the combined effect of the patient's own flora and invasive devices highlights the importance of improvements in the use and design of such devices (Chap. 135). Intensive educational programs can be associated with at least a temporary reduction in infection rates through improved asepsis in handling and earlier removal of invasive devices, but the maintenance of such gains is often difficult. Epidemiologic studies are used increasingly to assess the value of newer devices and site-specific control measures and to debunk some traditional yet ineffective and costly measures, such as routine culturing of the environment and personnel for "pathogens."

Urinary Tract Infections Approaches to the prevention of urinary tract infections have included the use of topical meatal antimicrobials, drainage bag disinfectants, antimicrobial-coated catheters, and sealed catheter-drainage tube junctions to eliminate inadvertent breaks in the system. Because of conflicting study results, none of these measures is considered routine. Systemic antimicrobials given for other purposes decrease the risk of urinary tract infection during the first 4 days of catheterization, after which resistant bacteria or yeasts emerge as pathogens. Selective decontamination of the gut is also associated with a reduced risk. Again, however, neither approach is routine. Irrigation of catheters, with or without antimicrobials, may actually increase the risk of infection.

Pneumonia Control measures for pneumonia are aimed at the remediation of risk factors in general patient care (e.g., minimizing aspiration-prone supine positioning) and at meticulous aseptic care of respirator equipment (e.g., disinfecting or sterilizing all in-line reusable components such as nebulizers, replacing tubing circuits at intervals of >48 h -- rather than more frequently -- to lessen the number of breaks in the system,

and teaching aseptic technique for suctioning). In a large multicenter trial, sucralfate, which provides stress-ulcer prophylaxis without altering gastric pH, did not reduce the risk of ventilator-associated pneumonia, despite the theoretical advantage of lessened risk for gastric colonization by gram-negative bacilli. The benefit of selective decontamination of the oropharynx and gut with nonabsorbable antimicrobials has been controversial.

Surgical Wound Infections The most important control measures for surgical wound infections include the use of antimicrobial prophylaxis at the start of high-risk procedures, attention to technical surgical issues and operating-room asepsis (e.g., not shaving the operative site until surgery and avoiding open or prophylactic drains), and preoperative therapy for active infection. In one study, rates of postoperative infection were lower among patients who had normothermia maintained during colorectal surgery. Reporting of surveillance results to surgeons has been associated with reductions in infection rates. The increasingly extensive review of infection rates by regulatory agencies and third-party payers emphasizes the importance of stratifying rates by patient-related risk factors and of developing meaningful systems for interhospital comparisons and for wound surveillance after the patient's discharge from the hospital or clinic (when more than 50% of infections first become apparent).

Infections Related to Vascular Access and Monitoring (See also Chap. 135) Control measures for infections associated with vascular access and monitoring include the moving of peripheral or arterial catheters to a new site at specified intervals (e.g., every 72 h for peripheral intravenous catheters), which may be facilitated by use of an intravenous team; application of disposable transducers and aseptic technique for the accessing of transducers or other vascular ports; removal of "idle" catheters; and consideration of use of central venous catheters impregnated with anti-infective agents. Unresolved issues include the best frequency for the rotation of central venous catheter sites (guidewire-assisted catheter changes at the same site do not lessen infection risk); the best antiseptics for site preparation and for catheter dressing; the appropriate role for mupirocin ointment, a topical antibiotic with excellent antistaphylococcal activity, in site care; and the relative degrees of risk posed by percutaneous central catheters and by newer designs -- tunneled, totally implanted, or peripherally inserted central catheters (PICC lines). Improvements in composition of semitransparent access-site dressings and potential nursing benefits (ease of bathing and site inspection and protection of the site from secretions) favor use of such coverings.

Isolation Techniques Written policies for the isolation of infectious patients are a standard component of infection-control programs. In 1996, the CDC revised its isolation guidelines to be simpler; to recognize the importance of all body fluids, secretions, and excretions in the transmission of nosocomial pathogens; and to focus precautions on the major routes of infection transmission.

The revised guidelines contain two tiers of precautions. *Standard precautions* are designed for the care of all patients in hospitals to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection. These precautions include gloving, as well as hand washing, for potential contact with blood; with all other body fluids, secretions, and excretions, regardless of whether they contain visible blood; with nonintact skin; and with mucous membranes. Depending on exposure

risks, standard precautions also include use of masks, eye protection, and gowns.

In the second tier are precautions for the care of patients with suspected or diagnosed colonization or infection with transmissible pathogens. These transmission-based guidelines collapse the older category- and disease-specific isolation guidelines into three sets of precautions based on probable routes of transmission: *airborne precautions*, *droplet precautions*, and *contact precautions*. Sets of precautions may be combined for diseases that have more than one route of transmission (e.g., varicella). Potentially contagious clinical syndromes, such as acute diarrhea, are included in the revised guidelines.

Because some prevalent antibiotic-resistant pathogens, particularly vancomycin-resistant enterococci (VRE), may be present on *intact* skin of patients in hospitals, some experts recommend gloving for all contact with patients who are acutely ill and/or from high-risk units, such asICUs. In recent trials, wearing gloves did not replace the need for hand washing because hands occasionally became contaminated during wearing or removal of gloves. Some studies have suggested that use of gowns and gloves compared with routine care of patients (i.e., using neither of these barriers) decreases the risk of nosocomial infection; however, more recent evaluation suggests that gowning by personnel does not add benefit beyond that conferred by gloving and hand washing. Nevertheless, requiring increased precaution levels can improve the compliance of health care workers with isolation recommendations by 30%.

EPIDEMIC PROBLEMS

Outbreaks are always big news but probably account for fewer than 5% of nosocomial infections. The investigation and control of epidemics in hospitals require that infection-control personnel develop a case definition, confirm that an outbreak really exists (since many apparent epidemics are actually pseudo-outbreaks due to surveillance or laboratory artifacts), review aseptic practices and disinfectant use, determine the extent of the outbreak, perform an epidemiologic investigation to determine modes of transmission, work closely with microbiology personnel to culture for common sources or personnel carriers as appropriate and to type epidemiologically important isolates, and heighten surveillance to judge the effect of control measures. Control measures generally include the early reinforcement of routine aseptic practices during a search for compliance problems that may have fostered the outbreak, the ensuring of the appropriate isolation of cases (and the institution of cohort isolation and nursing if needed), and the implementation of further controls on the basis of the findings of the investigation. Examples of some potential epidemic problems follow.

Chickenpox When health care workers are exposed to chickenpox in the community or through patients with initially unrecognized infections, or when these employees work during the 24 h before developing chickenpox, infection-control practitioners institute a varicella exposure investigation and control plan. The names of exposed workers and patients are obtained; medical histories are reviewed, and (if necessary) serologic tests for immunity are conducted; physicians are notified of susceptible exposed patients; postexposure prophylaxis with varicella-zoster immune globulin (VZIG) is considered for immunocompromised or pregnant contacts (see Table 183-1); preemptive use of acyclovir is considered as an alternative strategy in some susceptible persons; and

susceptible exposed employees are furloughed during the at-risk period for disease (8 to 21 days, or 28 days if VZIG has been administered). Preexposure varicella vaccination can markedly decrease risk for susceptible employees.

Tuberculosis The resurgence of pulmonary tuberculosis in the United States since 1987 and a series of nosocomial outbreaks of infection with multidrug-resistant strains -- primarily involving patients with AIDS and their caregivers -- have led to a reevaluation of tuberculosis control. Important control measures include prompt recognition, isolation, and treatment of cases; recognition of atypical presentations (e.g., lower-lobe infiltrates without cavitation); use of negative pressure, 100% exhaust, private isolation rooms with closed doors, and six air changes per hour; use of face masks (approved by the National Institute for Occupational Safety and Health) by caregivers entering isolation rooms; possible use of high-efficiency particulate air filter units and/or ultraviolet lights for disinfecting air when other engineering controls are not feasible or reliable; and follow-up skin-testing of susceptible personnel who have been exposed to infectious patients before isolation.

Group A Streptococci The potential for a group A streptococcal outbreak should be considered when even a single nosocomial case occurs. Most outbreaks involve surgical wounds and are due to the presence of an asymptomatic carrier in the operating room. Investigation can be confounded by carriage at extrapharyngeal sites such as the rectum and vagina. Health care workers in whom carriage has been linked to nosocomial transmission of group A streptococci are removed from the patient-care setting and are not permitted to return until carriage has been eliminated by antimicrobial therapy.

Aspergillus *Aspergillus* spores are common in the environment, particularly on dusty surfaces. When hospital ceiling tiles are removed to provide access for electrical wiring or plumbing or when dusty areas are disturbed during hospital renovation, the spores become airborne. Inhalation of spores by immunosuppressed (particularly neutropenic) patients creates a risk of pulmonary and/or paranasal sinus infection and disseminated aspergillosis. Routine surveillance among neutropenic patients for infections with filamentous fungi, such as *Aspergillus* and *Fusarium*, helps hospitals to determine whether they have unduly large environmental loads of these organisms. To lower the risk, hospitals should inspect and clean air-handling equipment on a routine schedule, review all planned hospital renovations with infection-control personnel and subsequently construct appropriate barriers, remove immunosuppressed patients from renovation sites, and consider the use of high-efficiency particulate air filters for rooms housing immunosuppressed patients.

Legionella Sporadic and epidemic cases of nosocomial *Legionella* pneumonia are most often due to the contamination of potable water and predominantly affect immunosuppressed patients, particularly those receiving glucocorticoid medication. The risk varies greatly within and among geographic regions, depending on the extent of hospital hot-water contamination, on the presence or absence of high-risk patient populations, and on specific hospital practices (e.g., inappropriate use of nonsterile water in respiratory therapy equipment). Laboratory-based surveillance for nosocomial *Legionella* should be performed, and a diagnosis of legionellosis should probably be considered more often than it is. If cases are detected, environmental samples (e.g., tap

water) should be cultured. If cultures yield *Legionella* and if typing of clinical and environmental isolates reveals a correlation, eradication measures should be pursued (Chap. 151). An alternative approach is to periodically culture tap water on wards housing high-risk patients. If *Legionella* is found, a concerted effort should be made to culture samples from all patients with nosocomial pneumonia for *Legionella*.

Antibiotic-Resistant Bacteria Outbreaks of antibiotic resistance can depend on any of the following events: Darwinian selection of bacterial chromosomal mutations, spread of plasmid- and/or transposon-borne resistance among bacterial species, and (re)admission to the hospital of patients chronically infected with resistant bacteria. After the introduction of resistant strains, dissemination occurs by cross-infection on unwashed hands of caregivers or, occasionally, via personnel carriage and/or environmental contamination. Outbreak control depends on close laboratory surveillance, with early detection of problems; on the reinforcement of routine asepsis (e.g., hand washing); on the implementation of barrier precautions for all colonized and/or infected patients; on the use of patient-surveillance cultures to more fully ascertain the extent of patient colonization; and on the timely initiation of an epidemiologic investigation when rates increase. Colonized personnel who are implicated in nosocomial transmission and patients who pose a threat may be decontaminated; for example, colonization with methicillin-resistant *Staphylococcus aureus* may be controlled with oral antibiotics, including trimethoprim-sulfamethoxazole and rifampin, and with topical agents, including hexachlorophene or chlorhexidine and mupirocin. In a few ICUs, selective decontamination has been used successfully as a temporary emergency control measure for outbreaks of infection due to gram-negative bacilli.

The most recent bacterial-resistance problem to plague hospitals is the emergence of VRE. Initially an ICU problem, VRE have now spread onto general wards in many hospitals. VRE are particularly problematic because of a substantial "iceberg" effect (i.e., the fact that, for each individual with a clinical infection, many other patients are colonized); the occurrence of both gastrointestinal and skin colonization (reflecting fecal contamination on the skin of ill, hospitalized patients); and the propensity for these organisms to contaminate the patient's environment, which may increase the risk of cross-infection. Control of VRE requires strict attention to hand washing by personnel, concerted use of barrier precautions or cohort nursing for patients known to be colonized or infected, and emphasis on thorough cleaning of the rooms of these patients.

Spread of vancomycin resistance to *S. aureus* is a major concern. Clinical infections with methicillin-resistant *S. aureus* strains that exhibit reduced susceptibility to vancomycin have been reported in a few patients, usually in the setting of prolonged or repeated treatment with vancomycin. The detection of these strains requires augmented laboratory activities, and their identification should trigger an aggressive epidemiologic investigation and aggressive infection-control measures.

Because the excessive use of broad-spectrum antibiotics underlies many resistance problems, antibiotic-control policies (Table 134-2) must be considered a cornerstone of resistance-control efforts. Although the efficacy of antibiotic-control measures in reducing rates of antimicrobial resistance has not been proved in prospective controlled

trials, it seems worthwhile to restrict the use of particular agents to narrowly defined indications or possibly to cycle the use of antibiotic classes to limit selective pressure on the nosocomial flora.

EMPLOYEE HEALTH SERVICE ISSUES

An institution's employee health service is a critical component of its infection-control efforts. New employees should be processed through the service, where a contagious-disease history can be taken; evidence of immunity to a variety of diseases, such as hepatitis B, chickenpox, measles, and rubella, can be sought; immunizations for hepatitis B, measles, rubella, and varicella can be given as needed and a reminder about the need for yearly influenza immunization can be imparted; baseline and "booster" purified protein derivative of tuberculin skin-testing can be performed; and education about personal responsibility for infection control can be initiated. Evaluations of employees should be codified to meet the requirements of accrediting and regulatory agencies.

The employee health service must have protocols for dealing with workers who have been exposed to contagious diseases, such as those percutaneously or mucosally exposed to the blood of patients infected with HIV. Postexposure HIV prophylaxis with a combination of antiretroviral agents (e.g., zidovudine and lamivudine, with or without indinavir or nelfinavir) is recommended. Protocols are also needed for dealing with caregivers who have common contagious diseases, such as chickenpox, group A streptococcal infections, respiratory infections, and infectious diarrhea, and for those who have less common but high-visibility public health problems, such as chronic hepatitis B or C or HIV infection, for which exposure-control guidelines have been published by theCDC and by the Society for Healthcare Epidemiology of America.

135. HOSPITAL-ACQUIRED AND INTRAVASCULAR DEVICE-RELATED INFECTIONS - *Dori F. Zaleznik*

Nosocomial infections are defined as infections acquired during or as a result of hospitalization. Generally, a patient who has been in the hospital for<48 h and develops an infection is considered to have been incubating the infection before hospital admission. Most infections that become manifest after 48 h are considered to be nosocomial. A patient may develop a nosocomial infection after being discharged from the hospital if the organism apparently was acquired in the hospital. Surgical wound infection developing in the weeks after hospital discharge is an example of such nosocomial infection.

INCIDENCE AND COSTS

Nosocomial infections contribute significantly to morbidity and mortality as well as to excess costs for hospitalized patients. It is estimated that 5% of patients admitted to an acute care hospital in the United States acquire a new infection, with>2 million nosocomial infections per year and an annual cost of >$2 billion. Some authorities estimate that the odds of death are doubled for patients who develop a nosocomial infection, although clearly such factors as underlying disease and severity of illness also play an important role in outcome.

Although immunosuppressed hosts are especially vulnerable to infections acquired in a hospital, common nosocomial infections occur even in immunocompetent hosts. The National Nosocomial Infections Surveillance (NNIS) Registry has been monitoring nosocomial infection rates since 1970. Its most recent report covers the period from October 1996 through April 1998 and includes both teaching and nonteaching hospitals and both small and large facilities. The most common nosocomial infections have remained the same. Urinary tract infections (UTIs), pneumonia, and surgical-site infections (SSIs, formerly termed wound infections) are most frequent. However, primary bloodstream infections, especially those associated with intravascular devices, have increased in frequency, as have infections in medical and surgical intensive care units (ICUs) and infections caused by antimicrobial-resistant pathogens.

The potential impact of nosocomial infections is considerable when assessed in terms of incidence, morbidity, mortality, and financial burden. Analyses of these factors examine nosocomial infections as both medical and economic issues. The clinical problem facing the physician is the development of a new fever in a patient in the hospital. In the evaluation of such a patient, information about the most common categories of infection may not be sufficient. Rather, the clinician must also use clinical clues from the patient's presentation and hospitalization to diagnose a nosocomial infection.

Approach to the Patient

The evaluation of a hospitalized patient with new fever should include a careful history (Chap. 17). Particular attention should be paid to symptoms of headache, cough, abdominal pain, diarrhea, flank pain, dysuria, urinary frequency, and leg pain. Other features related to the patient's hospitalization are also important, such as the presence and type of intravenous devices, the past or current use of a urinary catheter, the

surgical procedure conducted (if any), and the new medications administered, including those for surgical prophylaxis. The physical examination should be directed at possible sources of infection and should focus particularly on the skin (with a search for rash or embolic lesions); the lungs; the abdomen (especially the right upper quadrant); the costovertebral angles; surgical wounds; the calves; and current and old intravenous access sites (for signs of phlebitis). The laboratory evaluation of all hospitalized patients with new fever should include a complete blood count with differential, a chest radiograph, and blood and urine cultures. Other diagnostic tests to consider include liver function tests, plain-film or other studies of the abdomen, routine aerobic cultures of sputum or other relevant body fluids, and (in cases of diarrhea) testing of stool for *Clostridium difficile* toxin.

CATEGORIES OF INFECTION

Pneumonia Certainly the astute clinician will question the patient thoroughly and perform a rapid comprehensive physical examination. One way to continue the approach to the hospitalized patient with a new fever is to consider potential infections that may be life-threatening, such as pneumonia. Most at risk for developing nosocomial pneumonia are patients in anICU, especially those who are intubated; patients with an altered level of consciousness, especially those with nasogastric tubes; elderly patients; patients with chronic lung disease; postoperative patients; and any of the above patients taking H_2blockers or antacids. Nosocomial pneumonia in theNNISRegistry is diagnosed 4 to 7 times per 1000 hospitalizations. Among patients on ventilators, the occurrence of pneumonia is estimated at 15 cases per 1000 ventilator days in medical and surgical ICUs. Mortality figures for nosocomial pneumonia are as high as 50%.

Oropharyngeal and gastric colonization plays a critical role in the pathogenesis of pneumonia in hospitalized patients. The oropharynx can become colonized by many species of aerobic gram-negative organisms within 48 h of the patient's hospitalization; aspiration occurs commonly during sleep and is increased by such factors as a nasogastric tube, altered consciousness, decreased gag reflex, or delayed gastric emptying. As for gastric colonization, bacterial counts in the stomach rise in the presence of medications that raise gastric pH, such as H_2blockers and antacids, as well as in malnourished, achlorhydric, and some elderly patients. The prevalence of pneumonia is reportedly two to three times higher among intubated patients receiving H_2blockers or antacids for stress-ulcer prophylaxis than among intubated patients receiving sucralfate, a medication that heals ulcers without altering gastric pH. Gastric colonization is believed to influence the development of pneumonia by retrograde colonization of the oropharynx. Ventilated patients are also at risk of developing pneumonia by exposure to bacteria leaking around the cuff of the endotracheal tube or to bacteria from nebulizers, condensate within ventilator circuits, or humidifiers.

Outside the ICU, pneumonia should be suspected when a patient develops a new cough, fever, leukocytosis, sputum production, and a new infiltrate on chest x-ray. Diagnosis can be complicated in patients with congestive heart failure who have concomitant chest x-ray abnormalities or in patients with chronic sputum production. Some organisms, such as *Legionella* spp., may not be associated with peripheral leukocytosis.

InICUpatients, especially those who are intubated, the signs of pneumonia are relatively subtle, and thus the diagnosis is often relatively complex. In particular, the chest x-rays are difficult to interpret, because fluid overload, congestive heart failure, and acute respiratory distress syndrome (ARDS) are all common findings in intubated patients. Polymorphonuclear leukocytes (PMNs) are often present on Gram-stained preparations of purulent secretions from these patients. An important clue to pneumonia is a change in the output or character of these secretions. If their volume or thickness increases or their color changes, a sputum Gram's stain should be performed and pneumonia seriously considered in the differential diagnosis. Serial Gram's stains are useful, as the number of PMNs may increase substantially and the type(s) of organisms may shift with the development of pneumonia. For example, the baseline sputum sample from an intubated patient may contain about 25 PMNs per high-power field and have mixed gram-positive and gram-negative organisms of several morphologic types in moderate numbers. On the day of a new fever, the same patient may have copious amounts of more tenacious sputum with more PMNs and a predominance of enteric-appearing gram-negative rods. Even without distinct changes in the chest x-ray, this patient would be considered to have developed pneumonia. Another subtle sign of pneumonia in the intubated patient is a requirement for change in ventilator settings in the absence of fluid overload, a mechanical alteration (e.g., a shift in endotracheal tube placement), or a pneumothorax.

The major organisms of concern in nosocomial pneumonia are gram-negative aerobic bacteria. *Pseudomonas aeruginosa* was the most common isolate in theNNISsurvey ofICUs, with a frequency of 21%; *Staphylococcus aureus* was next most common at 20%. *Acinetobacter* has become a more common pathogen in ventilator-associated pneumonia. While surveys of organisms are useful, it is essential to know which pathogens are common in a given institution, as hospitals and especially ICUs differ in their resident flora. In some institutions, methicillin-resistant *S. aureus*, *Stenotrophomonas* (formerly *Xanthomonas*) *maltophilia*, *Flavobacterium* spp., and even *Legionella* spp. may be of particular concern. Viruses such as respiratory syncytial virus and adenovirus are receiving increased attention as etiologic agents of nosocomial pneumonia in both adults and children. In the past, viruses have been underrepresented in statistics on the agents of nosocomial pneumonia because the diagnosis of viral infection is more difficult and because many microbiology laboratories do not have the capability to isolate viruses.

Antibiotic resistance is another important issue to address in the management of a hospitalized patient. An outgrowth of theNNISsurveys is Project ICARE, which tracks antibiotic usage patterns and resistance rates in a subset of NNIS institutions. Rates of resistance are generally higher in ICUsand track with increased use of antibiotics. *P. aeruginosa*, *Enterobacter* spp., and enterococci are the pathogens of greatest concern in the development of antibiotic resistance. In addition to knowing the sensitivity patterns of the hospital flora, one must consider whether a patient has received continuous or multiple courses of antibiotic therapy. To reduce the likelihood of altering the sensitivity patterns of the patient's flora, antibiotic courses for pneumonia should be kept as short as possible, with coverage as narrow as possible for the organism(s) involved.

Bacteremia Another potentially life-threatening nosocomial infection to consider in the evaluation of the patient with a new fever is bacteremia, which is usually related to the

presence of an intravascular device (Chap. 134). While many common nosocomial infections such as pneumonia orUTI can be accompanied by bacteremia, primary bacteremia is defined by isolation of a recognized pathogen from the blood without an infection at another site. One carefully controlled study reported bloodstream infection in 2.7% of admissions to a surgicalICU, with 50% mortality and a prolongation of hospitalization by 24 days in survivors.

One difficulty in assessing the significance of bacteremia is to distinguish true pathogens from contaminating skin flora. This distinction is especially important in establishing an infection of an indwelling intravascular catheter because organisms that inhabit the skin, such as coagulase-negative staphylococci, also frequently cause infection. The most common point of entry for infection related to intravascular devices is the insertion site, with spread of the infection along the outside of the device initially. Other means of entry for infecting organisms include introduction via contaminated infusates or tubing, ports, or leaking connections and hematogenous seeding of a catheter during bacteremia. While gram-negative aerobic bacilli are probably the most feared nosocomial bloodstream pathogens, the NNISdata for 1980 through 1989 showed that the isolation of these organisms had not increased in frequency over the decade. The frequency of bloodstream isolation increased the most for coagulase-negative staphylococci, with the next highest increase for *Candida* spp. Other leading causes of line-related bacteremia were *S. aureus* and enterococci. Subsequent studies confirmed these findings. Nosocomial endocarditis is an important, newly recognized entity that develops largely as a complication of invasive procedures or intravascular devices and may account for as many as 10% of cases of infective endocarditis.

Establishing an infection of an intravascular device or primary bacteremia as the cause of fever in a hospitalized patient is a diagnosis of exclusion. If a patient has a fever and signs of cutaneous involvement (erythema, induration, tenderness, or purulent drainage) at the insertion site of a catheter, full cultures should be performed, the vascular-access line removed, and the catheter tip sent for quantitative culture. Studies have correlated the growth of³15 colonies from a catheter tip with infection of the line. More commonly, the exit site does not show signs of infection, and there is considerable debate about the necessity of removing a line from a febrile patient at that point. Although line changes over a guidewire have been shown to be safe, unless another site of infection is obvious, it is generally advisable to remove the line and to change the site when a patient develops a new fever. The traditional teaching is that an infected intravenous device should be removed. In current practice, however, especially with surgically implanted intravenous catheters, a decision may be made to attempt treatment with antibiotics while leaving the catheter in place. This practice is often successful when the infecting organism is a coagulase-negative *Staphylococcus* species but is less often effective with other organisms, particularly *Candida* spp. and gram-negative bacilli. Salvage of catheters used for hemodialysis is especially important and has been successfully accomplished with infections caused by a variety of organisms.

Another controversial management issue is whether to draw blood for culture through a line. While some studies report a correlation in the 90% range between culture results for blood drawn through vascular-access lines and those for peripheral blood, the former cultures can be either false-positive or false-negative. If the line culture is positive and

no peripheral blood has been drawn, it is impossible to determine whether the patient has true bacteremia or the culture merely reflects bacteria associated with the line. Whether bacteremia is high- or low-grade and whether it is sustained or transient may influence the duration of antibiotic therapy and cannot be determined from cultures of blood specimens obtained through a line.

An area of considerable interest and controversy is the prevention of catheter-related infections through the use of intravenous devices impregnated with chlorhexidine/silver sulfadiazine or minocycline/rifampin. A meta-analysis of 11 studies found a decrease in both catheter colonization and catheter-related bacteremia with chlorhexidine/silver sulfadiazine-impregnated catheters, with associated cost savings. One multicenter prospective randomized trial directly compared the two types of catheters and found the minocycline/rifampin-impregnated catheter to be superior. Antibiotic-resistant strains were not recovered in this trial, although concern has been raised that antibiotic impregnation may increase the development of resistance. The several other studies that do not support these findings include one in which the incidence of bacteremia did not decrease with the use of chlorhexidine/silver sulfadiazine-impregnated catheters.

Surgical-Site Infection Evaluation of fever in the postoperative patient must include careful evaluation of the surgical wound. AlthoughSSIreportedly accounts for 19% of nosocomial infections, the true incidence of postoperative wound infection is difficult to assess, particularly at a time when many patients are hospitalized for relatively short periods. In a number of studies, careful follow-up for the development of SSI after discharge -- especially observation of the wound by a trained observer, such as a nurse -- has shown the actual rates of SSI in all categories of surgery to be greater than the reported rates. SSI rates vary from 4.6 to 8.2% for nonteaching and large teaching hospitals, respectively. Rates also vary by procedure, with abdominal surgery resulting in the highest rates.

Risk factors for the development of postoperative wound infection include the presence of a drain; a long preoperative length of stay, with the rates doubling for each week of preoperative hospitalization; preoperative shaving of the field, especially if performed [3]24 h beforehand; a long duration of surgery; and the presence of an untreated remote infection. Infection rates also vary with the surgeon. Perioperative antibiotic prophylaxis has been shown to decrease rates of wound infection in a number of careful studies, including those of clean surgical procedures. Antibiotic coverage after the surgical wound is closed has not been shown to provide additional benefit.

A surgical wound should be examined for localized tenderness and induration, fluctuance, drainage of purulent material, and dehiscence of sutures. Mechanical factors, as well as infection, can cause wound dehiscence. Sternal wounds following cardiac surgery are of special concern because the consequences of infection can be severe. The surface of the wound may not present an obvious cause for concern, but ongoing fevers, serous drainage, and especially the development of rocking or instability of the sternum may be sufficient cause for surgical exploration of the wound in some cases. Mediastinitis or sternal osteomyelitis is a severe complication of cardiac surgery. Wounds associated with the placement of prosthetic devices, such as mechanical joints, are also of special concern. Infection of these wounds can lead to infection of the prosthesis, and clearance of prosthetic joint infections generally requires surgical

removal of the device.

The most common pathogens causingSSI are coagulase-negative *Staphylococcus* and *S. aureus*, but antibiotic-resistant bacteria and fungi are also becoming more frequent etiologies. Early infections may be associated with organisms that produce rapid, progressive skin infection, such as group A *Streptococcus* and *Clostridium* spp. Group A *Streptococcus* has been identified in some cases of recurrent infection of saphenous-vein graft harvest sites.

Urinary Tract Infection UTI, the most common type of nosocomial infection, is generally the easiest to treat and has the least severe sequelae. Four principal risk factors have been associated repeatedly with the development of UTI in hospitalized patients: female sex, prolonged urinary catheterization, lack of systemic antibiotic therapy, and breach of appropriate catheter care. The administration of systemic antibiotics to patients with urinary catheters in place for 1 to 5 days has been associated with a decrease in rates of bacteriuria. For patients with catheters in place for ³6 days, however, this benefit is not observed.

The pathogenesis of catheter-associatedUTIappears to differ in men and women. In women, the typical mechanism involves periurethral colonization with fecal flora and tracking of organisms up the catheter to the bladder; thus the pathogenesis resembles that of UTI in noncatheterized female patients, in whom bacteria track up the short female urethra. In contrast, periurethral colonization often cannot be demonstrated in men; most infections seem to arise from intraluminal spread of organisms to the bladder. Some organisms, such as *Proteus* and *Pseudomonas* spp., appear to facilitate the growth along the inside of the urinary catheter of a biofilm that encrusts and obstructs the flow of urine.

UTIis certainly an extremely common nosocomial infection; however, it is important to define this type of infection precisely. Especially in the evaluation of a febrile hospitalized patient, it is crucial to think carefully about all possible sources of infection and not to assume that UTI is the probable cause. In patients who have had urinary catheters in place for a number of days, fever, dysuria, frequency, leukocytosis, and especially flank pain or costovertebral angle tenderness are highly suggestive of bladder infection or pyelonephritis. In patients with fever but no other symptoms or signs referable to the urinary tract, one should look for ancillary findings suggestive of urinary tract involvement, such as white blood cells without epithelial cells in the urine sediment or leukocyte esterase or nitrite on urinalysis. A urine culture positive for a single organism should not be accepted as definitive evidence of UTI in an asymptomatic patient. While one might treat the febrile patient who has a positive urine culture with antibiotics, it is prudent to repeat the culture before the institution of therapy. Inability to recover any organism or the same organism on repeat culture, particularly if the patient does not respond to antibiotics, should raise questions about the validity of the diagnosis of UTI. In addition, isolation of two or more bacteria from a single specimen is most likely due to contamination unless there is reason to suspect a bladder diverticulum or a perinephric abscess.

Other Infectious Sources of Fever Several other types of infection may cause fever in the hospitalized patient and should be considered in the differential diagnosis of new

fever. In patients who have received antibiotics (even a single dose as surgical prophylaxis), antibiotic-associated diarrhea may develop. This condition is usually caused by the spore-forming organism *C. difficile*, which produces toxins that cause diarrhea. Some patients may appear quite toxic with this infection, with high fevers, leukocytosis, and profuse diarrhea. The organism is quite hardy and is difficult to eradicate from the hospital environment. The hands of hospital personnel have been implicated as a mode of transmission of this organism, as have electronic rectal thermometers. The colon may become colonized with *C. difficile* while the patient is in the hospital, but -- particularly if the patient is still taking antibiotics when sent home -- diarrhea may not develop until after discharge.

Unless patients are consuming foods from outside the hospital, food-borne diarrheal illness is uncommon among hospitalized patients. Thus, an extensive stool evaluation is generally not cost-effective in the management of these patients.

Other infections to consider in the hospitalized patient include decubitus ulcers, particularly in patients in chronic-care wards or confined to bed rest for prolonged periods, and sinusitis, especially in intubated patients.

NONINFECTIOUS SOURCES OF FEVER

A consideration of several common noninfectious causes of fever in hospitalized patients is part of a thorough evaluation of new fever. Drug treatment is the foremost noninfectious cause of fever. Drug fever may occur with or without an accompanying rash or eosinophilia and can be caused by a new medication or by medications the patient has been receiving for some time. Particular agents associated with drug fever include phenytoin, H_2blockers, procainamide, and antibiotics, most notably sulfonamides. Even drug-associated fevers can be quite high in some patients and may take up to 5 days to resolve after discontinuation of treatment with the offending agent. Other noninfectious causes of fever include phlebitis, often at the site of an old intravenous line and sometimes followed by suppurative thrombophlebitis with clots or septic emboli, and pulmonary emboli, especially in patients undergoing prolonged bed rest; prophylactic heparin or mechanical boots are often used to reduce the risk of pulmonary embolism in the latter patients. Other entities to consider include tissue necrosis following surgery, trauma, or burns; hematomas; pancreatitis; atelectasis; and acalculous cholecystitis.

CONCLUSION

The range of possibilities for the etiology of a new fever in a hospitalized patient is quite broad. An attention to detail, a careful history and physical examination, and a knowledge of the infections and organisms likely to cause nosocomial problems usually lead to an accurate diagnosis.

136. INFECTIONS IN TRANSPLANT RECIPIENTS - *Robert Finberg*, *Joyce Fingeroth*

The evaluation of infections in transplant recipients involves consideration of both the donor and the recipient of the transplanted organ. Infections following transplantation are complicated by the use of drugs that are necessary to enhance the likelihood of survival of the transplanted organ but that also cause the host to be immunocompromised. Thus what might have been a latent or asymptomatic infection in an immunocompetent donor or in the recipient prior to therapy becomes a life-threatening problem when the recipient becomes immunosuppressed.

A variety of organisms have been transmitted by organ transplantation (Table 136-1). Careful attention to the sterility of the medium used to process the organ combined with meticulous microbiologic evaluation reduces rates of transmission of bacteria that may be present or grow in the organ culture medium. From 2% to >20% of donor kidneys are estimated to be contaminated with bacteria -- in most cases, with the organisms that colonize the skin or grow in the tissue culture medium used to bathe the donor kidney while it awaits implantation. The reported rate of bacterial contamination of transplanted bone marrow is as high as 17% but is most commonly ~1%. The use of enrichment columns and monoclonal-antibody depletion procedures results in a higher incidence of contamination. Approximately 2% of cryopreserved marrow and peripheral blood stem cells transfused as part of treatment for cancer are contaminated. In one series of patients receiving contaminated products, 14% had fever or bacteremia, but none died. Results of cultures performed at the time of cryopreservation and at the time of thawing were helpful in guiding therapy for the recipient.

In many transplantation centers, transmission of infections that may be latent or clinically inapparent in the donor organ has resulted in the development of specific donor-screening protocols. In addition to ordering serologic studies focusing on viruses such as herpes-group viruses [herpes simplex virus (HSV) 1, HSV-2], varicella-zoster virus (VZV), cytomegalovirus (CMV), human herpesvirus (HHV) 6, Epstein-Barr virus (EBV), HHV-8, hepatitis B and C viruses, and HIV and on parasites such as *Toxoplasma gondii*, clinicians caring for organ donors should consider assessing stool (for parasites) and skin testing for *Mycobacterium tuberculosis*. It is expected that the recipient will have been likewise assessed. This chapter considers aspects of infection unique to various transplantation settings.

INFECTIONS IN BONE MARROW AND HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Bone marrow or hematopoietic stem cell transplantation for either immunodeficiency or cancer results in a transient state of complete immune incompetence. Immediately after transplantation, both phagocytes and immune cells (T and B cells) are absent, and the host is extremely susceptible to infection. The reconstitution that follows transplantation has been likened to maturation of the immune system in neonates. The analogy does not entirely predict infections seen in bone marrow transplant (BMT) and hematopoietic stem cell transplant (HSCT) recipients, however, because the new marrow matures in an old host who has several latent infections already.

TIMING OF INFECTIONS

In the first month after bone marrow or hematopoietic stem cell transplantation, infectious complications are similar to those in granulocytopenic patients receiving chemotherapy for acute leukemia (Chap. 85). Because of the anticipated 1- to 4-week duration of neutropenia in this population, many centers give prophylactic antibiotics to patients upon initiation of chemotherapy. Prophylactic trimethoprim-sulfamethoxazole or ciprofloxacin decreases the incidence of gram-negative bacteremia among these patients.

In the second month after transplantation, a major concern (particularly in allogeneicBMT/HSCTrecipients) isCMVdisease (Chap. 185), which rarely has its onset earlier than 14 days after transplantation and may become evident up to 4 months after the procedure (most commonly at 1 to 3 months). In cases in which the donor marrow is depleted of T cells [to prevent graft-versus-host disease (GVHD) or eliminate a T cell tumor], the disease may be manifested earlier. Patients who receive ganciclovir (for prophylaxis, preemptive treatment, or treatment; see below) may develop CMV infection even later than 4 months after transplantation; treatment appears to delay the development of the normal immune response to CMV infection. Although CMV disease may present as isolated fever, cytopenia, or gastrointestinal disease, the foremost cause of death from CMV infection in this setting is pneumonia.

The diagnosis of pneumonia inBMT/HSCTrecipients poses some special problems (Table 85-5). Because patients have undergone treatment with multiple chemotherapeutic agents and sometimes radiation, their differential diagnosis should include -- in addition to bacterial pneumonia -- CMVpneumonitis, pneumonia of other viral or fungal etiology, parasitic pneumonia, diffuse alveolar hemorrhage, and chemical- or radiation-associated pneumonitis. Since fungal disease and viruses such as respiratory syncytial virus (RSV), parainfluenza virus (types 1, 2, and 3), influenza A and B viruses, and adenovirus are also causes of pneumonia in this setting, it is important to diagnose CMV specifically (see below). *M. tuberculosis* has been an uncommon cause of pneumonia among BMT/HSCT recipients in western countries (<0.1 to 0.2%) but is common in Hong Kong (5.5%) and in countries where the prevalence of tuberculosis is high. The exposure history of the recipient is clearly critical in an assessment of posttransplantation infections.

Episodes of bacteremia due to encapsulated organisms and reactivation ofVZV mark the late posttransplantation period (6 months after bone marrow reconstitution). Because of the high and prolonged risk of *Pneumocystis carinii* pneumonia (especially among patients being treated for hematologic malignancies), most patients should be maintained on prophylactic doses of trimethoprim-sulfamethoxazole starting 1 month after engraftment and continuing for at least 1 year. Such prophylaxis may also protect patients seropositive for *T. gondii*, which may cause pneumonia as well as central nervous system (CNS) lesions. The advantages of maintaining patients on daily trimethoprim-sulfamethoxazole for 1 year after transplantation include protection against *Listeria monocytogenes* and nocardial disease as well as late bacterial infections with pneumococci and *Haemophilus influenzae*, which are a consequence of the inability of the immature bone marrow to respond to polysaccharide antigens. In patients withGVHD who require prolonged or indefinite courses of steroids and other

immunosuppressive agents (e.g., cyclosporine, tacrolimus), there is a high risk of fungal infections (usually with *Candida* or *Aspergillus*), even after engraftment and resolution of neutropenia.

VIRAL INFECTIONS

BMT/HSCTrecipients are susceptible to infection with a variety of viruses, including reactivation syndromes caused by mostHHVs(Table 136-2) and infections caused by viruses that circulate in the community.

Herpes Simplex Virus Within the first 2 weeks after transplantation, most patients who are seropositive forHSV-1 excrete the virus in the oropharynx. The ability to isolate HSV declines with time. Administration of prophylactic acyclovir to seropositiveBMT/HSCTrecipients has been shown to reduce mucositis and prevent HSV pneumonia (a rare condition reported almost exclusively in BMT recipients). Both esophagitis (usually due to HSV-1) and anogenital disease (commonly induced by HSV-2) may be prevented with acyclovir prophylaxis.*For further discussion, see Chap. 182.*

Varicella-Zoster Virus Reactivation of herpes zoster may occur within the first month but more commonly occurs several months after transplantation (seePlate IID-37). Reactivation rates are ~40% for allogeneic recipients and 25% for autologous recipients. Localized zoster can spread in an immunosuppressed patient. Fortunately, disseminated disease can usually be controlled with high doses of acyclovir. Because of the high incidence of dissemination of herpes zoster among patients with skin lesions, acyclovir is given prophylactically in some centers to prevent severe disease. Low doses of acyclovir (400 mg orally, three times daily) appear to be effective in preventing reactivation ofVZV. However, acyclovir also inhibits the development of VZV-specific immunity. Thus, its administration for only 6 months after transplantation does not prevent zoster from occurring when treatment is stopped. Some data suggest that administration of low doses of acyclovir for an entire year after transplantation is effective and may eliminate most cases of posttransplantation zoster.*For further discussion, see Chap. 183.*

Cytomegalovirus The onset of CMVdisease usually comes between 30 and 90 days after transplantation, when the granulocyte count is adequate but immunologic reconstitution has not occurred. CMV may cause interstitial pneumonia, bone marrow suppression, or graft failure. With the standard use of CMV-negative or filtered blood products, primary CMV infection should be a risk in allogeneic transplantation only when the donor is CMV-seropositive and the recipient is CMV-seronegative. Reactivation disease or superinfection with another strain from the donor is also common in CMV-positive recipients, and most seropositive patients who undergo bone marrow transplantation excrete CMV, with or without clinical findings. Serious CMV disease is much more common among allogeneic recipients and is often associated withGVHD. In addition to pneumonia and marrow suppression (and, less often, graft failure), manifestations of CMV disease inBMT/HSCTrecipients include fever with or without arthralgias, myalgias, and esophagitis. CMV ulcerations occur in both the lower and upper gastrointestinal tract, and it may be difficult to distinguish diarrhea due to GVHD from that due to CMV infection. The finding of CMV in the liver of a patient with GVHD

does not necessarily mean that CMV is responsible for hepatic enzyme abnormalities.

Management ofCMVdisease inBMT/HSCTrecipients includes strategies directed at prophylaxis, suppression, preemptive therapy, or treatment. Prophylaxis results in a lower incidence of disease at the cost of treating many patients who otherwise would not require therapy. Because of the high fatality rate associated with CMV pneumonia in these patients and the difficulty of early diagnosis of CMV infection, prophylactic ganciclovir has been used in some centers and has been shown to abort CMV disease during the period of maximal vulnerability (from engraftment to day 120 after transplantation). The foremost problem with the administration of this drug relates to adverse effects, which include dose-related bone marrow suppression (thrombocytopenia, leukopenia, anemia, and pancytopenia). Because the frequency of CMV pneumonia is lower among autologous BMT recipients (2 to 7%) than among allogeneic BMT recipients (10 to 40%), prophylaxis in the former group will not become the rule until a less toxic antiviral agent becomes available.

Like prophylaxis, suppressive treatment, which targets patients with polymerase chain reaction evidence ofCMV or CMV-positive urine cultures, entails the unnecessary treatment of many individuals (on the basis of a laboratory test that is not highly predictive of disease) with drugs that have adverse effects. Currently, because of the neutropenia associated with ganciclovir inBMT/HSCTrecipients, a preemptive approach -- treatment of those patients in whose blood CMV is detected by an antigen or DNA test -- is used at most centers. This approach is almost as effective as prophylaxis or suppression and causes less toxicity. The use of the leukocyte antigen test for CMV disease (fluorescent staining of leukocytes for CMV antigens) allows earlier diagnosis but leads to treatment of more patients than would be treated on the basis of blood cultures, with a consequent increase in very late disease (>120 days after transplantation). The use of quantitative viral load assays, which are not dependent on circulating polymorphonuclear leukocytes, should permit early accurate diagnosis in the future.

Treatment ofCMVpneumonia inBMT/HSCTrecipients requires both intravenous immune globulin (IVIG) and ganciclovir. In patients who cannot tolerate ganciclovir, foscarnet is a useful alternative, although it may produce nephrotoxicity and electrolyte imbalance. Transfusion of CMV-specific T cells from the donor decreased viral load in a small series of patients; this result suggests that immunotherapy may play a role in the treatment of this disease in the future.*For further discussion, see Chap. 185.*

Human Herpesviruses 6 and 7HHV-6, the cause of exanthem subitum in children (Chap. 185), is a ubiquitous herpesvirus that reactivates (as determined by culture of the virus from the blood) in ~50% of transplant recipients between 2 and 4 weeks after surgery. In some cases, reactivation of HHV-6 appears to be associated with neutropenia; since, likeCMV, this virus can be found in marrow cells, it is possible that HHV-6 reactivation is responsible for some of the neutropenia that follows bone marrow transplantation. Although encephalitis developing after transplantation has been associated with HHV-6 in cerebrospinal fluid (CSF), the causality of the association is not well defined. HHV-6 DNA is sometimes found in lung samples after transplantation. However, its role in pneumonitis is unclear. While HHV-6 has been shown to be sensitive to foscarnet (and in some instances to ganciclovir) in vitro, the efficacy of

antiviral treatment has not been well studied. Little is known about the related herpesvirus HHV-7 or its role in posttransplantation infection.*For further discussion, see Chap. 185.*

Epstein-Barr Virus PrimaryEBVinfection can be fatal to transplant recipients; EBV reactivation can cause EBV-B cell lymphoproliferative disease (LPD), which may also be fatal to patients taking immunosuppressive drugs. The localization of EBV to B cells leads to several interesting phenomena inBMT/HSCTrecipients. The marrow ablation that occurs as part of the BMT/HSCT procedure may eliminate latent EBV from the host. Infection can then be reacquired immediately after transplantation by transfer of infected donor B cells. Alternatively, transplantation from a seronegative donor may result in cure. The recipient is then at risk for a second primary infection.

EBV-LPDcan develop in the recipient's B cells (if any should survive marrow ablation) but is more likely to be a consequence of outgrowth of infected donor cells. Both lytic and latent EBV replication are more likely during immunosuppression (e.g., they are associated withGVHD and the use of antibodies to T cells). Although less likely in autologous transplantation, reactivation can occur in T cell-depleted autologous recipients (e.g., patients being treated for a T cell lymphoma with marrow depletion using antibodies to T cells). EBV-LPD, which usually becomes apparent 1 to 3 months after engraftment, can cause high fevers and cervical adenopathy resembling the symptoms of infectious mononucleosis but more commonly presents as an extranodal mass. The incidence of 0.6% among allogeneicBMT/HSCTrecipients contrasts with figures of ~5% for renal transplant recipients and up to 20% for cardiac transplant patients. In all cases, EBV-LPD is more likely to occur with continued immunosuppression (especially that caused by the use of antibodies to T cells and cyclosporine or tacrolimus).

EBV-specific T cells generated from the donor have been used experimentally to prevent and to treat EBV-LPDin the allogeneic recipient. Some studies indicate that EBV-LPD can be treated with antibodies to B cell surface antigens. Use of an anti-CD20 monoclonal antibody (Rituximab) to treat B cell lymphomas that express this surface protein has elicited some dramatic responses. Studies are in progress to assess efficacy in EBV-LPD, in which the involved B cells commonly bear CD20. The role of antivirals is uncertain because no available agents have been documented to have activity against latent EBV infection. Ganciclovir has been postulated to have activity on the basis of its ability to inhibit proliferation of B cells, but this activity is associated with toxicity. Both interferona and retinoic acid have been used in the treatment of EBV-LPD, as hasIVIG, but no large studies have assessed the efficacy of these agents. Chemotherapeutic regimens have been used as a last resort, even though patients' tolerance and long-term results have been disappointing in this setting.*For further discussion, see Chap. 184.*

Human Herpesvirus 8 TheEBV-related gamma herpesvirusHHV-8, which is causally associated with Kaposi's sarcoma, with primary effusion lymphoma, and sometimes with multicentric Castleman's disease, has rarely resulted in disease inBMT/HSCTrecipients. The reasons may be a relatively low seroprevalence in the population and the limited duration of profound T cell suppression after bone marrow/hematopoietic stem cell transplantation.*For further discussion, see Chap. 185.*

Other (Nonherpes) Viruses Both RSVand parainfluenza viruses, particularly type 3, can cause severe or even fatal pneumonia inBMTrecipients. Infections with both of these agents sometimes occur as disastrous nosocomial epidemics. Therapy with aerosolized ribavirin as well as RSV immunoglobulin or monoclonal antibody to RSV (Palivizumab) has been reported to lessen the severity of RSV disease, but there are no large studies to prove efficacy. Influenza is also seen in BMT recipients and generally mirrors the presence of infection in the community. Several drugs are available for the treatment of influenza (amantadine/rimantadine, ribavirin?) but have limited effects, primarily reducing symptoms and shortening the duration of illness. The newly approved neuraminidase inhibitors are active against both influenza A virus and influenza B virus. Their role in ameliorating disease in this patient population is unknown. Adenovirus can be isolated from BMT recipients at rates varying from 5 to 18%. Although hemorrhagic cystitis, pneumonia, and fatal disseminated infection have been reported, adenovirus infection, which (likeCMVinfection) usually occurs in the first or second month after transplantation, is often asymptomatic. Therapy with intravenous ribavirin is questionably effective. Cidofovir has proved effective in animal models and in case reports. Infections with parvovirus B19 (presenting as anemia or occasionally pancytopenia) and enteroviruses (sometimes fatal) can occur. Pleconaril, a newly developed capsid-binding agent, is being studied for treatment of enterovirus infection. Rotaviruses are a common cause of gastroenteritis in BMT/HSCTrecipients. BK and, to a lesser extent, JC virus (polyomavirus hominis 1 and 2, respectively) are found in the urine of some transplant recipients. BK viruria may be associated with hemorrhagic cystitis. Progressive multifocal leukoencephalopathy caused by JC virus is rare among BMT/HSCT recipients compared with the rate among patients with impaired T cell function due to HIV infection. There is no known treatment for this disease; however, cidofovir and other agents are under study.

INFECTIONS IN SOLID ORGAN TRANSPLANT RECIPIENTS

Morbidity and mortality among solid organ transplant recipients have been reduced by the use of more effective antibiotics. The organisms that cause infections in recipients of solid organ transplants are different from those that infectBMT/HSCTrecipients because solid organ recipients do not go through a period of neutropenia. As the transplantation procedure involves surgery, however, solid organ recipients are subject to infections at anastomotic sites and to wound infections. Compared with BMT/HSCT recipients, organ transplant patients are immunosuppressed for more prolonged periods (often permanently). Thus they are susceptible to the same organisms as patients with chronically impaired T cell immunity (Chap. 85, especiallyTable 85-1).

During the early period (<1 month after transplantation), infections are most often caused by extracellular bacteria (staphylococci, streptococci, *Escherichia coli*, other gram-negative organisms), which often originate in surgical wound or anastomotic sites. The spectrum of infection is largely determined by the type of transplant.

In subsequent weeks, the consequences of the administration of agents that suppress cell-mediated immunity and of the acquisition or reactivation (from the transplanted organ) of viruses and parasites become apparent.CMVinfection is often a problem in the first 6 months after transplantation and may present as severe systemic disease or as

an infection of the transplanted organ.HHV-6 reactivation (assessed by blood culture) occurs within the first 2 to 4 weeks after transplantation and may be associated with fever and granulocytopenia.

CMVis associated not only with generalized immunosuppression but also with organ-specific, rejection-related syndromes: glomerulopathy in kidney transplant recipients, bronchiolitis obliterans in lung transplant recipients, vasculopathy in heart transplant recipients, and the vanishing bile duct syndrome in liver transplant recipients. A complex interplay between increased CMV replication and enhanced graft rejection is well established: Increasing immunosuppression leads to increased CMV replication, which is associated with graft rejection. For this reason, considerable attention has been focused on the diagnosis, treatment, and prophylaxis of CMV infection in organ transplant recipients.

Beyond 6 months after transplantation, infections characteristic of patients with defects in cell-mediated immunity -- e.g., infections with *Listeria*, *Nocardia*, various fungi, and other intracellular pathogens -- may be a problem. Elimination of these late infections will not be possible until specific tolerance to the transplanted organ can be achieved without the administration of drugs that lead to generalized immunosuppression. Meanwhile, vigilance, prophylaxis/preemptive therapy (when indicated), and rapid diagnosis and treatment of infections can be lifesaving in solid organ transplant recipients, who, unlike mostBMTrecipients, continue to be immunosuppressed.

Solid organ transplant recipients are susceptible toEBV-LPDfrom as early as 2 months to many years after transplantation. The prevalence of this complication is increased by potent and prolonged use of T cell-suppressive drugs. The condition may be reversed (in some cases) by decreasing the degree of immunosuppression. Among organ transplant patients, those with heart and lung transplants -- who receive the most intensive immunosuppressive regimens -- are most likely to develop EBV-LPD, particularly in the lungs. Although disease usually originates in recipient B cells, several cases of donor origin have been reported. There is a notable tendency for EBV-LPD to develop in the transplanted organ. High organ-specific content of B lymphoid tissues (i.e., bronchial-associated lymphoid tissue in the lung), anatomic factors (i.e., lack of access of host T cells to the transplanted organ because of disturbed lymphatics), and differences in major histocompatibility loci between the host T cells and the organ (i.e., lack of cell migration or lack of effective T cell/macrophage cooperation) may result in defective elimination of EBV-infected B cells.

INFECTIOUS COMPLICATIONS OF KIDNEY TRANSPLANTATION (See Table 136-3)

Early Infections Infections developing soon after kidney transplantation are often caused by bacteria associated with skin or wound infections. Some data indicate a role for perioperative antibiotic prophylaxis, and many centers give cephalosporins or a penicillin with an aminoglycoside to decrease the risk of postoperative complications. Urinary tract infections developing soon after transplantation are usually related to anatomic alterations resulting from surgery. Such early infections may require prolonged treatment (e.g., 6 weeks of antibiotic administration for pyelonephritis). Urinary tract infections that occur >6 months after transplantation do not seem to be associated with the high rate of pyelonephritis or relapse seen with infections that occur in the first 3

months and may be treated for shorter periods.

Prophylaxis with trimethoprim-sulfamethoxazole [1 double-strength tablet (800 mg sulfamethoxazole, 160 mg trimethoprim) per day] for the first 4 months after transplantation decreases the incidence of early and middle-period infections (see below and Table 136-4).

Middle-Period Infections Because of continuing immunosuppression, kidney transplant recipients are predisposed to lung infections characteristic of those in patients with T cell deficiency (i.e., infections with intracellular bacteria, mycobacteria, nocardiae, fungi, viruses, and parasites). The high mortality associated with *Legionella pneumophila* infection (Chap. 151) led to the closing of renal transplant units in hospitals with endemic legionellosis.

About 50% of all renal transplant recipients presenting with fever 1 to 4 months after transplantation have evidence ofCMVdisease; CMV itself accounts for the fever in over two-thirds of cases and thus is the predominant pathogen during this period. CMV infection (Chap. 185) may also present as arthralgias or myalgias. During this period, this infection may represent primary disease (in the case of a seronegative recipient of a kidney from a seropositive donor) or may present as reactivation disease or superinfection. Patients may have atypical lymphocytosis. Unlike immunocompetent patients, however, they often do not have lymphadenopathy or splenomegaly. Therefore, clinical suspicion and laboratory confirmation are necessary for diagnosis. The clinical syndrome may be accompanied by bone marrow suppression (particularly leukopenia). CMV also causes glomerulopathy and is associated with an increased incidence of other opportunistic infections. Because of the frequency and severity of CMV disease, a considerable effort has been made to prevent and treat it in renal transplant recipients. Administration of an immune globulin preparation enriched with antibodies to CMV (CMV-Ig) decreases the incidence in the group at highest risk for severe infections (seronegative recipients of seropositive kidneys). Ganciclovir is useful for the treatment of serious CMV disease. One study showed a significant (50%) reduction in CMV disease and rejection at 6 months in patients who received prophylactic valacyclovir (an acyclovir congener) for the first 90 days after renal transplantation. If confirmed, these results will likely change practice.

Infection with the other herpes-group viruses may become evident within 6 months after transplantation or later. Early after transplantation,HSV may cause either oral or anogenital lesions that are usually responsive to acyclovir. Large ulcerating lesions in the anogenital area may lead to bladder and rectal dysfunction as well as predisposing to bacterial infection.VZV may cause fatal disseminated infection in nonimmune kidney transplant recipients, but in immune patients reactivation zoster usually does not disseminate outside the dermatome; thus disseminated VZV infection is a less fearsome complication in kidney transplantation than in bone marrow transplantation.HHV-6 may reactivate and (although usually asymptomatic) may be associated with fever, rash, marrow suppression, or encephalitis.

EBVreactivation disease is more serious; it may present as an extranodal proliferation of B cells that invade theCNS, nasopharynx, liver, small bowel, heart, and transplanted kidney. The disease is diagnosed by the finding of a proliferation of EBV-positive B

cells. The incidence of EBV-LPDis higher among patients given high doses of cyclosporine, tacrolimus, or other immunosuppressive agents (including anti-T cell antibodies). Fortunately, disease often regresses once immunocompetence is restored.HHV-8 infection can be transmitted with the donor kidney and is associated with the development of Kaposi's sarcoma in the recipient. Kaposi's sarcoma (primary vs. reactivation of HHV-8) often appears within 1 year after transplantation, although the range of onset times is wide (1 month to ~20 years).

The papovaviruses BK and JC (polyomaviruses hominis 1 and 2) have been cultured from the urine of kidney transplant recipients (as they have from that ofBMTrecipients). The excretion of BK virus is associated with ureteral strictures and that of JC virus with progressive multifocal leukoencephalopathy (rare). Adenoviruses may persist with continued immunosuppression in these patients.

Kidney transplant recipients are also subject to infections with other intracellular organisms. These patients may develop pulmonary infections with *Nocardia*, *Aspergillus*, and *Mucor* as well as infections with other pathogens in which the T cell/macrophage axis plays an important role. In patients without intravenous catheters, *L. monocytogenes* is the most common cause of bacteremia³1 month after renal transplantation. Kidney transplant recipients may develop *Salmonella* bacteremia, which can lead to endovascular infections and require prolonged therapy. Pulmonary infections with *P. carinii* are common unless the patient is maintained on trimethoprim-sulfamethoxazole prophylaxis. *Nocardia* infection (Chap. 165) may present in the skin, bones, lungs, orCNS(where it usually takes the form of single or multiple brain abscesses). *Nocardia* infection generally occurs ³1 month after transplantation and may follow immunosuppressive treatment for an episode of rejection. Pulmonary findings are nonspecific: localized disease with or without cavities is most common, but the disease may disseminate. The diagnosis is made by culture of the organism from sputum or from the involved nodule. As with *P. carinii*, prophylaxis with trimethoprim-sulfamethoxazole appears to be efficacious in the prevention of disease. The occurrence of *Nocardia* infections>2 years after transplantation suggests that a long-term prophylactic regimen may be justified.

Toxoplasmosis can occur in seropositive patients, usually developing in the first few months after kidney transplantation. Again, trimethoprim-sulfamethoxazole is helpful in prevention. In endemic areas, histoplasmosis, coccidioidomycosis, and blastomycosis may cause pulmonary infiltrates or disseminated disease.

Late Infections Late infections (>6 months after kidney transplantation) includeCMVretinitis and a variety ofCNScomplications. Patients (particularly those whose immunosuppression has been increased) are at risk for subacute meningitis due to *Cryptococcus neoformans*. Cryptococcal disease may present in an insidious manner (sometimes as a skin infection before the development of clear CNS findings). *Listeria* meningitis may have an acute presentation and requires prompt therapy to avoid a fatal outcome.

Patients who continue to take glucocorticoids are predisposed to infection. "Transplant elbow" is a recurrent bacterial infection in and around the elbow that is thought to result from a combination of poor tensile strength of the skin of steroid-treated patients and

steroid-induced proximal myopathy that requires patients to push themselves up with their elbows to get out of chairs. Bouts of cellulitis (usually caused by *Staphylococcus aureus*) recur until patients are provided with elbow protection.

Kidney transplant recipients are susceptible to invasive fungal infections -- such as those due to *Aspergillus* and *Rhizopus*, which may present as superficial lesions before dissemination. Mycobacterial infection (particularly that with *M. marinum*) can be diagnosed by skin examination. Infection with *Prototheca wickerhamii* (an achlorophyllic alga) has been diagnosed by skin biopsy. Warts caused by human papillomaviruses (HPVs) are a late consequence of persistent immunosuppression; local therapy is usually satisfactory.

HEART TRANSPLANTATION

Early Infections Sternal wound infection and mediastinitis are early complications of heart transplantation. An indolent course is common, with fever or a mildly elevated white blood cell count preceding the development of site tenderness or drainage. Clinical suspicion based on evidence of sternal instability and failure to heal may lead to the diagnosis. Although common residents of the skin (e.g., *S. aureus* and *S. epidermidis*) as well as gram-negative organisms (e.g., *Pseudomonas aeruginosa*) and fungi (e.g., *Candida*) are often involved, mediastinitis in these patients (in rare cases) can also be due to *Mycoplasma hominis* (Chap. 178). Since this organism requires an anaerobic environment for growth and may be difficult to see on conventional medium, the laboratory should be alerted that *M. hominis* infection is suspected. *M. hominis* mediastinitis has been cured with a combination of surgical debridement (sometimes requiring muscle-flap placement) plus clindamycin and tetracycline. Organisms associated with mediastinitis may be cultured from accompanying pericardial fluid.

Middle-Period Infections *T. gondii* (Chap. 217) resident in the heart of a seropositive donor may be transmitted to a seronegative recipient. Thus serologic screening for *T. gondii* infection is important before and in the months after cardiac transplantation. Rarely, active disease can be introduced at the time of transplantation. The overall incidence of toxoplasmosis is so high in this setting that some prophylaxis is warranted. Although alternatives are available, the most frequently used agent is trimethoprim-sulfamethoxazole, which prevents infection with *Pneumocystis*, *Nocardia*, and other bacterial pathogens.CMV has also been transmitted by heart transplantation.CNSinfections can be caused by *Toxoplasma*, *Nocardia*, and *Aspergillus*. *L. monocytogenes* meningitis should be considered in heart transplant recipients with fever and headache.

CMVinfection is associated with poor outcomes after heart transplantation. The virus is usually cultivable 1 to 2 months after transplantation, causes manifestations (usually fever and atypical lymphocytosis, often associated with leukopenia and thrombocytopenia) at 2 to 3 months, and produces severe disease (e.g., pneumonia) at 3 to 4 months. Seropositive recipients usually develop cultivable virus faster than patients whose primary CMV infection is a consequence of transplantation. Between 40 and 70% of patients develop symptomatic CMV disease in the form of (1) CMV pneumonia, the most likely form of CMV disease to be fatal; (2) CMV esophagitis and gastritis, sometimes accompanied by abdominal pain with or without ulcerations and

bleeding; and (3) the CMV syndrome consisting of CMV in the blood with fever, leukopenia, thrombocytopenia, and hepatic enzyme abnormalities. Ganciclovir is efficacious in the treatment of CMV infection; prophylaxis with ganciclovir or possibly with other antivirals, as described for renal transplantation, may reduce the incidence of CMV-related disease.

Late Infections EBVinfection usually presents as a lymphoma-like proliferation of B cells late after heart transplantation, particularly in patients maintained on heavy immunosuppression. A subset of heart and heart-lung transplant recipients may develop early (within 2 months) fulminant EBV-LPD. Treatment includes the reduction of immunosuppression if possible and the consideration of B cell antibodies (Rituximab), immunomodulatory agents, or chemotherapy, as discussed earlier under bone marrow/hematopoietic stem cell transplantation.HHV-8-associated disease, including primary effusion lymphoma, has been reported in heart transplant recipients. Prophylaxis for *P. carinii* infection is required for these patients (see below).

LUNG TRANSPLANTATION

Early Infections It is not surprising that lung transplants are predisposed to the development of pneumonia. The combination of ischemia and the resulting mucosal damage together with accompanying denervation and lack of lymph drainage probably contributes to the high rate of pneumonia (66% in one series). The prophylactic use of high doses of broad-spectrum antibiotics for the first 3 or 4 days after surgery decreases the incidence of pneumonia. Gram-negative pathogens (Enterobacteriaceae and *Pseudomonas* species) are troublesome in the first 2 weeks after surgery (the period of maximal vulnerability). Pneumonia can also be caused by *Candida* (possibly as a result of colonization of the donor lung), *Aspergillus*, and *Cryptococcus*.

Mediastinitis may occur at an even higher rate among lung transplant recipients than among heart transplant recipients and most commonly develops within 2 weeks of surgery. Pneumonitis due to CMV(which may be transmitted as a consequence of transplantation) usually presents between 2 weeks and 3 months after surgery, with primary disease occurring later than reactivation disease.

Middle-Period Infections The incidence ofCMVinfection, either reactivated or primary, is between 75 and 100% if either the donor or the recipient is seropositive for CMV. CMV-induced disease appears to be most severe in recipients of lung and heart-lung transplants. Whether this severity relates to the mismatch in lung antigen-presenting and host immune cells or is attributable to other (nonimmune) factors is not known. More than half of lung transplant recipients with symptomatic CMV disease have pneumonia. Difficulty in distinguishing the radiographic picture of CMV infection from organ rejection further complicates therapy. CMV can also cause bronchiolitis obliterans in lung transplants. The development of pneumonitis related toHSV has led to the prophylactic use of acyclovir. Such prophylaxis may also decrease rates of CMV disease, but ganciclovir is more active against CMV and is also active against HSV. Ganciclovir prophylaxis for CMV disease in lung transplant recipients is recommended.

Late Infections The incidence of *P. carinii* infection (which may present with a paucity of findings) is high among lung and heart-lung transplant recipients. Some form of

prophylaxis for *P. carinii* pneumonia is indicated in all organ transplant situations (Tables 136-4 and136-5). Trimethoprim-sulfamethoxazole prophylaxis for 12 months after transplantation may be sufficient to prevent *P. carinii* disease in patients whose degree of immunosuppression is not increased.

As in other transplant recipients, infection withEBV may cause either a mononucleosis-like syndrome orLPD. The tendency of the B cell blasts to present in the lung appears to be greater after lung transplantation than after the transplantation of other organs. Reduction of immunosuppression causes remission in some cases, but airway compression can be fatal and more rapid intervention may therefore become necessary. The approach to EBV-LPD is similar to that described in other sections.

LIVER TRANSPLANTATION

Early Infections As in other types of transplantation, early bacterial infections are a major problem after liver transplantation. Many centers administer systemic broad-spectrum antibiotics for the first 5 days after surgery, even in the absence of documented infection. However, despite prophylaxis, infectious complications are common and are correlated with the duration of the surgical procedure and the type of biliary drainage. An operation lasting>12 h is associated with an increased likelihood of infection. Patients who have a choledochojejunostomy with drainage of the biliary duct to a Roux-en-Y jejunal bowel loop have more fungal infections than those whose bile is drained via a choledochocholedochostomy with anastomosis of the donor common bile duct to the recipient common bile duct.

Peritonitis and intraabdominal abscesses are common complications of liver transplantation. Bacterial peritonitis may result from biliary leaks and primary or secondary infection after leakage of bile. Peritonitis in liver transplant recipients is often polymicrobial, commonly involving enterococci, aerobic gram-negative bacteria, staphylococci, anaerobes, or *Candida*. Only one-third of patients with intraabdominal abscesses have bacteremia. Abscesses within the first month after surgery may occur not only over the liver but also in the spleen, pericolic area, and pelvis. Treatment includes antibiotic administration and drainage as necessary.

Liver transplant patients have a high incidence of fungal infections, and the occurrence of fungal infection (often candidiasis) correlates with preoperative use of glucocorticoids, a long duration of treatment with antibacterial agents, and posttransplantation use of immunosuppressive agents.

Middle-Period Infections The development of postsurgical biliary stricture predisposes patients to cholangitis. These patients may lack the characteristic signs and symptoms of cholangitis: fever, abdominal pain, and jaundice. Alternatively, these findings may be present but may suggest graft rejection. The diagnosis of cholangitis in liver transplant recipients therefore requires documentation of bacteremia or demonstration of aggregated neutrophils in bile duct biopsy specimens. Unfortunately, invasive studies of the biliary tract (either T-tube cholangiography or endoscopic retrograde cholangiopancreatography) may themselves lead to cholangitis. For this reason, many clinicians recommend prophylaxis with antibiotics covering gram-negative organisms and anaerobes when these procedures are performed in liver transplant recipients.

Viral hepatitis is a common complication of liver transplantation (Chap. 295). Reactivation of hepatitis B and C infections, for which transplantation may be performed, is problematic. To prevent hepatitis B infection, high-dose intravenous hepatitis B immune globulin is often administered. The long-term efficacy of lamivudine (3TC) in inhibiting hepatitis B viral replication after transplantation is being studied. A combination of interferon a and ribavirin is being tested for treatment/prophylaxis of hepatitis C infection.

As in other transplantation settings, reactivation disease with herpes-group viruses is common (Table 136-2). Herpesviruses can be transmitted in donor organs. AlthoughCMVhepatitis occurs in ~4% of liver transplant recipients, it is usually not so severe as to require retransplantation. CMV disease develops in the majority of seronegative recipients of organs from CMV-positive donors, but fatality rates are lower in liver transplant recipients than in lung or heart-lung transplant recipients. Disease due to CMV is associated with the vanishing bile duct syndrome after liver transplantation. Patients respond to treatment with ganciclovir; prophylaxis with CMV immune globulin and acyclovir or oral ganciclovir may modify disease. A role forHHV-6 in posttransplantation fever and leukopenia has been proposed.EBV-LPDafter liver transplantation shows a propensity for involvement of the liver, and such disease may be of donor origin.

PANCREAS TRANSPLANTATION

Transplantation of the pancreas is complicated by early abdominal infection in ~20 to 40% of cases. To prevent contamination of the allograft with enteric bacteria and yeasts, some surgeons, instead of draining the pancreas through the bowel, drain secretions into the urinary tract or bladder. A cuff of duodenum is often used in the anastomosis between the pancreatic graft and the bladder. In addition to bicarbonate loss, this technique causes a high rate of urinary tract infection (30 to 40%) and sterile cystitis. Over the long term, bowel drainage is better tolerated. An alternative method -- the transplantation of islet cells only -- may eliminate the problems characteristically posed by wound and urinary tract sepsis in pancreas transplant recipients.

Issues related to the development ofCMVinfection,EBV-LPD, and infections with opportunistic pathogens in patients receiving a pancreas are similar to those in other solid organ transplant recipients.

MISCELLANEOUS INFECTIONS IN SOLID ORGAN TRANSPLANTATION

Indwelling Intravenous Catheter Infections The prolonged use of indwelling intravenous catheters for administration of medication, blood products, and nutrition is common in diverse transplantation settings and poses a risk of local and bloodstream infection. Significant insertion-site infection is most commonly caused by *S. aureus*. Bloodstream infection most frequently develops within a week of catheter placement or in patients who become neutropenic. Coagulase-negative staphylococci are the most common isolates from the blood.**For further discussion of differential diagnosis and therapeutic options, see Chap. 85.*

Tuberculosis The incidence of tuberculosis occurring within 12 months after solid organ transplantation ranges broadly worldwide (0.35 to 15%), reflecting prevalences in local populations. Nonrenal transplantation,GVHDwithin 6 months, and intensity of immunosuppression are predictive of tuberculosis reactivation and development of disseminated disease in a host with latent disease. Tuberculosis has rarely been transmitted from the donor organ. In contrast to the low mortality inBMT/HSCTrecipients, mortality in solid organ transplant patients is reported to be 29%. Isoniazid toxicity has not been a significant problem except in the liver transplantation setting.

Virus-Associated Malignancies In addition to malignancy associated with gammaherpesvirus infection (EBV,HHV-8) and simple warts (HPV), transplant recipients, particularly those who require long-term immunosuppression, are more likely than the general population to develop tumors that are virus-associated or suspected of being virus-associated. The interval to tumor development is usually >1 year. Transplant recipients develop nonmelanoma skin or lip cancers that, in contrast to de novo skin cancers, have a high squamous cell-to-basal cell ratio. Whether HPV plays a major role in these lesions is being investigated. Cervical and vulvar carcinomas, quite clearly associated with HPV, develop with increased frequency in female transplant recipients. In renal transplant recipients, rates of melanoma are modestly increased and rates of cancers of the kidney and bladder are increased.

VACCINATION OF TRANSPLANT RECIPIENTS

In addition to receiving antibiotic prophylaxis, transplant recipients should be vaccinated against likely pathogens (Table 136-6). In the case ofBMTrecipients, optimal responses cannot be achieved until after reconstitution, despite previous immunization of both donor and recipient. Recipients of allogeneic BMTs must be reimmunized if they are to be protected against pathogens. The situation is less clear-cut in the case of autologous transplantation. T and B cells in the peripheral blood may reconstitute the response if they are transferred in adequate numbers. However, cancer patients (particularly those with Hodgkin's disease, in whom vaccination has been extensively studied) who are undergoing chemotherapy do not respond normally to immunization, and titers of antibodies to infectious agents fall more rapidly than in healthy individuals. Therefore, even immunosuppressed patients who have not had marrow transplants may need booster vaccine injections. If memory cells are specifically eliminated as part of a marrow "cleanup" procedure, it will be necessary to reimmunize the recipient with a new primary series. Optimal times for immunizations of different transplant populations are being evaluated. Immunization of household and other contacts (including health care personnel) against influenza every season is likely to benefit the patient by preventing local spread.

In the absence of compelling data as to optimal timing, it is reasonable to administer the pneumococcal and *H. influenzae* type b conjugate vaccines to both autologous and allogeneicBMTrecipients 12 months after transplantation and again 12 months later (since the response to the initial vaccine dose is weak in the early posttransplantation period). These two vaccines are particularly important for patients who have undergone splenectomy. In addition, *Neisseria meningitidis* polysaccharide vaccine, diphtheria vaccine, tetanus vaccine, and inactivated polio vaccine can all be given at these same

intervals (12 and 24 months after transplantation). Some authorities recommend a new primary series for tetanus/diphtheria and inactivated polio vaccine (vaccination 12, 14, and 16 months after transplantation). Because of the risk of spread, household contacts of BMT recipients (or of patients immunosuppressed as a result of chemotherapy) should receive only inactivated polio vaccine. Live-virus measles/mumps/rubella (MMR) vaccine can be given to autologous BMT recipients 24 months after transplantation and to most allogeneic BMT recipients at the same point if they are not receiving maintenance therapy with immunosuppressive drugs and do not have ongoingGVHD. The risk of spread from a household contact is lower for MMR than for polio vaccine. In patients who have active GVHD and/or are taking high maintenance doses of glucocorticoids, it may be prudent to avoid all live-virus vaccines. In the absence of detectable antibody titers, vaccination to prevent hepatitis B and hepatitis A also seems advisable.

In the case of solid organ transplant recipients, administration of all the usual vaccines and of the indicated booster doses should be completed before immunosuppression, if possible, to maximize responses. For patients taking immunosuppressive agents, the administration of pneumococcal vaccine should be repeated every 5 years. No data are available for meningococcal polysaccharide vaccine, but it is probably reasonable to administer it along with the pneumococcal vaccine or more frequently (every 3 years for persons with significant exposure risk). *H. influenzae* conjugate vaccine is safe and should be efficacious in this population; therefore, its administration before transplantation is recommended. Booster doses of this vaccine are not recommended for adults. Solid organ transplant recipients who continue to receive immunosuppressive drugs (glucocorticoids, cyclosporine) should not receive live-virus vaccines. A person in this group exposed to measles should be given immune globulin. Similarly, an immunocompromised patient who is seronegative for varicella and who comes into contact with a person who has chickenpox should be given varicella-zoster immune globulin as soon as possible (and certainly within 96 h) or, if this is not possible, started immediately on a 10- to 14-day course of acyclovir therapy. Susceptible household contacts of transplant recipients should receive live attenuatedVZVvaccine, but vaccinees should avoid direct contact with the patient if a rash develops.

Immunocompromised patients who travel may benefit from some but not all vaccines. In general, they should receive any killed or inactivated vaccine preparation appropriate to the area they are visiting; this recommendation includes the vaccines for Japanese encephalitis, hepatitis A and B, poliomyelitis, meningococcal infection, and typhoid. The live typhoid vaccines are not recommended for use in most immunocompromised patients, but inactivated typhoid or the purified polysaccharide vaccine can be used. Live yellow fever vaccine should not be administered. Phenol-inactivated cholera vaccine is probably of little use in this setting. On the other hand, immunization with the purified-protein hepatitis B vaccine is indicated if patients are likely to be exposed. Patients who will reside for>6 months in areas where hepatitis B is common (Africa, Southeast Asia, the Middle East, Eastern Europe, parts of South America, and the Caribbean) should receive hepatitis B vaccine. Inactivated hepatitis A vaccine should be used in the appropriate setting (Chap. 122). If hepatitis A vaccine is not administered, travelers should consider receiving passive protection with immune globulin (the dose depending on the duration of travel in the high-risk area).

SECTION 4 -APPROACH TO THERAPY FOR BACTERIAL DISEASES

137. TREATMENT AND PROPHYLAXIS OF BACTERIAL INFECTIONS - *Gordon L. Archer*, *Ronald E. Polk*

The development of drugs that prevent and cure bacterial infections is one of the twentieth century's major contributions to human longevity and quality of life. Antibacterial agents are among the most commonly prescribed drugs of any kind worldwide. Used appropriately, these drugs are lifesaving. However, their indiscriminate use drives up the cost of health care, leads to a plethora of side effects and drug interactions, and fosters the emergence of bacterial resistance, rendering previously valuable drugs useless. The rational use of antibacterial agents depends on an understanding of their mechanisms of action, pharmacokinetics, toxicities, and interactions; bacterial strategies for resistance; and bacterial susceptibility in vitro. In addition, patient-associated parameters, such as the site of infection and the immune and excretory status of the host, are critically important to appropriate therapeutic decisions. This chapter provides specific data required for making an informed choice of antibacterial agent.

MECHANISMS OF ACTION

Antibacterial agents, like all antimicrobial drugs, are directed against unique targets not present in mammalian cells. The goal is to limit toxicity to the host and maximize chemotherapeutic activity affecting invading microbes only. The mechanisms of action of the antibacterial agents to be discussed in this section are summarized in Table 137-1 and are depicted inFig. 137-1.

INHIBITION OF CELL-WALL SYNTHESIS

One major difference between bacterial and mammalian cells is the presence in bacteria of a rigid wall external to the cell membrane. The wall protects bacterial cells from osmotic rupture, which would result from the cell's usual marked hyperosmolarity (by up to 20 atm) relative to the host environment. The structure conferring cell-wall rigidity and resistance to osmotic lysis in both gram-positive and -negative bacteria is peptidoglycan, a large, covalently linked sacculus that surrounds the bacterium. In gram-positive bacteria, peptidoglycan is the only layered structure external to the cell membrane and is thick (20 to 80 nm); in gram-negative bacteria, there is an outer membrane external to a very thin (1-nm) peptidoglycan layer.

Chemotherapeutic agents directed at any stage of the synthesis, export, assembly, or cross-linking of peptidoglycan lead to inhibition of bacterial cell growth and, in most cases, to cell death. Peptidoglycan is composed of (1) a backbone of two alternating sugars, *N*-acetylglucosamine and *N*-acetylmuramic acid; (2) a chain of four amino acids that extends down from the backbone (stem peptides); and (3) a peptide bridge that cross-links the peptide chains. Peptidoglycan is formed by the addition of subunits (a sugar with its five attached amino acids) that are assembled in the cytoplasm and transported through the cytoplasmic membrane to the cell surface. Subsequent cross-linking is driven by cleavage of the terminal stem-peptide amino acid. Antibacterial agents act to inhibit cell-wall synthesis in several ways, as described below.

Bacitracin, a cyclic peptide antibiotic, inhibits the conversion to its active form of the lipid carrier that moves the water-soluble cytoplasmic peptidoglycan subunits through the cell membrane to the cell exterior. Cell-wall subunits accumulate in the cytoplasm and cannot be added to the growing peptidoglycan chain.

Glycopeptides (vancomycin and teicoplanin) are high-molecular-weight antibiotics that bind to the terminal D-alanine-D-alanine component of the stem peptide while the subunits are external to the cell membrane but still linked to the lipid carrier. This binding sterically inhibits the addition of subunits to the peptidoglycan backbone.

b-Lactam antibiotics (penicillins, cephalosporins, carbapenems, and monobactams;Table 137-2), characterized by a four-memberedb-lactam ring, prevent the cross-linking reaction called *transpeptidation*. The energy for attaching a peptide cross-bridge from the stem peptide of one peptidoglycan subunit to another is derived from the cleavage of a terminal D-alanine residue from the subunit stem peptide. The cross-bridge amino acid is then attached to the penultimate D-alanine by transpeptidase enzymes. The b-lactam ring of the antibiotic forms an irreversible covalent acyl bond with the transpeptidase enzyme (probably because of the antibiotic's steric similarity to the enzyme's D-alanine-D-alanine target), preventing the cross-linking reaction. Transpeptidases and similar enzymes involved in cross-linking are called *penicillin-binding proteins* (PBPs) because they all have active sites that bind b-lactam antibiotics.

Virtually all the antibiotics that inhibit bacterial cell-wall synthesis are bactericidal. That is, they eventually result in the cell's death due to osmotic lysis. However, much of the loss of cell-wall integrity following treatment with cell wall-active agents is due to the bacteria's own cell-wall remodeling enzymes (autolysins) that cleave peptidoglycan bonds in the normal course of cell growth. In the presence of antibacterial agents that inhibit cell-wall growth, autolysis proceeds without normal cell-wall repair; weakness and eventual cellular lysis occur.

INHIBITION OF PROTEIN SYNTHESIS

Most of the antibacterial agents that inhibit protein synthesis interact with the bacterial ribosome. The difference between the composition of bacterial and mammalian ribosomes gives these compounds their selectivity.

Aminoglycosides (gentamicin, kanamycin, tobramycin, streptomycin, netilmicin, neomycin, and amikacin) are a group of structurally related compounds containing three linked hexose sugars. They exert a bactericidal effect by binding irreversibly to the 30S subunit of the bacterial ribosome and blocking initiation of protein synthesis. The reason for the lethal effect of aminoglycosides (as opposed to the largely bacteriostatic effect of other protein synthesis-inhibiting antibacterial drugs, including the macrolides, the lincosamides, chloramphenicol, and tetracycline) is not completely understood. Uptake of aminoglycosides and their penetration through the cell membrane constitute an aerobic, energy-dependent process. Thus, aminoglycoside activity is markedly reduced in an anaerobic environment. *Spectinomycin*, an aminocyclitol antibiotic, also acts on the 30S ribosomal subunit but has a different mechanism of action from the

aminoglycosides and is bacteriostatic rather than bactericidal.

Macrolides (erythromycin, clarithromycin, and azithromycin) consist of a large lactone ring to which sugars are attached. They bind specifically to the 50S portion of the bacterial ribosome. After attachment of mRNA to the initiation site of the 30S ribosomal subunit (the process blocked by aminoglycosides), the 50S subunit becomes bound to the 30S component to form the 70S ribosomal complex, and protein chain elongation proceeds. Binding of macrolides to the 50S ribosomal subunit inhibits protein chain elongation.

Lincosamides (clindamycin and lincomycin), although structurally unrelated to macrolides, bind to a site on the 50S ribosome nearly identical to the binding site for macrolides. Although the mechanism and site of action of macrolides and lincosamides are similar, the number and types of bacteria against which these two groups of agents are active differ.

Chloramphenicol consists of a single aromatic ring and a short side chain. This antibiotic binds reversibly to the 50S portion of the bacterial ribosome at a site close to but not identical with the binding sites of the macrolides and lincosamides. The ribosomal binding of chloramphenicol inhibits peptide bond formation.

Tetracyclines (tetracycline, doxycycline, and minocycline) consist of four aromatic rings with various substituent groups. They interact reversibly with the bacterial 30S ribosomal subunit, blocking the binding of aminoacyl tRNA to the mRNA-ribosome complex. This mechanism is markedly different from that of the aminoglycosides, which also bind to the 30S subunit. The specificity of tetracyclines for bacteria depends both on their selectivity for bacterial ribosomes and on their requirement for active, energy-dependent transport into the bacterial cell by a system not found in mammalian cell membranes.

Mupirocin (pseudomonic acid) is produced by the bacterium *Pseudomonas fluorescens*. Its mechanism of action is unique in that it inhibits the enzyme isoleucine tRNA synthetase by competing with bacterial isoleucine for its binding site on the enzyme. Inhibition of this enzyme depletes cellular stores of isoleucine-charged tRNA and therefore leads to a cessation of protein synthesis. The antibiotic is selective for bacteria because mammalian isoleucine tRNA synthetase lacks affinity for the compound.

INHIBITION OF BACTERIAL METABOLISM

The *antimetabolites* are all synthetic compounds that interfere with bacterial synthesis of folic acid. Products of the folic acid synthesis pathway function as coenzymes for the one-carbon transfer reactions that are essential for the synthesis of thymidine, all purines, and several amino acids. Inhibition of folate synthesis leads to cessation of bacterial cell growth and, in some cases, to bacterial cell death. The principal antibacterial antimetabolites are sulfonamides (sulfisoxazole, sulfadiazine, and sulfamethoxazole) and trimethoprim.

Sulfonamides are structural analogues of *p*-aminobenzoic acid (PABA), one of the three structural components of folic acid (the other two being pteridine and glutamate). The

first step in the synthesis of folic acid is the addition of PABA to pteridine by the enzyme dihydropteroic acid synthetase. Sulfonamides compete with PABA as substrates for the enzyme. The selective effect of sulfonamides is due to the fact that bacteria synthesize folic acid, while mammalian cells cannot synthesize the cofactor and must have exogenous supplies. However, the activity of sulfonamides can be greatly reduced by the presence of excess PABA or by the exogenous addition of end products of one-carbon transfer reactions (e.g., thymidine and purines). High concentrations of the latter substances may be present in some infections as a result of tissue and white cell breakdown, compromising sulfonamide activity.

Trimethoprim is a diaminopyrimidine, a structural analogue of the pteridine moiety of folic acid. It is a competitive inhibitor of dihydrofolate reductase; this enzyme is responsible for reduction of dihydrofolic acid to tetrahydrofolic acid, the essential final component in the folic acid synthesis pathway that is necessary for all one-carbon transfer reactions. Like the sulfonamides, trimethoprim is bactericidal in the absence of thymine but is only bacteriostatic when this pyrimidine is present in high concentration. The selective antibacterial activity of trimethoprim is based on the extreme sensitivity of bacterial dihydrofolate reductase to inhibition by this drug in comparison with the mammalian enzyme. The bacterial enzyme is approximately 50,000 times more sensitive to such inhibition.

INHIBITION OF NUCLEIC ACID SYNTHESIS OR ACTIVITY

Numerous antibacterial compounds have disparate effects on nucleic acids. The *quinolones*, including nalidixic acid and its fluorinated derivatives (norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, sparfloxacin, grepafloxacin, and trovafloxacin), are synthetic compounds that inhibit the activity of the A subunit of the bacterial enzyme DNA gyrase as well as topoisomerase IV. DNA gyrase and topoisomerases are responsible for negative supercoiling of DNA, an essential conformation for DNA replication in the intact cell. Inhibition of the activity of DNA gyrase and topoisomerase IV is lethal to bacterial cells. The antibiotic *novobiocin* also interferes with the activity of DNA gyrase, but it interferes with the B subunit.

Rifampin, used primarily against *Mycobacterium tuberculosis*, is also active against a variety of other bacteria. Rifampin binds tightly to the B subunit of bacterial DNA-dependent RNA polymerase, thus inhibiting transcription of DNA into RNA. Mammalian-cell RNA polymerase is not sensitive to the compound.

Nitrofurantoin, a synthetic compound, causes DNA damage. The nitrofurans, compounds containing a single five-membered ring, are reduced by a bacterial enzyme to highly reactive, short-lived intermediates that are thought to cause DNA strand breakage, either directly or indirectly.

Metronidazole, a synthetic imidazole, is active against a wide range of anaerobic bacteria and protozoa. This activity is totally dependent on the organism's anaerobic electron-transport system for energy production. In the presence of this system, the nitro group of metronidazole is reduced to a series of transiently produced, reactive intermediates that are thought to cause DNA damage. The unique redox system of anaerobes accounts for the selective antibacterial activity of metronidazole. This

compound is also a mutagen and a radiosensitizer of hypoxic mammalian cells.

ALTERATION OF CELL-MEMBRANE PERMEABILITY

The *polymyxins* (polymyxin B and colistin, or polymyxin E) are cyclic, basic polypeptides. They behave as cationic, surface-active compounds that disrupt the permeability of both the outer and the cytoplasmic membranes of gram-negative bacteria.

Gramicidin A is a polypeptide of 15 amino acids that acts as an ionophore, forming pores or channels in lipid bilayers.

MECHANISMS OF RESISTANCE

Some bacteria have *intrinsic resistance* to certain classes of antibacterial agents (e.g., obligate anaerobic bacteria to aminoglycosides and gram-negative bacteria to vancomycin). Clearly these agents can never be used alone in the treatment of infections caused by resistant bacteria. In addition, bacteria that are ordinarily susceptible to antibacterial agents can acquire resistance. *Acquired resistance* is one of the major limitations to effective antibacterial chemotherapy. Resistance can develop by mutation of resident genes or by acquisition of new genes. New genes mediating resistance are usually spread from cell to cell by way of mobile genetic elements such as plasmids, transposons, and bacteriophages. The resistant bacterial populations flourish in areas of high antimicrobial use, where they enjoy a selective advantage over susceptible populations.

The major mechanisms used by bacteria to resist the action of antimicrobial agents are inactivation of the compound, alteration or overproduction of the antibacterial target through mutation of the target protein's gene, acquisition of a new gene that encodes a drug-insensitive target, decreased permeability of the cell envelope to the agent, and active elimination of the compound from the periplasm or interior of the cell. Specific mechanisms of bacterial resistance to the major antibacterial agents are outlined below, summarized inTable 137-1, and depicted inFig. 137-1.

b-LACTAMS

Bacteria develop resistance to b-lactam antibiotics by a variety of mechanisms. Most common is the destruction of the drug byb-lactamases. Theb-lactamases of gram-negative bacteria are confined to the periplasm, between the inner and outer membranes, while gram-positive bacteria secrete their b-lactamases into the surrounding medium. These enzymes have a higher affinity for the antibiotic than the antibiotic has for its target. Binding results in hydrolysis of theb-lactam ring. Genes encodingb-lactamases have been found in both chromosomal and extrachromosomal locations and in both gram-positive and -negative bacteria; these genes are often on mobile genetic elements. One strategy that has been devised for circumventing resistance mediated byb-lactamases is to combine the susceptibleb-lactam with an inhibitor that avidly binds the inactivating enzyme, preventing its attack on the antibiotic. Unfortunately, the inhibitors (e.g., clavulanic acid, sulbactam, and tazobactam) do not bind all classes of b-lactamase and thus cannot be depended on to prevent the

inactivation of b-lactam antibiotics by such enzymes. No b-lactam antibiotic or inhibitor has been produced that can resist all of the manyb-lactamases that have been identified.

A second mechanism of bacterial resistance to b-lactam antibiotics is an alteration inPBPtargets so that the PBPs have a markedly reduced affinity for the drug. While this alteration may occur by mutation of existing genes, the acquisition of new PBP genes (as in staphylococcal resistance to methicillin) or of new pieces of PBP genes (as in streptococcal, gonococcal, and meningococcal resistance to penicillin) is more important.

A final resistance mechanism is the coupling, in gram-negative bacteria, of a decrease in outer-membrane permeability with rapid efflux of the antibiotic from the periplasm to the cell exterior. Mutations of genes encoding outer-membrane proteins called *porins* decrease the entry ofb-lactam antibiotics into the cell, while additional proteins form channels that actively pump b-lactams out of the cell. Resistance of Enterobacteriaceae to some cephalosporins and resistance of *Pseudomonas* spp. to cephalosporins and ureidopenicillins are the best examples of this mechanism.

VANCOMYCIN

Clinically important resistance to vancomycin was first described among enterococci in France in 1988. Vancomycin-resistant enterococci have subsequently become disseminated worldwide. The genes encoding resistance are carried on plasmids that can transfer themselves from cell to cell. Resistance is mediated by enzymes that substitute D-lactate for D-alanine on the peptidoglycan stem peptide so that there is no longer an appropriate target for vancomycin binding. This alteration does not appear to affect cell-wall integrity, however. This type of acquired vancomycin resistance is so far confined to enterococci and is seen in *Enterococcus faecium* rather than in the more common pathogen *E. faecalis*. Most clinically important staphylococci (i.e., *Staphylococcus aureus* and *S. epidermidis*) remain susceptible. However, in 1996, an isolate of *S. aureus* recovered from an infected patient in Japan was shown to be eight times less susceptible to vancomycin than were usual isolates. Since that report, an additional three *S. aureus* isolates with intermediate susceptibility to vancomycin have been recovered from infected patients in the United States, as have numerous coagulase-negative staphylococci with reduced vancomycin susceptibility. These isolates have not acquired the genes that mediate vancomycin resistance in enterococci but are mutant bacteria with markedly thickened cell walls. These mutants were apparently selected in patients who were undergoing prolonged vancomycin therapy.

AMINOGLYCOSIDES

The most common aminoglycoside resistance mechanism is inactivation of the antibiotic. Aminoglycoside-modifying enzymes, usually encoded on plasmids, transfer phosphate, adenyl, or acetyl residues from intracellular molecules to hydroxyl or amino side groups on the antibiotic. The modified antibiotic is less active because of diminished binding to its ribosomal target. Modifying enzymes that can inactivate any of the available aminoglycosides have been found in both gram-positive and -negative bacteria.

A second aminoglycoside resistance mechanism that has been identified predominantly in clinical isolates of *Pseudomonas aeruginosa* is decreased antibiotic uptake, presumably due to alterations in the bacterial outer membrane.

MACROLIDES AND LINCOSAMIDES

Resistance in gram-positive bacteria, the usual target organisms for macrolides and lincosamides, is due to the production of an enzyme -- most commonly plasmid-encoded -- that methylates ribosomal RNA, interfering with binding of the antibiotics to their target. Methylation mediates resistance to erythromycin, clarithromycin, azithromycin, and clindamycin. Streptococci can also actively efflux these compounds.

CHLORAMPHENICOL

Most bacteria resistant to chloramphenicol produce a plasmid-encoded enzyme, chloramphenicol acetyltransferase, that inactivates the compound by acetylation.

TETRACYCLINES

The most common mechanism of tetracycline resistance in gram-negative bacteria is a plasmid-encoded active-efflux pump that is inserted into the cytoplasmic membrane and extrudes antibiotic from the cell. Resistance in gram-positive bacteria is due either to active efflux or to ribosomal alterations that diminish binding of the antibiotic to its target. Genes involved in ribosomal protection are found on mobile genetic elements.

MUPIROCIN

Although the topical compound mupirocin was relatively recently introduced into clinical use, resistance is already becoming widespread in some areas. The mechanism appears to be either mutation of the target isoleucine tRNA synthetase so that it is no longer inhibited by the antibiotic or plasmid-encoded production of a form of the target enzyme that binds mupirocin poorly.

TRIMETHOPRIM AND SULFONAMIDES

The most prevalent mechanism of resistance to trimethoprim and the sulfonamides in both gram-positive and -negative bacteria is the acquisition of plasmid-encoded genes that produce a new, drug-insensitive target -- specifically, an insensitive dihydrofolate reductase for trimethoprim and an altered dihydropteroate synthetase for sulfonamides.

QUINOLONES

Resistance to the newer fluoroquinolones emerged rapidly among *Staphylococcus* and *Pseudomonas* spp. after the introduction of these agents. The most common mechanism is the development of one or more mutations in target DNA gyrases and topoisomerase IV that prevent the antibacterial agent from interfering with the activity of the enzyme. Some gram-negative bacteria develop mutations that both decrease

outer-membrane porin permeability and cause active drug efflux from the cytoplasm. Mutations that result in active quinolone efflux are also found in gram-positive bacteria.

RIFAMPIN

Bacteria rapidly become resistant to rifampin by developing mutations in the B subunit of RNA polymerase that render the enzyme unable to bind the antibiotic. The rapid selection of resistant mutants is the major limitation to the use of this antibiotic against otherwise-susceptible staphylococci and requires that it be used in combination with another antistaphylococcal agent.

MULTIPLE ANTIBIOTIC RESISTANCE

The acquisition by one bacterium of resistance to multiple antibacterial agents is becoming increasingly common. The two major mechanisms are the acquisition of multiple unrelated resistance genes and the development of mutations in a single gene or gene complex that mediate resistance to a series of unrelated compounds. The construction of multiresistant strains by acquisition of multiple genes occurs by sequential steps of gene transfer and environmental selection in areas of high-level antimicrobial use. In contrast, mutations in a single gene can conceivably be selected in a single step. Bacteria that are multiresistant by virtue of the acquisition of new genes include hospital-associated gram-negative bacteria, enterococci, and staphylococci and community-acquired strains of salmonellae, gonococci, and pneumococci. Mutations that confer resistance to multiple unrelated antimicrobial agents occur in the genes encoding outer-membrane porins and efflux proteins of gram-negative bacteria. These mutations decrease bacterial intracellular and periplasmic accumulation ofb-lactams, quinolones, tetracycline, chloramphenicol, and trimethoprim. Multiresistant bacterial isolates pose increasing problems in U.S. hospitals; strains resistant to all available antibacterial chemotherapy have already been identified.

PHARMACOKINETICS

The *pharmacokinetic profile* of an antibacterial agent refers to concentrations in serum and tissue versus time and reflects the processes of absorption, distribution, metabolism, and excretion. Important characteristics include peak and trough serum concentrations and mathematically derived parameters such as half-life, clearance, and distribution volume. Pharmacokinetic information is useful for estimating the appropriate antibacterial dose and frequency of administration, for adjusting dosages in patients with impaired excretory capacity, and for comparing one drug with another.*For further discussion of basic pharmacokinetic principles, see Chap. 70.*

ABSORPTION

Data on absorption can refer to oral, intramuscular, or intravenous administration.

Oral Administration Most patients with infection are treated with oral antibacterial agents in the outpatient setting. Advantages of oral therapy over parenteral therapy include lower cost, generally fewer adverse effects (including complications of indwelling lines), and greater acceptance by patients. The percentage of an orally administered

antibacterial agent that is absorbed (i.e., the agent's *bioavailability*) ranges from as little as 10 to 20% (erythromycin and penicillin G) to nearly 100% (clindamycin, metronidazole, doxycycline, and trimethoprim-sulfamethoxazole). These differences in bioavailability are not clinically important as long as concentrations at the site of infection are sufficient to inhibit or kill the pathogen. However, therapeutic efficacy may be compromised when absorption is reduced as a result of physiologic or pathologic conditions (such as the presence of food for some drugs or the shunting of blood away from the gastrointestinal tract in patients with hypotension), drug interactions (such as that of quinolones and metal cations), or noncompliance. The oral route is usually used for patients with relatively mild infections in whom absorption is not thought to be compromised by the preceding conditions. In addition, the oral route can be used in more severely ill patients after they have responded to parenteral therapy.

Intramuscular Administration Although the intramuscular route of administration usually results in 100% bioavailability, it is not as widely used in the United States as the oral and intravenous routes, in part because of the pain often associated with intramuscular injections and the relative ease of intravenous access in the hospitalized patient. Intramuscular injection may be suitable for specific indications requiring an "immediate" and reliable effect (e.g., with long-acting forms of penicillin, including benzathine and procaine, and with single doses of ceftriaxone for uncomplicated gonococcal infection).

Intravenous Administration The intravenous route is appropriate when oral antibacterial agents are not effective against a particular pathogen, when bioavailability is uncertain, or when larger doses are required than are feasible with the oral route. After intravenous administration, bioavailability is 100%; serum concentrations are maximal at the end of the infusion. For many patients requiring long-term antimicrobial therapy, outpatient intravenous administration with the use of convenient portable pumps may be cost-effective and safe when oral therapy is not feasible. Alternatively, some oral antibacterial drugs such as fluoroquinolones are sufficiently active against Enterobacteriaceae to rival parenteral therapy; their use may allow the patient to return home from the hospital earlier or to avoid hospitalization entirely.

DISTRIBUTION

To be effective, an antibacterial agent must exceed the minimal concentration required to inhibit bacterial growth (MIC;Chap. 121). Serum concentrations usually exceed the MIC for susceptible bacteria, but since most infections are extravascular, the antibiotic must also distribute to the site of the infection. Concentrations of most antibacterials in interstitial fluid are similar to free drug concentrations in serum. However, when the infection is located in a "protected" site where penetration is poor, such as cerebrospinal fluid (CSF), the eye, the prostate, or infected cardiac vegetations, high parenteral doses or local administration for prolonged periods may be required for cure. In addition, even though an antibacterial agent may penetrate to the site of infection, its activity may be antagonized by factors in the local environment, such as an unfavorable pH or inactivation by cellular degradation products. For example, since the activity of aminoglycosides is reduced at acidic pH, the acidic environment in many infected tissues may be partly responsible for the relatively poor efficacy of aminoglycoside monotherapy. In addition, the abscess milieu reduces the activity of many antibacterial

compounds, so that surgical drainage may be required for cure.

Most bacteria that cause human infections are located extracellularly. Intracellular pathogens such as *Legionella*, *Chlamydia*, *Brucella*, and *Salmonella* may persist or cause relapse if the antibacterial agent does not enter the cell. In general, b-lactams, vancomycin, and aminoglycosides penetrate cells poorly, whereas macrolides, tetracyclines, metronidazole, chloramphenicol, rifampin, trimethoprim-sulfamethoxazole, and quinolones penetrate cells well.

METABOLISM AND ELIMINATION

Like other drugs, antibacterial agents are disposed of by hepatic elimination (metabolism or biliary elimination), by renal excretion in unchanged or metabolized form, or by a combination of the two processes. For most antibacterial drugs, metabolism leads to loss of in vitro activity, although some agents, such as cefotaxime, rifampin, and clarithromycin, have bioactive metabolites that may contribute to their overall efficacy.

The most practical application of knowing the mode of excretion of an antibacterial agent is adjustment of the dosage when elimination capability is impaired. Direct, nonidiosyncratic toxicity from antibacterial drugs most often results from failure to reduce the dosage appropriately in a patient with impaired elimination. For agents that are primarily cleared intact by glomerular filtration, drug clearance is linearly correlated with creatinine clearance. Unfortunately, for drugs whose elimination is primarily hepatic, no simple marker (such as serum creatinine) is useful for dosage adjustment in subjects with liver disease. Even in patients with severe hepatic disease, residual metabolic capability is usually sufficient to preclude accumulation and toxic effects. However, for drugs that undergo hepatic metabolism and have a narrow therapeutic index (such as chloramphenicol), alternative therapy may be warranted in patients with liver disease, since the technology for the monitoring of serum levels is not widely available.

PRINCIPLES OF ANTIBACTERIAL CHEMOTHERAPY

The choice of an antibacterial compound for a particular patient and a specific infection involves more than just a knowledge of the agent's mechanism of action and pharmacokinetic profile. The basic tenets of chemotherapy, to be elaborated below, include the following: First, material containing the infecting organism(s) should be obtained before the start of treatment so that presumptive identification can be made by microscopic examination of stained specimens and the organism can be grown for definitive identification and susceptibility testing. Second, once the organism is identified and its susceptibility to antibacterial agents is determined, the regimen with the narrowest effective spectrum should be chosen. Third, the choice of antibacterial agent is guided by the pharmacokinetic and adverse-reaction profile of active compounds, the site of infection, the immune status of the host, and evidence of efficacy from well-performed clinical trials. Finally, if all other factors are equal, the least expensive antibacterial regimen should be chosen.

SUSCEPTIBILITY OF BACTERIA TO ANTIBACTERIAL DRUGS IN VITRO

The determination of the susceptibility of the patient's infecting organism to a panel of appropriate antibacterial agents is an essential first step in devising a chemotherapeutic regimen. The details of susceptibility testing are discussed elsewhere (Chap. 121). Such testing is designed to estimate the susceptibility of a bacterial isolate to an antibacterial drug under standardized conditions that favor rapidly growing aerobic or facultative organisms and to assess bacteriostasis only. Specialized testing is required for the assessment of bactericidal antimicrobial activity; for the detection of resistance among such fastidious organisms as obligate anaerobes, *Haemophilus* spp., and pneumococci; and for the determination of resistance phenotypes with variable expression, such as resistance to methicillin or oxacillin among staphylococci.

RELATIONSHIP OF PHARMACOKINETICS AND IN VITRO SUSCEPTIBILITY TO CLINICAL RESPONSE

The relationship between the report of susceptibility in vitro and the clinical pharmacokinetics of the antibacterial agent helps predict clinical response. Bacteria are usually considered to be *susceptible* to a drug if the achievable peak serum concentration exceeds theMIC by at least fourfold. The *breakpoint* is the concentration of the antibiotic that separates susceptible from resistant bacteria (Fig. 137-2). When a majority of the isolates of a given bacterial species are inhibited at concentrations below the breakpoint, the species is considered to be within the spectrum of the antibiotic (see "Choice of Antibacterial Therapy," below).

The pharmacodynamic profile of an antibiotic is the quantitative relationship among the time course of antibiotic concentrations in serum and tissue, in vitro susceptibility, and microbial response. Three pharmacodynamic parameters quantify these relationships: the ratio of the area under the curve (AUC) for the plasma concentration vs. time curve toMIC(AUC/MIC), the ratio of the maximal serum concentration to the MIC (C_{max}/MIC), and the time during a dosing interval that plasma concentrations exceed the MIC (*t* > MIC). The pharmacodynamic profile of an antibiotic class is characterized as either concentration dependent (fluoroquinolones, aminoglycosides), such that the increase in antibiotic concentration leads to a more rapid rate of bacterial death, or time dependent (b-lactams, vancomycin), such that the reduction in bacterial density is proportional to the time that concentrations exceed the MIC. For concentration-dependent antibiotics, the C_{max}/MIC or AUC/MIC ratio correlates best with the reduction in microbial density in vitro and in animal investigations. Dosing strategies attempt to maximize these ratios by the administration of a "large" dose relative to the MIC for anticipated pathogens, often at "long" intervals (relative to the serum half-life). Once-daily dosing of aminoglycoside antibiotics is the practical consequence of these relationships. In contrast, dosage strategies for time-dependent antibiotics emphasize the administration of sufficient doses at appropriate intervals to maintain serum concentrations above the MIC, typically for at least 40 to 50% of the dosing interval. The clinical implications of these relationships are in the early stages of investigation, but their elucidation should eventually result in more rational antibacterial regimens.

STATUS OF THE HOST

Various host factors must be considered in the devising of antibacterial chemotherapy.

The host's antibacterial *immune function* is of importance, particularly as it relates to opsonophagocytic function. Since the major host defense against acute, overwhelming bacterial infection is the polymorphonuclear leukocyte, patients with neutropenia must be treated aggressively and empirically with bactericidal drugs for suspected infection (Chap. 85). Likewise, patients who have deficient humoral immunity (e.g., those with chronic lymphocytic leukemia and multiple myeloma) and individuals with surgical or functional asplenia (e.g., those with sickle cell disease) should be treated empirically for infections with encapsulated organisms, especially the pneumococcus.

Pregnancy increases the risk of toxicity of certain antibacterial drugs for the mother (e.g., the hepatic toxicity of tetracycline), affects drug disposition and pharmacokinetics, and -- because of the risk of fetal toxicity -- severely limits the choice of agents for treating infections. Certain antibacterials are contraindicated in pregnancy either because their safety has not been established or because they are known to be toxic. These agents include all fluoroquinolones, clarithromycin, erythromycin estolate (but not erythromycin base), and tetracyclines. Data on the safety of many other antibacterial drugs are limited, but these drugs may be used cautiously when there is no suitable alternative and the perceived benefit outweighs the risk. These agents include the aminoglycosides, azithromycin, clindamycin, imipenem, metronidazole, trimethoprim, and vancomycin. Chloramphenicol, nitrofurantoin, and the sulfonamides are contraindicated in the third trimester but can be used cautiously in the first two trimesters.

In patients with *concomitant viral infections*, the incidence of adverse reactions to antibacterial drugs may be unusually high. For example, persons with infectious mononucleosis and those infected with HIV may react more often to ampicillin and folic acid synthesis inhibitors, respectively.

In addition, the patient's age, sex, racial heritage, and excretory status all determine the incidence and type of side effects that can be expected with certain antibacterial agents.

SITE OF INFECTION

The location of the infected site may play a major role in the choice and dose of antimicrobial drug. Patients with suspected *meningitis* should receive drugs that can cross the blood-CSFbarrier; in addition, because of the relative paucity of phagocytes and opsonins at the site of infection, the agents should be bactericidal. Chloramphenicol, one of the standard drugs used in the treatment of meningitis, is bactericidal for common organisms causing meningitis (i.e., meningococci, pneumococci, and *Haemophilus influenzae*, but *not* enteric gram-negative bacilli), is highly lipid-soluble, and enters the CSF well. However,b-lactams, the mainstay of therapy for most of these infections, do not normally reach high levels in CSF. Their efficacy is based on the increased permeability of the blood-brain and blood-CSF barriers to hydrophilic molecules during inflammation and the extreme susceptibility of most infectious organisms to even small amounts of b-lactam drug.

The vegetation, which is the major site of infection in *bacterial endocarditis*, is also a focus that is protected from normal host-defense mechanisms. Antibacterial therapy needs to be bactericidal, with the selected agent administered parenterally over a long

period and at a dose that produces serum levels at least eight times higher than the minimal bactericidal concentration (MBC) for the infecting organism. Likewise, *osteomyelitis* involves a site that is somewhat resistant to opsonophagocytic removal of infecting bacteria; furthermore, avascular bone (sequestrum) represents a foreign body that thwarts normal host-defense mechanisms. *Chronic prostatitis* is exceedingly difficult to cure because most antibiotics do not penetrate the nonfenestrated capillaries serving the prostate, especially when acute inflammation is absent. Drugs that are "ion trapped" after entering prostatic tissue, such as trimethoprim and fluoroquinolones, may be uniquely effective because of this mechanism. *Intraocular infections*, especially endophthalmitis, are difficult to treat because drug penetration into the vitreous from blood is hindered by retinal capillaries lacking fenestration. Inflammation does little to disrupt this barrier. Thus, direct injection into the vitreous is necessary in many cases. Antibiotic penetration into *abscesses* is usually poor. Even when an antibiotic does penetrate into the abscess, local conditions, such as low pH or the presence of enzymes that hydrolyze the drug, may antagonize its activity.

In contrast, *urinary tract infections*, when confined to the bladder, are relatively easy to cure, in part because of the higher concentration of most antibiotics in urine than in blood. Since blood is the usual reference fluid in defining susceptibility, even organisms found to be "resistant" to achievable serum concentrations may be susceptible to achievable urine concentrations. For drugs that are used only for the treatment of urinary tract infections, such as nitrofurantoin and methenamine salts, achievable urine concentrations are used to determine susceptibility.

COMBINATION CHEMOTHERAPY

One of the tenets of antibacterial chemotherapy is that if the infecting bacterium has been identified, the most specific chemotherapy possible should be used. The use of a single agent with a narrow spectrum of activity against the pathogen diminishes the alteration of normal flora and thus limits the overgrowth of resistant nosocomial organisms (e.g., *Candida albicans*, enterococci, *Clostridium difficile*, or methicillin-resistant staphylococci), avoids the potential toxicity of multiple-drug regimens, and reduces cost. However, certain circumstances call for the use of more than one antibacterial agent. These are summarized below.

1. *Prevention of the emergence of resistant mutants.* Spontaneous mutations occur at a detectable frequency in certain genes encoding the target proteins for some antibacterial agents. The use of these agents can eliminate the susceptible population, select out resistant mutants at the site of infection, and result in the failure of chemotherapy. Resistant mutants are usually selected when theMIC of the antibacterial agent for the infecting bacterium is close to achievable levels in serum or tissues and/or when the site of infection limits the access or activity of the agent. Among the most common examples are rifampin for staphylococci, imipenem for *Pseudomonas*, and ciprofloxacin for staphylococci and *Pseudomonas*. Small-colony variants of staphylococci resistant to aminoglycosides also emerge during monotherapy with these antibiotics. A second antibacterial agent with a mechanism of action different from that of the first is added to prevent the emergence of these resistant mutants (e.g., imipenem plus an aminoglycoside for systemic *Pseudomonas* infections). However, since resistant mutants have emerged following combination chemotherapy, this

approach is not uniformly successful.

2. *Synergistic or additive activity.* Against some bacteria, two or more agents are clearly more active than one; whether or not this is the case is usually judged on the basis of testing in vitro. Synergistic or additive activity involves a lowering of theMIC orMBC of each or all of the drugs tested in combination against a specific bacterium. In *synergy*, *each* agent is more active when combined with a second drug than it would be alone, and the drugs' combined activity is therefore greater than the sum of the individual activities of each drug. In an *additive relationship*, the combined activity of the drugs is equal to the sum of their individual activities. Among the best examples of a synergistic or additive effect, confirmed both in vitro and by animal studies, are the enhanced bactericidal activities of certainb-lactam/aminoglycoside combinations against enterococci, viridans streptococci, and *P. aeruginosa*. The synergistic or additive activity of these combinations has also been demonstrated for selected isolates of enteric gram-negative bacteria and staphylococci. The combination of trimethoprim and sulfamethoxazole has synergistic or additive activity against many enteric gram-negative bacteria. Most other antimicrobial combinations display indifferent activity (i.e., the combination is *no better* than the more active of the two agents alone), and some combinations (e.g., penicillin plus tetracycline against pneumococci) may be antagonistic (i.e., the combination is *worse* than either drug alone).

3. *Therapy directed against multiple potential pathogens.* For certain infections, either a mixture of pathogens is suspected or the patient is desperately ill with an as-yet-unidentified infection (see "Empirical Therapy," below). In these situations, the most important of the likely infecting bacteria must be covered by therapy until culture and susceptibility results become available. Examples of the former infections are intraabdominal or brain abscesses and infections of limbs in diabetic patients with microvascular disease. The latter situations include fevers in neutropenic patients, acute pneumonia from aspiration of oral flora by hospitalized patients, and septic shock or sepsis syndrome.

EMPIRICAL THERAPY

In certain situations, antibacterial therapy is begun before a specific bacterial pathogen has been identified. The choice of agent is guided by the results of studies identifying the usual pathogens at that site or in that clinical setting, by pharmacodynamic considerations, and by the resistance profile of the expected pathogens in a particular hospital or geographic area. Situations in which empirical therapy is appropriate include the following:

1. *Life-threatening infection*. Any suspected bacterial infection in a patient with a life-threatening illness should be treated presumptively. Therapy is usually begun with more than one agent and is later tailored to a specific pathogen if one is eventually identified.

2. *Treatment of infections in unhospitalized patients with no cultures performed*. In many situations, it is appropriate to treat non-life-threatening infections without obtaining cultures. These situations include outpatient infections such as community-acquired cases of pneumonia, cystitis, cellulitis or local wound infection, sinusitis, otitis, urethritis,

and prostatitis. However, if any of these infections recurs or fails to respond to initial therapy, every effort should be made to obtain cultures to guide re-treatment.

CHOICE OF ANTIBACTERIAL THERAPY

The antibacterial spectrum of specific agents and the infections for which they represent the treatment of choice are detailed below. No attempt has been made to include all the potential situations in which antibacterial agents may be used. A more detailed discussion of specific bacteria and infections that they cause can be found elsewhere in this volume.

b-LACTAMS (Table 137-2)

All *penicillins* (except for the semisynthetic, penicillinase-resistant antistaphylococcal agents) are hydrolyzed byb-lactamases and are ineffective against isolates that produce these enzymes. Penicillin G has a spectrum that includes spirochetes (*Treponema pallidum*, *Borrelia*, and *Leptospira*), streptococci (groups A and B, viridans, and *Streptococcus pneumoniae*), enterococci, most *Neisseria* spp., a few staphylococci, many fastidious oral bacteria (including many *Porphyromonas* and *Prevotella* spp., streptococci, *Actinomyces*, and *Fusobacterium*), *Clostridium* spp. (except *C. difficile*), *Pasteurella multocida*, *Erysipelothrix rhusiopathiae*, and *Streptobacillus moniliformis*. However, penicillin G resistance is widespread among staphylococci; is increasing rapidly among gonococci, enterococci, and pneumococci; and is emerging among meningococci, viridans streptococci, and oral anaerobes such as *Porphyromonas* and *Prevotella*. Penicillin G is the *drug of choice* for syphilis, yaws, leptospirosis, group A and B streptococcal infections, actinomycosis, oral and periodontal infections, meningococcal meningitis and meningococcemia, viridans streptococcal endocarditis, clostridial myonecrosis, tetanus, anthrax, rat-bite fever, *P. multocida* infections, and erysipeloid (*E. rhusiopathiae*).

Ampicillin extends the spectrum of penicillin G to some gram-negative rods. It is active against some isolates of *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, *Shigella*, and *H. influenzae* and is one of the *drugs of choice* for susceptible organisms causing urinary tract infections, salmonellosis, *H. influenzae* meningitis and epiglottitis, and *Listeria monocytogenes* meningitis. High rates of resistance have lessened its value as empirical therapy in some situations. For example, more than 80% of isolates of *E. coli* and *P. mirabilis* are resistant in some hospitals, as are 10 to 30% of isolates of *H. influenzae*; moreover, in some outbreaks of infection due to salmonellae, all isolates are ampicillin-resistant.

The *penicillinase-resistant penicillins* are used solely for the treatment of staphylococcal infections and are the *drugs of choice* for systemic or deep staphylococcal infections caused by susceptible organisms. Unfortunately, on average, approximately 30% of *S. aureus* isolates and more than 60% of coagulase-negative staphylococcal isolates acquired in U.S. hospitals are resistant to these agents (i.e., methicillin-resistant). The spectrum of these agents also includes most of the same gram-positive bacteria that are susceptible to penicillin G.

The spectrum of the *antipseudomonal penicillins* includes the bacteria covered by

ampicillin as well as some additional nonpseudomonal enteric gram-negative bacilli. For example, piperacillin is active against many indole-positive *Proteus*, *Enterobacter*, *Klebsiella*, *Providencia*, and *Serratia* spp. However, the susceptibility of these penicillins tob-lactamase markedly limits their utility as empirical therapy when infections caused by gram-negative enteric organisms are suspected. The major use of these compounds is in the treatment of proven or suspected infections with *P. aeruginosa* and *Acinetobacter*, for which they are among the *drugs of choice*. Their relative antipseudomonal activities can be ranked as follows: piperacillin >mezlocillin/ticarcillin >carbenicillin.

The addition of*b-lactamase inhibitors* (clavulanic acid, sulbactam, or tazobactam) to ampicillin, amoxicillin, ticarcillin, or piperacillin extends the spectrum of these agents to include many organisms that are resistant by virtue of b-lactamase production. These organisms include *E. coli*, *Klebsiella* spp., all *Proteus* spp., *H. influenzae*, *Moraxella catarrhalis*, *Providencia* spp., and *Bacteroides* spp. Such combinations are also active against staphylococci that produce b-lactamase but are not methicillin-resistant. However, the efficacy of these combinations in serious staphylococcal infections has not been adequately proven. Furthermore, *Enterobacter*, *Pseudomonas*, *Acinetobacter*, and various enteric gram-negative isolates either produceb-lactamases not inhibited by these compounds or develop resistance attributable to non-b-lactamase-mediated mechanisms.

The *first-generation cephalosporins* have a spectrum that includes penicillinase-producing, methicillin-susceptible staphylococci and streptococci. While these drugs may be used when infections with gram-positive bacteria are suspected, they are *not* the drugs of choice for such infections. They have excellent activity against many isolates of *E. coli*, *Klebsiella pneumoniae*, and *P. mirabilis* and are among the *drugs of choice* in presumptive therapy for community-acquired urinary tract infections. They have no activity against *Bacteroides fragilis*, enterococci, methicillin-resistant staphylococci, *Pseudomonas*, *Acinetobacter*, *Enterobacter*, indole-positive *Proteus*, and *Serratia* and poor activity against *H. influenzae*.

The *parenteral second-generation cephalosporins* extend the gram-negative spectrum of first-generation compounds. The various second-generation agents have differing activities. Cefuroxime and cefamandole retain activity against gram-positive cocci and are also active against *H. influenzae*, *Neisseria*, some *Enterobacter* isolates, and indole-positive *Proteus* but exhibit poor activity against *B. fragilis*. Cefoxitin and cefotetan have reasonably good activity against *B. fragilis*, but cefotetan is less effective against some other *Bacteroides* spp. (Chaps. 130 and167). Both of the latter drugs display poor activity against gram-positive cocci and *Enterobacter*. No second-generation cephalosporin is active against *Pseudomonas* or *Acinetobacter*.

Oral second-generation cephalosporins have fair activity against gram-positive cocci and *H. influenzae* and are widely used in outpatient therapy for otitis media, sinusitis, and lower respiratory tract infections, although cheaper agents that are equally effective are preferable. Cefixime, cefuroxime axetil, and cefpodoxime are among the *drugs of choice* for single-dose treatment of gonococcal urethritis.

Third-generation cephalosporins all have a broad spectrum of activity against enteric

gram-negative rods and are especially useful for treating hospital-acquired infections caused by multiresistant organisms. In addition, ceftazidime and cefepime have excellent antipseudomonal activity. The other third-generation cephalosporins have poor antipseudomonal activity. Since resistance to third-generation cephalosporins is increasing among all nosocomial gram-negative rods, the use of these agents should be guided by susceptibility testing. The gram-positive spectrum of the third-generation cephalosporins is variable. All are less active than first-generation cephalosporins against methicillin-susceptible staphylococci; ceftazidime has the least antistaphylococcal activity of this group. However, ceftriaxone, ceftizoxime, and cefotaxime have excellent activity against streptococci, especially *S. pneumoniae*. Ceftazidime is not recommended for treatment of streptococcal infections.

Because of its excellent gram-negative spectrum; its activity against *Haemophilus*, many *S. pneumoniae* strains, and penicillin-resistant *Neisseria*; its long serum half-life; and its high serum andCSFlevels, ceftriaxone has become one of the *drugs of choice* for empirical therapy for bacterial meningitis (except that caused by *Listeria* and by highly penicillin-resistant pneumococcal strains), all gonococcal infections, salmonellosis, and typhoid fever. The third-generation cephalosporins are among the *drugs of choice* for nonpseudomonal hospital-acquired pneumonia. Cefepime is more resistant to chromosomal b-lactamase produced by *Enterobacter* spp. than are other third-generation cephalosporins. Third-generation cephalosporins have poor activity against *Bacteroides* and no activity against methicillin-resistant staphylococci, *Enterococcus*, *Acinetobacter*, or *Stenotrophomonas*.

The *carbapenems* currently available in the United States are imipenem and meropenem. Imipenem is marketed in combination with the renal dipeptidase inhibitor cilastatin, which enables imipenem to escape renal inactivation and thus to reach higher urinary levels. Imipenem and meropenem have excellent activity in vitro against virtually all bacterial pathogens except *Stenotrophomonas*, methicillin-resistant staphylococci, and *E. faecium*. Limitations to their use are their relatively low blood levels, short serum half-life, and high cost. Imipenem has dose-related central nervous system side effects that appear to be less frequent with meropenem. Resistance to imipenem and meropenem is a problem only among nosocomial isolates of *P. aeruginosa*, approximately 20% of which are resistant. Because of their broad spectrum, carbapenems can be used as empirical therapy for serious nosocomial infections thought to be caused by multiple bacterial species or multiresistant organisms. Imipenem and meropenem are often used to treat hospital-acquired infections caused by *Enterobacter* spp. because these organisms produce inducibleb-lactamases that inactivate third-generation cephalosporins but not the carbapenems. The latter antibiotics are often held in reserve as therapy for nosocomial infections due to gram-negative pathogens resistant to third-generation cephalosporins.

The only *monobactam* currently available is aztreonam. This antibiotic has a spectrum limited to facultative gram-negative enteric bacilli. It has no activity against any gram-positive or anaerobic bacterium. Its gram-negative spectrum is similar to that of ceftazidime, with equally good activity against *Pseudomonas*. Its primary advantages are its theoretical ability to preserve the normal gram-positive and anaerobic flora and the lack of cross-reactive immediate hypersensitivity in patients who have had this type of reaction to otherb-lactam antibiotics.

VANCOMYCIN

The spectrum of vancomycin is limited to gram-positive cocci, especially enterococci, streptococci, and staphylococci. Vancomycin serves as second-line therapy for most gram-positive bacterial infections but is the *drug of choice* for infections caused by methicillin-resistant staphylococci or *Corynebacterium jeikeium* and for serious infections in penicillin-allergic patients. Given orally (a route by which it is not absorbed), vancomycin can be used to treat antibiotic-associated pseudomembranous colitis caused by *C. difficile* in patients who have failed to respond to metronidazole, the *drug of choice*. Vancomycin has also been recommended as initial empirical therapy for presumed pneumococcal meningitis because of increasing pneumococcal resistance to penicillins and cephalosporins. Resistance to vancomycin is increasing rapidly among isolates of *E. faecium* in large hospitals, particularly in areas of high vancomycin use. In addition, *S. aureus* isolates with reduced susceptibility to vancomycin have now been detected. Because of the growing threat of vancomycin-resistant enterococci and the potential for increasing resistance among staphylococci, a national advisory committee has established guidelines for appropriate and limited use of this antibiotic.

AMINOGLYCOSIDES

The aminoglycosides are rapidly bactericidal in vitro at low concentrations, with activity limited to facultative gram-negative bacteria and staphylococci. They have no activity against anaerobic bacteria and are not effective in environments that are acidic or have a low oxygen tension. However, their spectrum includes virtually all gram-negative bacteria that are not strict anaerobes, and they are among the *drugs of choice* for any suspected gram-negative bacteremic infection, particularly in neutropenic patients. Aminoglycosides are synergistically bactericidal in combination with a penicillin for the treatment of staphylococcal, enterococcal, or viridans streptococcal endocarditis and are usually combined with ab-lactam antibiotic for the treatment of gram-negative bacteremia. Aminoglycosides are also among the *drugs of choice* for severe infections of the upper urinary tract. The major limitations to use of aminoglycosides are their renal and otic toxicity, their diminished activity at certain sites of infection (e.g., abscesses and the central nervous system), and the resistance of target bacteria. Among the available agents, gentamicin is generally preferred because of its low cost; however, tobramycin has slightly greater activity against *P. aeruginosa*, and amikacin retains activity against many tobramycin- and gentamicin-resistant gram-negative bacteria because it is inactivated by fewer aminoglycoside-modifying enzymes. Streptomycin is still one of the *drugs of choice* in initial therapy for tularemia, plague, glanders, and brucellosis and is a second-line agent for the treatment of tuberculosis.

MACROLIDES

Erythromycin has broad-spectrum activity against gram-positive bacteria, with additional activity against *Legionella*, *Mycoplasma*, *Campylobacter*, and some *Chlamydia* isolates. It is the *drug of choice* for infections due to *Legionella*, *Campylobacter*, and *Mycoplasma* and is among the *drugs of choice* for community-acquired pneumococcal pneumonia and group A streptococcal pharyngitis in penicillin-allergic patients. However, resistance to erythromycin among group A streptococci and pneumococci is increasing

dramatically in some areas. Erythromycin also appears to be one of the *drugs of choice* for infections caused by the agent of bacillary angiomatosis (*Bartonella henselae*) in immunocompromised patients. The newer macrolides clarithromycin and azithromycin have an antibacterial spectrum similar to that of erythromycin in vitro. However, azithromycin has greater activity against *Chlamydia*. Clarithromycin, in combination with a proton pump inhibitor, has been designated a *drug of choice* for the treatment of gastric infections due to *Helicobacter pylori* (gastritis, gastric and duodenal ulcers). Both azithromycin and clarithromycin are active against nontuberculous mycobacteria, and both appear to have fewer gastrointestinal side effects than does erythromycin.

LINCOSAMIDES

The only lincosamide used in the United States is clindamycin. It shares the gram-positive coccal spectrum of erythromycin but is more active, in some cases showing bactericidal activity, against susceptible staphylococci. However, resistance among staphylococci and some streptococci, mediated by the same genes responsible for macrolide resistance, limits clindamycin's usefulness against gram-positive cocci. In general, all staphylococci resistant to erythromycin should be considered resistant to clindamycin regardless of the results of in vitro susceptibility testing. However, at least half of the streptococci resistant to erythromycin are truly susceptible to clindamycin. In these bacteria, resistance is mediated by a drug-efflux pump that removes macrolides but not lincosamides. Despite increasing resistance, clindamycin remains useful for most anaerobic infections because of its broad spectrum of activity against both gram-positive and -negative strict anaerobes. It is also a *drug of choice* for the treatment of severe, invasive group A streptococcal infections. In contrast, clindamycin, like erythromycin, has no clinically significant activity against facultative gram-negative enteric bacilli. Appropriate use is limited only by resistance or the development of pseudomembranous colitis, the major serious side effect of this drug.

CHLORAMPHENICOL

Chloramphenicol has a broad spectrum of activity against gram-positive and -negative bacteria, although plasmid-mediated resistance has diminished its effective spectrum. This antibiotic is rarely used in adult infections because of the rare idiosyncratic side effect of irreversible bone-marrow aplasia and the availability of other agents with similar activity. It remains one of the *drugs of choice* for the treatment of typhoid fever and plague and is still useful for the treatment of brucellosis and both pneumococcal and meningococcal meningitis in penicillin-allergic patients.

TETRACYCLINES

Tetracyclines have a broad spectrum of bacteriostatic activity against gram-positive and -negative bacteria and are widely used in a variety of community-acquired infections. These agents are among the *drugs of choice* for chronic bronchitis, granuloma inguinale, brucellosis (with streptomycin), tularemia, glanders, melioidosis, spirochetal infections caused by *Borrelia* (Lyme disease and relapsing fever; doxycycline), infections caused by *Vibrio vulnificus*, some *Aeromonas* infections, infections due to *Stenotrophomonas* (minocycline), plague, and ehrlichiosis (doxycycline). The tetracyclines are also used in penicillin-allergic patients for the treatment of

leptospirosis, syphilis, actinomycosis, and skin and soft-tissue infections caused by gram-positive cocci. They are among the *drugs of choice* for infections due to chlamydiae (doxycycline), rickettsiae, and ehrlichiae and for granulomatous skin infection due to *Mycobacterium marinum* (minocycline). Doxycycline is also among the drugs recommended for the treatment of community-acquired pneumonia.

SULFONAMIDES AND TRIMETHOPRIM

The folic acid synthesis inhibitors have a broad spectrum of bacteriostatic activity individually; in combination, they can be bactericidal against facultative gram-negative bacteria and staphylococci. The fixed combination of sulfamethoxazole and trimethoprim, the major folic acid synthesis inhibitors used in therapy for bacterial infections, has modest activity against some streptococci and no activity against strict anaerobes. However, resistance to the combination of sulfamethoxazole and trimethoprim is common among methicillin-resistant staphylococci and penicillin-resistant pneumococci and is increasing among *E. coli* strains that cause urinary tract infections. The individual sulfonamides are rarely used in the treatment of bacterial infections but are among the *drugs of choice* for the treatment of nocardial infections, leprosy (dapsone, a sulfone), and toxoplasmosis (sulfadiazine). Although increasing resistance has been reported among gram-negative organisms, trimethoprim-sulfamethoxazole remains one of the *drugs of choice* for the treatment of uncomplicated urinary tract infections (except for those caused by enterococci) and is widely used in the treatment of otitis media. It can be used in therapy for upper respiratory tract infections in which *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis* is suspected; for gonococcal and meningococcal infections; for chancroid; and for infections thought to be caused by *Aeromonas*, *Stenotrophomonas*, *Burkholderia cepacia*, *Acinetobacter*, and *Yersinia enterocolitica*. For nosocomial infections due to *Stenotrophomonas*, trimethoprim-sulfamethoxazole is the *drug of choice*.

FLUOROQUINOLONES

The fluoroquinolones have excellent activity against most facultative gram-negative rods and variable activity against gram-positive cocci; only trovafloxacin is active against obligate anaerobes. The quinolones are the oral agents with greatest activity against *P. aeruginosa*; ciprofloxacin is the most active against this species. All the quinolones except norfloxacin are well absorbed orally; ciprofloxacin, levofloxacin, trovafloxacin, and ofloxacin are also administered as intravenous formulations. The quinolones are among the *drugs of choice* for urinary tract infections, bacterial gastroenteritis, community-acquired pneumonia, and enteric fever and may be useful in therapy for serious hospital-acquired infections caused by gram-negative organisms. While older quinolones (ciprofloxacin, ofloxacin, and norfloxacin) have limited activity against gram-positive bacteria, the newer quinolones have an expanded spectrum of activity against gram-positive cocci, including staphylococci (both methicillin-susceptible and methicillin-resistant) and streptococci (especially *S. pneumoniae*). However, because of the potential for development of severe liver toxicity, it has been recommended that trovafloxacin use be limited to hospitalized patients with serious or life-threatening infections. Quinolones can also be used as prophylaxis for persons at risk for meningococcal meningitis. However, rapid expansion in the use of quinolones should be coupled with a consideration of the potential for development of resistance among all

bacteria targeted by these drugs.

RIFAMPIN

Rifampin has been used in combinations for the treatment of serious infections due to methicillin-resistant staphylococci (e.g., coagulase-negative staphylococcal foreign-body infections). Because the spontaneous selection of rifampin-resistant mutants occurs rapidly, rifampin should never be used alone in the treatment of staphylococcal infections. Rifampin is also used for chemoprophylaxis in persons at risk of meningococcal meningitis and for the treatment of *Legionella* pneumonia.

METRONIDAZOLE

Metronidazole has a spectrum limited to anaerobic bacteria. It is one of the *drugs of choice* for the treatment of any abscess in which the involvement of obligate anaerobes is suspected (e.g., lung, brain, or intraabdominal abscesses) because of its spectrum and its ability to penetrate into the area of infection. Other antibacterial agents should be used in combination with metronidazole if facultative and aerobic pathogens are also thought to be involved. Metronidazole is the *drug of choice* for the treatment of bacterial vaginosis and antibiotic-associated pseudomembranous colitis.

URINARY TRACT ANTISEPTICS

Urinary tract antiseptics are active only in the lower urinary tract and cannot be used for the treatment of upper urinary tract or systemic infections. Their activity is limited to susceptible gram-negative enteric bacteria. The available agents in this category include nitrofurantoin and methenamine salts.

TOPICAL ANTIBACTERIAL AGENTS

Mupirocin is available only as a topical preparation for use against staphylococci and streptococci. Its major applications are for impetigo and eradication of the staphylococcal carrier state. It is the *drug of choice* for the elimination of nasal carriage of both methicillin-susceptible and methicillin-resistant staphylococci. Unfortunately, the emergence of resistance is limiting its usefulness in some hospitals.

Although their efficacy has never been well documented, topical preparations that include sulfonamides, polymyxin B, neomycin, bacitracin, gramicidin, and novobiocin in a variety of combinations are widely used as eye drops, irrigation solutions, and ointments for superficial skin infections.

ADVERSE REACTIONS

Adverse drug reactions are frequently classified by mechanism as either dose-related ("toxic") effects or unpredictable reactions. Unpredictable reactions are further categorized as either idiosyncratic or allergic. Dose-related reactions include aminoglycoside-induced nephrotoxicity, penicillin-induced seizures, and vancomycin-induced anaphylactoid reactions. Many of these reactions can be avoided by reducing dosage, limiting the duration of therapy, or reducing the frequency or rate of

administration. Adverse reactions to antibacterial agents are a common cause of morbidity, requiring alteration in therapy and additional expense, and they occasionally result in death. The elderly, often those with the more severe infections, may be especially prone to certain adverse reactions.*For further discussion of adverse drug reactions, see Chap. 71.*

b-LACTAMS

The therapeutic index for b-lactam antibiotics is broad, and dose-related adverse reactions are uncommon and largely preventable. The greatest concern is allergic reactions. All types can occur, including anaphylaxis (type 1, hypersensitivity reactions), nephritis and Coombs-positive hemolytic anemia (type 2, cytotoxic reactions), drug fever and serum sickness (type 3, immune-complex formation), contact dermatitis (type 4, cell-mediated effects), and maculopapular eruption (type 5, idiopathic reactions). Approximately 1 to 4% of treatment courses result in an allergic reaction, and approximately 0.004 to 0.015% of treatment courses result in anaphylaxis. Fewer than half the patients who claim an allergy to penicillin react to skin testing with the major and minor determinants (penicilloyl-polylysine and benzylpenicillin degradation products, respectively); those with negative skin tests only rarely react adversely to subsequent therapeutic doses. Generally, a suitable alternative to b-lactams is available for patients who have a severe allergy, and penicillin desensitization can be carefully undertaken if there is no suitable alternative. A small proportion (<2%) of persons who are allergic to penicillin react similarly when a cephalosporin is administered; thus, cephalosporins are contraindicated in patients with a history of an immediate reaction to penicillin, although they are often used in patients with a history of mild reactions. The same precaution applies to imipenem, but aztreonam is antigenically distinct and can be administered safely to the penicillin-allergic patient.

Other reactions thought to have an allergic basis include nephritis (associated with methicillin and occasionally nafcillin), hepatitis (related to oxacillin), leukopenia (following high doses of most b-lactams administered for prolonged periods), and severe skin rashes (toxic epidermal necrolysis and Stevens-Johnson syndrome). These reactions are not IgE-mediated, and skin testing is not predictive of their occurrence. For unclear reasons, most patients who have infectious mononucleosis develop a rash when given ampicillin or amoxicillin.

Miscellaneous reactions tob-lactams include gastrointestinal side effects ranging in severity from mild diarrhea (5 to 10%) to pseudomembranous colitis (<1%). Although the probability of antibiotic-associated colitis is low, a large number of cases occur becauseb-lactams are so commonly prescribed. Drugs excreted to a large extent through the bile, such as ampicillin and ceftriaxone, may be especially prone to cause diarrhea. The addition of clavulanic acid to amoxicillin further increases the frequency of diarrhea. Ceftriaxone, because of extremely high concentrations in bile, can cause "sludging" in the gallbladder and occasionally produces symptoms compatible with acute cholecystitis.

In high doses -- and most often in patients with renal impairment who receive an excessive dose -- penicillins (especially ticarcillin and penicillin G) can cause bleeding from impaired platelet aggregation. Ticarcillin is a disodium salt and in high doses can

cause hypokalemia and fluid overload.

Seizures are occasionally observed with b-lactams, especially penicillin G and imipenem. This reaction is most common when excessive doses relative to renal function are administered or when the patient has a history of seizures.

VANCOMYCIN

When vancomycin was first used clinically in 1956, local intolerance at the infusion site was common, as were systemic reactions, including ototoxicity and nephrotoxicity. Current formulations are of higher purity and, when proper dosage guidelines are followed, are very safe, although phlebitis can still be troublesome. The most common adverse reaction is called *red man syndrome* and is characterized by pruritus, flushing, and erythema of the head and upper torso. This anaphylactoid reaction usually follows the first dose, is dependent on dose size and infusion time, and results from vancomycin-induced release of histamine. The reaction is usually mild in adult patients who receive 1 g over 60 min and diminishes with repeated doses. If vancomycin is mistakenly given as a bolus, severe hypotension may result. In unusually sensitive patients, extending the infusion time or administering H_1receptor antagonists is usually effective in preventing this reaction or reducing its severity. Patients with this reaction must not be mislabeled as having an allergy to vancomycin, since vancomycin may be the only effective treatment for certain infections, such as those due to methicillin-resistant staphylococci.

Nephrotoxicity from vancomycin is mild and occurs in fewer than 5% of patients. Although some data suggest that aminoglycosides and vancomycin are synergistically nephrotoxic, this point is difficult to prove, and the simultaneous use of these agents should not be avoided if clinically indicated, as in the treatment of enterococcal endocarditis in penicillin-allergic patients.

Ototoxicity from vancomycin is rare as long as doses are appropriately reduced in patients with renal insufficiency. Other uncommon adverse reactions include leukopenia, skin rashes, and true allergy. Serum concentrations of vancomycin are of little use in predicting toxicity but may be of value in selecting dosages for patients with unstable renal function.

AMINOGLYCOSIDES

Aminoglycoside antibiotics have a narrow therapeutic index. The two most common adverse reactions are nephrotoxicity and ototoxicity. Rarely, respiratory depression is observed. Nephrotoxicity results from accumulation of the aminoglycoside in the peritubular space, with damage to the proximal tubule and a corresponding reduction in the glomerular filtration rate. The incidence of nephrotoxicity, defined as a >0.5% increase over baseline in the serum creatinine level, is approximately 5 to 10% among adult patients who receive therapy for 10 to 14 days. However, many cofactors also influence the frequency of toxicity, such as extremes of age (toxicity is uncommon among children, more common among the elderly), concomitant drug therapy, and hydration status. Nephrotoxicity is manifested clinically by a gradual rise in serum creatinine levels after a few days of therapy and is reversible if the dosage is reduced or

treatment is discontinued. Serum creatinine levels should be monitored every 3 to 5 days or more often if changes are seen. There is not an important difference among the most useful agents (gentamicin, tobramycin, and amikacin) in terms of the frequency of nephrotoxicity; streptomycin is a rare cause of nephrotoxicity. Some data suggest that once-daily administration may cause less nephrotoxicity.

Ototoxicity from aminoglycoside therapy presents as either auditory or vestibular damage. Since the aminoglycosides can destroy hair cells in the inner ear, ototoxicity may be permanent. The risk of ototoxicity increases with prolonged therapy, higher serum concentrations (especially in patients with renal impairment), hypovolemia, and concurrent treatment with other ototoxins, especially ethacrynic acid. Clinically apparent ototoxicity, manifested by diminished acuity or vestibular imbalance, is uncommon (probably occurring in<1% of cases) when the duration of therapy is kept to a minimum. With more sensitive monitoring (e.g., audiograms), asymptomatic high-tone hearing loss is more commonly noted. There are no clinically important differences among the aminoglycosides in the overall frequency of ototoxicity.

Neuromuscular depression from aminoglycosides is caused by reduced acetylcholine activity at postsynaptic membranes and can result in rare but severe respiratory depression. Risk factors include hypocalcemia, peritoneal administration, use of neuromuscular blockers, and preexisting respiratory depression. This complication can be largely avoided if the aminoglycoside is administered intravenously over 30 min or by intramuscular injection; if respiratory depression occurs, it is reversed by the administration of calcium.

Fear of toxicity should not prevent the use of aminoglycosides for a legitimate indication, since toxicity is usually mild and reversible. The value of measuring serum concentrations is controversial; these measurements are usually unnecessary when the patient is receiving once-daily therapy.

MACROLIDES

Serious adverse reactions to the macrolide antibiotics are very rare. Gastrointestinal effects, such as burning, nausea, and vomiting, are the most common adverse reactions to the macrolides; depending on dosage, these reactions may occur in up to 50% of patients, occasionally requiring early discontinuation of therapy. The mechanism is thought to be the binding of erythromycin to motilin receptors, with a consequent increase in gastrointestinal motility. Gastrointestinal side effects appear equally common for all the oral formulations and also occur with intravenous administration. Clarithromycin and azithromycin are better tolerated than erythromycin, although gastrointestinal distress is still their most common adverse effect.

Less common reactions include hepatotoxicity and ototoxicity. Hepatotoxicity is a rare, nonfatal complication that is usually associated with erythromycin estolate and presents as an allergic cholestatic jaundice. Ototoxicity is rare after oral administration but may occur in a dose-dependent pattern in up to 20% of adults who receive intravenous erythromycin (4 g/d) and have audiograms performed. Ototoxicity is usually reversible and mild. Allergic cutaneous reactions are observed in rare cases.

LINCOSAMIDES

The most common adverse effect of clindamycin is gastrointestinal distress. Diarrhea has been reported in up to 20% of patients and pseudomembranous colitis in 0.01 to 10%. The mechanism of pseudomembranous colitis is production of a toxin by *C. difficile* (Chap. 145). *C. difficile* colonizes the gastrointestinal tract and may produce a toxin when the normal flora is suppressed by clindamycin and other antibiotics, especiallyb-lactams. This toxin causes mucosal damage that results in cramps, pain, and diarrhea that may be bloody. Pseudomembranous colitis may follow both intravenous and oral administration and may not become manifest until after completion of therapy. Oral metronidazole or oral vancomycin is effective in treating symptomatic patients with toxin-positive stools, but some spores may survive, and relapse is frequent. Metronidazole is the *drug of choice* since oral treatment with vancomycin can select for vancomycin-resistant enterococci. Although diarrhea and pseudomembranous colitis can be caused by most antibacterial agents, the incidence in relation to the amount used appears to be highest for clindamycin. Allergic reactions (such as rashes and fever), hepatotoxicity, and neutropenia are observed only rarely.

CHLORAMPHENICOL

Chloramphenicol causes two types of bone marrow suppression: a dose-related, reversible suppression of all elements, which occurs commonly during therapy at the maximal recommended doses (4 g/d in adults), and an idiosyncratic, irreversible aplastic anemia, which occurs in approximately 1 in every 25,000 to 40,000 exposures. The irreversible form has been reported to follow all types of chloramphenicol treatment, including ocular administration, and often develops months after therapy is discontinued.

In premature neonates and infants, chloramphenicol can cause a dose-related "gray syndrome" that is characterized by cyanosis, hypotension, and death and that results from an inability of the newborn to metabolize the drug. These potentially serious toxicities and the availability of newer drugs have substantially reduced the indications for chloramphenicol.

TETRACYCLINES

Gastrointestinal effects are the most common adverse reactions to the tetracyclines. These problems may be related to a direct irritant effect, since tetracyclines can also cause esophageal ulceration when they dissolve before reaching the stomach. It is important that nighttime doses be taken with sufficient fluid. Concurrent food intake may improve tolerance, but absorption of tetracycline HCl is impaired when the drug is taken with food.

Hepatotoxicity has been reported after administration of >2 g of tetracycline intravenously and at lower doses during pregnancy. There are currently no indications for intravenous tetracycline treatment in pregnancy. All tetracyclines can cause phototoxic skin reactions; these reactions are most common with doxycycline. Other dermal reactions, including rash, are uncommon. Tetracyclines are contraindicated in children <8 years of age because of mottling of the permanent teeth; doxycycline may

be less likely than the other tetracyclines to cause this problem. Worsening of renal function in patients with preexisting renal dysfunction has been reported with use of tetracycline, although some of the increased azotemia may be due to amino acid catabolism. Doxycycline and perhaps minocycline appear to be free from these renal side effects. Alternative effective agents are nearly always available for use in patients with renal dysfunction. Minocycline can cause vertigo in up to 70% of women receiving therapeutic doses and in a lower percentage of men.

SULFONAMIDES AND TRIMETHOPRIM

The sulfonamides are generally safe, but the list of possible adverse reactions is very long. These compounds occasionally cause a number of allergic reactions, from relatively minor skin rashes (including maculopapular rashes and urticarial reactions typically appearing after a week of therapy) to severe or even life-threatening reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. The severe hypersensitivity reactions have occurred most commonly after treatment with the long-acting sulfonamides, such as sulfamethoxypyridazine, which are no longer used. Pyrimethamine plus sulfadoxine (Fansidar), used for malaria prophylaxis, may cause severe allergic reactions, including hepatic and hematologic toxicities, in addition to dermatologic toxicity. Photosensitivity reactions are also relatively common with sulfonamides.

Many patients infected with HIV who receive trimethoprim-sulfamethoxazole have adverse dermatologic reactions. These reactions are usually not life-threatening and appear to regress in many cases despite continuation of therapy. In high doses, trimethoprim interferes with the renal secretion of potassium. Hyperkalemia is relatively common among HIV-positive patients and is most often found after 7 days of trimethoprim-sulfamethoxazole therapy for pneumonia caused by *Pneumocystis carinii*.

Sulfonamides and trimethoprim may also cause severe hematologic complications, including agranulocytosis, hemolytic and megaloblastic anemia, and thrombocytopenia. These dose-related side effects may be greater in patients with renal insufficiency. Hemolytic anemia is most common in patients with glucose-6-phosphate dehydrogenase deficiency who take long-acting compounds; trimethoprim-sulfamethoxazole rarely causes hemolysis in such subjects. Granulocytopenia from trimethoprim-sulfamethoxazole is especially common in HIV-infected patients, occurring in 10 to 50% of this group.

Renal insufficiency, caused by crystals of the relatively insoluble acetyl metabolite, is observed primarily with the long-acting sulfonamides. Many cases of crystalluria in HIV-infected patients taking sulfadiazine for toxoplasmosis have been reported. A high level of fluid intake may prevent this complication.

It is recommended that sulfonamides not be administered to the newborn because of concerns that bilirubin may be displaced from protein-binding sites, with subsequent jaundice and kernicterus.

In addition to the preceding problems, sulfonamides may occasionally cause drug fever with serum sickness, hepatic toxicity (including necrosis), and systemic lupus

erythematosus.

FLUOROQUINOLONES

Fluoroquinolones are relatively safe; adverse reactions rarely require discontinuation of therapy. The most common reactions include gastrointestinal distress, such as nausea or diarrhea (<5%), and central nervous system effects, including insomnia and dizziness (<5%). Trovafloxacin is prone to causing dizziness, especially among women. However, of more serious concern is the report of more than 100 cases of symptomatic liver toxicity in patients receiving trovafloxacin, including 14 cases of acute liver failure strongly associated with trovafloxacin exposure. As a result, the Food and Drug Administration has recommended that this quinolone be used only in hospitalized patients with serious or life-threatening conditions in which the benefits offered by the drug outweigh its potential risks. Phototoxicity can be severe, especially with sparfloxacin. Rarely, hepatic and renal dysfunction and anaphylactoid and allergic reactions are observed. Tendon rupture has also been associated with quinolone use in rare instances. The use of these drugs is contraindicated in patients <18 years of age because of evidence in animals of cartilage damage in developing joints. In carefully selected situations in which the perceived benefits outweigh the risks (e.g., in adolescent patients with cystic fibrosis who have pulmonary exacerbations), fluoroquinolones may be useful for short-term therapy. They are contraindicated in pregnancy because of concern for the developing fetus.

RIFAMPIN

Rifampin is generally well tolerated but has several important side effects. Some patients have transient rises in hepatic aminotransferases, but these levels usually return to normal without discontinuation of the drug. Although hepatitis from rifampin itself develops only rarely, the drug is thought by some investigators to potentiate the hepatic toxicity of concomitantly administered isoniazid. Intermittent administration of rifampin (usually fewer than three times per week) has been associated with symptoms that seem to have an immunologic basis. These include flulike symptoms and (rarely) hemolysis, thrombocytopenia, shock, and renal failure. Minor gastrointestinal side effects, skin rashes, and interstitial nephritis have also been reported. Patients should be warned that rifampin and its metabolites cause secretions such as urine, tears, sweat, and saliva to turn orange and that contact lenses may be stained.

METRONIDAZOLE

Serious adverse reactions to metronidazole are uncommon. Gastrointestinal side effects such as nausea are most frequent but rarely necessitate discontinuation of therapy. Pseudomembranous colitis in association with metronidazole has been reported but is very rare. A metallic taste is relatively common, and stomatitis and glossitis are occasionally reported. Disulfiram-like reactions can occur if ethanol is ingested concurrently. Peripheral neuropathy develops in some patients, and seizures and encephalopathy have been reported after high doses and in patients with hepatic failure.

Concerns about mutagenicity and carcinogenicity from metronidazole have led to recommendations that it not be used in pregnancy (especially during the first trimester)

when alternative agents are available. Although retrospective studies have found no association between metronidazole and carcinogenesis, long-term administration of high doses should be avoided when therapeutic alternatives exist.

DRUG INTERACTIONS

Historically, clinically important interactions involving antibacterial drugs were generally of little concern, since b-lactams were the most widely used agents and rarely interacted with other drugs in a manner that affected the patient adversely. However, fluoroquinolones, macrolides, and rifampin are now more widely used, and interactions are of increasing concern.Table 137-3 lists the most common and best-documented interactions of antibacterial agents with other drugs and characterizes the clinical relevance of these interactions. Coadministration of drugs paired inTable 137-3 does not necessarily have clinically important adverse consequences. The result depends on the timing of administration, the dose and duration of therapy, the baseline serum concentration of the non-antibacterial drug administered, the patient's susceptibility to the pharmacologic effect of the non-antibacterial drug, and other, less-well-described cofactors. Recognition of the potential for an interaction before the administration of an antibacterial agent is crucial to the rational use of these drugs, since adverse consequences can often be prevented if the interaction is anticipated.Table 137-3 is intended only to heighten awareness of the potential for an interaction. Additional sources should be consulted to identify appropriate options.**For further discussion of drug interactions, see Chap. 70.*

MACROLIDES

Erythromycin and clarithromycin can inhibit the P450 enzyme CYP3A and thus the metabolism of many concurrently administered drugs, such as cisapride, theophylline, carbamazepine, terfenadine, astemizole, warfarin, and ergot alkaloids. The magnitude of the theophylline interaction is highly variable and is proportional to the dose and duration of erythromycin treatment. In contrast, cyclosporine levels predictably increase when erythromycin is administered, since CYP3A is responsible for cyclosporine metabolism. Decreased metabolism of terfenadine, astemizole, cisapride, and pimozide has been reported to cause severe cardiac dysfunction. Azithromycin has little effect on the metabolism of other drugs. In approximately 10% of patients receiving digoxin, concentrations increase when erythromycin is also given.

TETRACYCLINES

The most important interaction involving tetracyclines is the reduction in absorption when these drugs are coadministered with di- and trivalent cations, such as antacids, iron compounds, or dairy products. A similar interaction is seen with quinolones (see below). Food also adversely affects absorption of most tetracyclines. Inducers of hepatic isoenzymes, such as phenytoin and barbiturates, increase the clearance of doxycycline; although the clinical significance of this effect is unknown, use of an alternative antibiotic may be appropriate.

SULFONAMIDES

Sulfonamides may increase the hypoprothrombinemic effect of warfarin by inhibition of its metabolism and possibly by protein-binding displacement. Sulfonamides may also potentiate the effects of oral hypoglycemic agents and phenytoin through reduction in metabolism or displacement from serum protein.

FLUOROQUINOLONES

There are two clinically important drug interactions involving fluoroquinolones. First, like tetracyclines, all fluoroquinolones are chelated by divalent and trivalent cations, which prevent most of the dose from being absorbed. Second, certain fluoroquinolones (grepafloxacin, ciprofloxacin, and -- to a much lesser extent -- levofloxacin and trovafloxacin) can inhibit hepatic enzymes that metabolize theophylline, with resultant theophylline toxicity. The same mechanism accounts for increases in serum caffeine concentrations, but the clinical significance of this interaction is unknown. Scattered reports indicate that quinolones can also potentiate the nephrotoxicity of cyclosporine, exaggerate the effects of warfarin, and increase neurotoxicity when coadministered with nonsteroidal anti-inflammatory agents. However, these interactions have not been confirmed by controlled trials.

RIFAMPIN

Rifampin is an excellent inducer of many cytochrome P450 enzymes and increases the hepatic clearance of a number of drugs, including the following (with the indicated predictable outcomes): HIV-1 protease inhibitors (loss of viral suppression), oral contraceptives (pregnancy), warfarin (decreased prothrombin times), cyclosporine and prednisone (organ rejection or exacerbations of any underlying inflammatory condition), and verapamil and diltiazem (increased dosage requirements). Before rifampin is prescribed for any patient, a review of concomitant drug therapy is essential.

METRONIDAZOLE

Metronidazole can cause a disulfiram-like syndrome when alcohol is ingested; thus, patients taking metronidazole should be instructed to avoid alcohol. Inhibition of the metabolism of warfarin by metronidazole leads to significant rises in prothrombin times.

PROPHYLAXIS OF BACTERIAL INFECTIONS

Antibacterial agents are occasionally indicated for use in patients who have no evidence of infection but who have been or are expected to be exposed to bacterial pathogens under circumstances that constitute a major risk of infection. The basic tenets of antimicrobial prophylaxis are as follows: First, the risk or potential severity of infection should be greater than the risk of side effects from the antibacterial agent. Second, the antibacterial agent should be given for the shortest period necessary to prevent target infections. Third, the antibacterial agent should be given before the expected period of risk (e.g., surgical prophylaxis) or as soon as possible after contact with an infected individual (e.g., prophylaxis for meningococcal meningitis).

Table 137-4 lists the major indications for antibacterial prophylaxis in adults. (The use of antibacterial agents in children to prevent rheumatic fever and otitis media under certain

circumstances is also common practice.) The table includes only those indications that are widely accepted, supported by well-designed studies, or recommended by expert panels. Prophylaxis is also used but is less widely accepted for recurrent cellulitis in conjunction with lymphedema, recurrent pneumococcal meningitis in conjunction with deficiencies in humoral immunity orCSFleaks, traveler's diarrhea, gram-negative sepsis in conjunction with neutropenia, and spontaneous bacterial peritonitis in conjunction with ascites.

The major use of antibacterial prophylaxis in the United States is for infections following surgical procedures. Antibacterial agents are administered just before the surgical procedure -- and, for long operations, during the procedure as well -- to ensure high levels in serum and tissues during surgery. The objective is to eradicate bacteria originating from the air of the operating suite, the skin of the surgical team, or the patient's own flora that may contaminate the wound. In all but colorectal surgical procedures, prophylaxis is predominantly directed against staphylococci. Prophylaxis is intended to prevent wound infection or infection of implanted devices, not all infections that may occur during the postoperative period (e.g., urinary tract infections or pneumonia). Prolonged prophylaxis merely alters the normal flora and favors infections with organisms resistant to the antibacterial agents used.

ANTIBACTERIAL COSTS AND INAPPROPRIATE USE

Use of antibacterial agents in hospitals in the United States accounts for an important percentage of all drug costs and may represent the largest expenditure for any pharmacologic class. In the outpatient setting, the costs of antibacterial drugs are second only to those of cardiovascular agents. A survey of office-based physicians found that between 1980 and 1992 there was a marked increase in the use of expensive broad-spectrum antimicrobials. It is not unusual for the purchase cost (in 2000 dollars) of a newer parenteral antibiotic to be $1000 to $2000 for a 10- to 14-day course of treatment. Therapy with a new oral antibiotic can easily cost $50 to $75. Administration costs, monitoring costs, and pharmacy charges must be added to these figures. While some newer antibacterial agents undeniably represent important advances in therapy, many newer drugs offer no advantage over older, less expensive agents.

Clinicians are understandably confused by the bewildering array of available drugs. Numerous surveys have reported that approximately 50% of antibiotic use is in some way "inappropriate." Aside from the monetary cost of unnecessary antibiotics, there are the costs of excess morbidity from adverse effects and drug interactions and the eventual costs of treating more resistant organisms. The following suggestions are intended to provide guidance through the antibiotic maze.

First, objective evidence regarding the merits of newer drugs is available through publications such as *The Medical Letter*, including the annual update of *Drugs of Choice*. Second, clinicians should become comfortable using a few drugs recommended by independent experts and should resist the temptation to use a new drug unless the merits are clear. A new antibacterial agent with a "broader spectrum and greater potency" or a "longer half-life and higher tissue levels" does not necessarily mean greater clinical efficacy. Third, the clinician must become familiar with local bacterial

susceptibility profiles. It may not be necessary to use a new drug with "improved activity against *P. aeruginosa*" if that pathogen is rarely encountered or if it retains full susceptibility to older drugs. Finally, with regard to inpatient use of antibacterial drugs, appropriate empirical treatment with one or more broad-spectrum agents may often be simplified, with use of a narrower-spectrum agent or even an oral drug, once the results of cultures and susceptibility tests become available. While there is an understandable temptation not to alter effective therapy, switching to a more specific agent, once the patient has improved clinically, does not compromise eventual outcome. If these guidelines are followed, the care of patients will not be undermined, many unnecessary complications and expenses will be avoided, and the useful life of valuable drugs will be extended.

SECTION 5 -DISEASES CAUSED BY GRAM-POSITIVE BACTERIA

138. PNEUMOCOCCAL INFECTIONS - *Daniel M. Musher*

Streptococcus pneumoniae (the pneumococcus) was recognized as a major cause of pneumonia in the 1880s and has been a central focus of study leading to the modern understanding of humoral immunity. The name *Diplococcus pneumoniae* was assigned to the organism in 1926 on the basis of its appearance in Gram-stained sputum. In 1974, the organism was renamed *Streptococcus pneumoniae* because of its growth in chains in liquid medium. Around 1900, pneumococcal serotypes were recognized when the injection of killed organisms into a rabbit stimulated the production of serum antibody that agglutinated and caused increased capsular density of the immunizing strain as well as of some but not all other pneumococcal isolates. Ninety serotypes have now been identified, each possessing a unique polysaccharide capsule.

MICROBIOLOGY

Pneumococci are identified in the clinical laboratory as gram-positive cocci that grow in chains and are catalase-negative. They produce pneumolysin, a toxin that breaks down hemoglobin into a greenish degeneration product, thereby causinga hemolysis on blood agar. More than 98% of pneumococcal isolates are susceptible to ethylhydrocupreine (optochin), and virtually all pneumococcal colonies are dissolved by bile salts.

Peptidoglycan and teichoic acid are the principal constituents of the pneumococcal cell wall. The cell wall's integrity depends on the presence of numerous peptide side chains cross-linked by the activity of enzymes such as trans- and carboxypeptidases.b-Lactam antibiotics inactivate these enzymes by covalently binding their active site. Unique to *S. pneumoniae* and present in all strains is C (for "cell-wall") substance, a polysaccharide consisting of teichoic acid with a phosphorylcholine residue. Surface-exposed choline-binding proteins serve as a site of attachment for potential virulence factors, such as PspA, which may prevent phagocytosis. Nearly every clinical isolate of *S. pneumoniae* has a polysaccharide capsule.

There are two systems for numbering the 90 known distinct capsules of *S. pneumoniae*. In the American system, serotypes are numbered in the order in which they were identified. The strains that most frequently cause human disease were generally the earliest to be identified and thus tend to have lower numbers. The more widely accepted Danish system places serotypes into groups based on antigenic similarities; for example, Danish group 19 includes types 19F ("first recognized"), 19A, 19B, and 19C, which in the American system would be types 19, 57, 58, and 59, respectively. Serotyping was clinically relevant in the 1930s, when type-specific antisera were administered as therapy, and (although genetic typing is more specific) it has again become important for epidemiologic studies of the spread of antibiotic-resistant isolates in communities and among countries. Capsule switching has been documented and to some extent limits the epidemiologic reliability of serotyping.

EPIDEMIOLOGY

S. pneumoniae colonizes the nasopharynx and can be isolated from 5 to 10% of healthy

adults and from 20 to 40% of healthy children. Once the organisms have colonized an adult, they are likely to persist for 2 to 4 weeks but may persist for as long as 6 months. Pneumococci spread from one individual to another as a result of extensive close contact; transmission may be enhanced by poor ventilation. Day-care centers have been a site of spread, especially of penicillin-resistant strains of serotypes 6B, 14, 19F, and 23F. Outbreaks occur among adults in crowded living conditions -- e.g., in military barracks, prisons, and shelters for the homeless -- as well as among susceptible populations in settings such as nursing homes. The risk of pneumococcal pneumonia is not increased by contact in schools or workplaces (including hospitals).

The incidence of pneumococcal bacteremia is relatively high among infants up to 2 years of age and low among teenagers and young adults; rates increase beginning at around age 55. A surveillance study in South Carolina showed the incidences of pneumococcal bacteremia among infants, young adults, and persons³70 years of age to be 160, 5, and 70 cases per 100,000 population, respectively. Most cases of pneumococcal bacteremia in adults are due to pneumonia, and there are three to four cases of nonbacteremic pneumonia for every bacteremic case. Thus, it is estimated that there are 20 cases of pneumococcal pneumonia annually per 100,000 young adults and 280 cases annually per 100,000 persons over the age of 70. The incidence of pneumococcal bacteremia among adults exhibits a distinct midwinter peak and a striking dip in summer. In children, the incidence of bacteremia is relatively constant throughout the year except for a marked dip in midsummer. For reasons that are unclear, certain populations, including Native Americans, Native Alaskans, and African Americans, appear to be unusually susceptible to invasive pneumococcal disease. This enhanced susceptibility, not unlike that to infection with *Haemophilus influenzae*, is thought to have a genetic basic that thus far remains unelucidated.

PATHOGENETIC MECHANISMS

S. pneumoniae attaches to human nasopharyngeal cells through the specific interaction of bacterial surface adhesins, such as pneumococcal surface antigen A or choline-binding proteins, with epithelial cell receptors. Epithelial cell glycoconjugates containing the disaccharide GlcNAcb1-4Gal or asialo-GM1 glycolipid are possible binding sites. Pneumococcal phase variation, in which organisms switch between transparent and opaque, may also play a role in adherence. Upon culture, a mixed population of transparent and opaque pneumococcal colonies can be identified. Organisms from opaque colonies have relatively little peptidoglycan and relatively large capsules; those from transparent colonies have much more phosphorylcholine (which contributes to their capacity to adhere to mammalian cells) and less capsular polysaccharide. When an opaque colony is inoculated intranasally into an experimental animal, only those organisms that form transparent colonies persist. In contrast, after intraperitoneal inoculation, organisms that yield transparent colonies are rapidly cleared from the blood, while those that make opaque colonies resist clearance.

Once the nasopharynx has been colonized, infection results if the organisms are carried into anatomically contiguous areas such as the eustachian tubes or the nasal sinuses and if their clearance is hindered, for example, by mucosal edema due to allergy or viral infection. Similarly, pneumonia ensues if organisms are inhaled or aspirated into the bronchioles or alveoli and then are not cleared -- in many cases, because viral infection

or cigarette smoke or other toxic substances have increased mucus production and/or damaged ciliary action. A mechanism by which pneumococci may bind to pneumocytes after viral infection has been suggested. Pneumocytes activated by cytokines have been shown to express the receptor for platelet-activating factor. This receptor binds the phosphorylcholine residue on pneumococcal C substance, facilitating the adherence of pneumococci. Studies suggest that pneumococci may invade tissues by penetrating mucosal layers; the clinical significance of this finding remains to be determined.

Once pneumococci reach an area where they do not naturally belong, they activate complement by classic and alternative pathways and stimulate cytokine production, which leads to the attraction of polymorphonuclear neutrophils (PMNs). The polysaccharide capsule, however, renders the organisms resistant to phagocytosis. In the absence of anticapsular antibody, phagocytic cells such as alveolar macrophages have a limited capacity to ingest and kill pneumococci; a large bacterial inoculum and/or the compromise of phagocytic function allows the initiation of lung infection. Infection of the meninges, joint spaces, bones, and peritoneal cavity results from the spread of pneumococci through the bloodstream, usually but not always from a recognized focus of infection in the respiratory tract.

The capacity to cause disease reflects the ability of pneumococci to escape ingestion and killing by host phagocytic cells, on the one hand, and to stimulate an inflammatory response and damage tissues, on the other. Encapsulated pneumococci are poorly ingested and killed in vivo in the immunologically naive host or in vitro by mammalian phagocytic cells in the absence of anticapsular antibody and complement. Unencapsulated pneumococci virtually never cause invasive disease (although they can cause conjunctivitis), and mutants lacking a capsule are essentially avirulent in experimental animals. Symptoms of disease are largely attributable to the generation of an inflammatory response that may cause pain by increasing pressure (as in otitis media) or may interfere with vital bodily functions, such as oxygenation of blood (as in pneumonia) or cerebral function (as in meningitis). Cell-wall constituents of *S. pneumoniae*, including teichoic acid, C substance, and (in particular) peptidoglycan, activate complement by the alternative pathway; the reaction between cell-wall structures and antibody also activates the classic complement pathway. The result is the release of C5a, a potent attractant forPMNs, into the surrounding medium. Inflammation is also facilitated by the ability of peptidoglycan to stimulate cytokine production, which activates endothelial cells to express selectin and integrin receptors for inflammatory cells. Inflammation in the central nervous system (CNS) during meningitis is a major contributor to neuronal cell injury. Pneumolysin, a thiol-activated toxin, exerts a variety of effects on ciliary cells and PMNs and also activates the classic complement pathway by direct binding of Clq. Injection of pneumolysin into the lungs of experimental animals produces the histologic features of pneumonia; in mice, immunization with this substance or challenge with genetically engineered mutants that do not produce pneumolysin is associated with a significant reduction in virulence. Autolysin may contribute to the pathogenesis of pneumococcal disease by lysing bacteria, thereby releasing their constituents and heightening the reaction with human tissues. The release of excitatory amino acids in neuronal tissue may contribute to damage caused by meningitis.

HOST DEFENSE MECHANISMS

Mechanisms of host defense may be immunologically nonspecific or specific. Nonspecific mechanisms include laminar airflow across mucous layers that filter inspired air, the glottal reflex, laryngeal closure, the cough reflex, the clearance of organisms from the lower airways by ciliated cells, and the ingestion by pulmonary macrophages andPMNs of small bacterial inocula that manage to reach alveolar spaces. Respiratory virus infection, chronic pulmonary disease, or heart failure compromises these mechanisms, predisposing to the development of pneumococcal pneumonia. Antibody to PspA and other pneumococcal constituents such as pneumolysin may be prevalent in the population and may contribute to immunity that is immunologically specific but not type specific.

Anticapsular antibody provides serotype-specific protection against pneumococcal infection. However, most healthy adults lack IgG antibody to most pneumococcal capsular polysaccharides. Antibody appears after colonization, infection, or vaccination. In the first few weeks after colonization, nonspecific mechanisms probably protect the host from infection. Thereafter, newly developed anticapsular antibody provides a high degree of specific protection. In contrast to this normal situation, adults who are at risk of aspirating pharyngeal contents and/or who have diminished mechanisms of lower airway clearance are at risk of developing pneumonia before antibody is produced. Similarly, children whose nasal mucosal membranes become acutely congested around the time of colonization are at risk of developing otitis media. Persons with a diminished capacity to form antibody remain susceptible for as long as they are colonized.

The risk of serious pneumococcal infection is greatly increased in persons with conditions that compromise IgG synthesis and/or the phagocytic function ofPMNs and macrophages; this risk is also elevated in the presence of conditions associated with debilitation or malnutrition. Nearly all adults who are hospitalized for pneumococcal pneumonia have at least one of the conditions listed inTable 138-1 and/or fall into one of the groups known to be at high risk on epidemiologic grounds. Prior hospitalization either predisposes to or serves as a strong marker for pneumococcal infection. The susceptibility of elderly individuals to pneumococcal pneumonia may reflect diminished clearance mechanisms as well as debilitation, malnutrition, and comorbid diseases. Although IgG responses to capsular polysaccharides, as measured by enzyme-linked immunosorbent assay (ELISA), are more or less normal in elderly persons, the functional capacity of the antibody appears to be decreased. The remarkably high incidence of pneumococcal infection -- perhaps 100-fold above baseline -- among persons with AIDS is noteworthy.

Once a pneumococcal infection has been initiated, the absence of a spleen predisposes to fulminant disease. The liver is able to remove opsonized (antibody-coated) pneumococci from the circulation; in the absence of antibody, however, only the slow passage of blood through the splenic sinuses and prolonged contact with reticuloendothelial cells in the cords of Billroth allow time for bacterial clearance. Patients without spleens may die of pneumococcal pneumonia and sepsis at such an early stage of the illness that pulmonary consolidation is not evident on x-ray before death but rather is found only at autopsy.

SPECIFIC INFECTIONS CAUSED BY *S. PNEUMONIAE*

S. pneumoniae causes infections of the middle ear, sinuses, trachea, bronchi, and lungs (Table 138-2) by direct spread from the nasopharyngeal site of colonization. Infections of theCNS, heart valves, bones, joints, and peritoneal cavity usually arise by hematogenous spread; in rare cases peritoneal infection develops via ascent through the fallopian tubes. The CNS may also be infected by contiguous spread of organisms, as in patients who have a tear in the dura. Primary bacteremia -- i.e., the presence of pneumococci in the blood with no apparent source -- occurs commonly in children under 2 years of age and as a small percentage of all pneumococcal bacteremias in adults; if no therapy is given, a source may become apparent. Pleural infection results either from direct extension of pneumonia to the visceral pleura or from hematogenous spread of bacteria from a pulmonary or extrapulmonary focus; the route cannot be determined in any individual case.

Otitis Media and Sinusitis When fluid from the middle ear is cultured during acute otitis media or fluid from a paranasal sinus is cultured during acute sinusitis, *S. pneumoniae* is the most common isolate or is second only to nontypable *H. influenzae*. Whether in adults or in children, pneumococci are identified in about 40 to 50% of cases of otitis in which an etiologic agent is isolated. Prior infection by a respiratory virus or allergy is thought to contribute significantly to these pneumococcal infections by causing congestion of the openings to the eustachian tubes or the paranasal sinuses. Prospective studies of young children have shown that colonization precedes infection in most cases. For reasons that are unclear, serotypes 6B, 14, 19F, and 23F predominate both as colonizing and as infecting organisms of children; therefore, these serotypes are currently being studied most intensively for use in vaccines to be administered to young children.

Meningitis Except during outbreaks of meningococcal infection, *S. pneumoniae* is the most common etiologic agent of bacterial meningitis in adults. Because of the remarkable success of *H. influenzae* type b vaccine, *S. pneumoniae* now predominates among cases in infants and toddlers as well (but not among those in newborns). Meningitis develops either by the direct extension of infection from the sinuses or the middle ear or as a result of bacteremia with seeding of the choroid plexus. Favoring the former possibility are the association between acute otitis media and meningitis as well as the documented role of *S. pneumoniae* as the most common cause of recurrent bacterial meningitis associated with head trauma, cerebrospinal fluid (CSF) leak, and/or dural tear. Favoring the latter are the association between pneumococcal bacteremia from any source and meningitis as well as an autopsy study of temporal bone from children who died of bacterial meningitis, which yielded no evidence of extension from the middle ear.

In the meninges and subarachnoid space, pneumococcal peptidoglycan stimulates an intense inflammatory response mediated by the release of interleukin (IL)1, IL-6, C5a, tumor necrosis factor (TNF), and other proinflammatory cytokines. This inflammatory response results in raised intracranial pressure, brain edema, and decreased blood flow leading to meningismus, drowsiness, or coma. Focal neurologic signs may result from vasculitis with venous or arterial thrombosis, from cranial neuropathy due to entrapment or infarction, from local cerebritis, from subdural effusion, or from brain herniation (Chap. 372).

No distinctive clinical or laboratory feature differentiates meningitis due to *S. pneumoniae* from that due to other bacteria. Patients note the sudden onset of fever, headache, and stiffness or pain in the neck. Without treatment, there is a progression over 24 to 48 h to confusion and then obtundation. On physical examination, the patient looks acutely ill and has a rigid neck. In such cases lumbar puncture should not be delayed for computed tomography (CT) of the head unless papilledema or focal neurologic signs are evident. TypicalCSFfindings consist of pleocytosis (500 to 10,000 cells/uL) with a predominance ofPMNs, an elevated protein level (100 to 500 mg/dL), and a decrease in glucose content. If antibiotics have not been given, large numbers of pneumococci can be seen in a Gram-stained specimen of CSF in nearly all cases, and specific therapy can be administered, although *Listeria* may be misidentified as the pneumococcus. If an effective antibiotic has already been given, the number of bacteria may be greatly decreased and microscopic examination of a Gram-stained specimen may yield negative results. In this situation, immunologic methods for the detection of pneumococcal capsule in the CSF may identify an etiologic agent in up to two-thirds of cases, although these methods have fallen out of favor. Most physicians prefer to use empirical broad-spectrum antibiotic therapy until the etiologic agent has been definitively identified and its susceptibility has been reported.

Pneumonia The distinctive symptoms and signs of pneumococcal pneumonia are (1) cough and sputum production, which reflect the proliferation of bacteria and the resulting inflammatory response in the alveoli; (2) fever; and (3) radiographic detection of an infiltrate.

Predisposing Conditions Pneumococcal pneumonia is most common at the extremes of age. Despite the undisputed role of *S. pneumoniae* as a major pathogenic bacterium for humans, the great majority of adults with pneumococcal pneumonia have underlying diseases that predispose them to infection. Otherwise-healthy military recruits involved in outbreaks of infection may be an exception to this rule; however, many of those affected have an antecedent viral-type illness that may reduce normal host resistance. In addition to prior viral respiratory illness, the most common predisposing conditions are alcoholism, malnutrition, chronic pulmonary disease of any kind, cigarette smoking, infection with HIV, diabetes mellitus, cirrhosis of the liver, anemia, prior hospitalization for any reason, renal insufficiency, and coronary artery disease (with or without recognized congestive heart failure). HIV infection is such an important predisposing factor that some authorities recommend that any young adult with pneumococcal pneumonia be tested for antibody to HIV.

Presenting Symptoms Patients often present with a preexisting respiratory condition that has distinctly deteriorated. If a viral upper respiratory illness is the predisposing factor, the patient may have felt unwell for several days, with coryza or a nonproductive cough and low-grade fever; at the time of onset of pneumonia, the temperature may rise to 38.9 to 39.4°C (102 to 103°F), and sputum production becomes prominent. In a patient who has chronic bronchitis, the sputum may increase in volume, become yellow or green and thicker than usual, and be associated with a fever that becomes progressively higher over 48 to 72 h. In a small proportion of cases, the onset of disease follows a hyperacute pattern in which the patient suddenly has a single episode of shaking chills followed by sustained fever and a cough productive of blood-tinged

sputum. This clinical picture is unfortunately called "classic," a vague term that is best avoided because many physicians believe that it means "most common," which is clearly not the case. In elderly subjects, the onset of disease may be especially insidious and may not suggest pneumonia at all. Persons in their eighties may have minimal cough, no sputum production, and no fever, instead appearing tired or confused. For the reasons noted above, the most abrupt progression of pneumococcal disease is seen in patients who have previously undergone splenectomy; these individuals may go from apparent good health to death in as little as 24 h. In pneumonia, pleuritic chest pain may result from extension of the inflammatory process to the visceral pleura; persistence of this pain, especially after the first day or two of treatment, raises concern about empyema (see "Complications," below). Nausea and vomiting or diarrhea, sometimes quite prominent, occur in up to 20% of cases. Clearly, the range of symptoms is sufficiently broad that there is no characteristic presentation to distinguish pneumococcal from other types of bacterial pneumonia (or from some types of nonbacterial pneumonia).

Physical Findings Patients with pneumococcal pneumonia usually appear ill and have a grayish, anxious appearance that differs from that of persons with viral or mycoplasmal pneumonia. Typically, the temperature is 38.9 to 39.4°C (102 to 103°F), the pulse 90 to 110 beats per minute, and the respiratory rate >20 breaths per minute. Elderly patients may have only a slight temperature elevation or be afebrile. Hypothermia is associated with increased morbidity and mortality. Herpes labialis appears in a small percentage of cases. Pain may cause diminished respiratory excursion (splinting) on the affected side. Dullness to percussion is noted in about half of cases, and vocal fremitus is increased. Breath sounds may be bronchial or tubular, and crackles are heard in most cases if enough air is being moved to generate them. Flatness to percussion at the lung base and inability to detect the expected degree of diaphragmatic motion suggest the presence of pleural fluid, which raises the possibility of empyema; the failure to assess fremitus, to distinguish dullness from flatness by percussion, or to examine for diaphragmatic excursion may leave the physician at the mercy of often ambiguous radiologic interpretations. The finding of a heart murmur, certainly if new, raises concern about endocarditis, a rare but serious complication. Hypoxia or the generalized response to pneumonia may cause the patient to be confused, but the appearance of confusion should raise concern about meningitis. Obtundation or neck stiffness should lead to an immediate consideration of this complication.

Radiographic Findings (Fig. 138-CD1) Pneumococcal pneumonia involves only one lung segment or a portion thereof in one-fourth of cases; it involves more than one segment but only one lobe or a portion thereof in another one-fourth of instances. Thus multilobar disease is seen in half of cases. Air-space consolidation is the predominant finding and is detected in 80% of cases. Air bronchogram (visualization of the air-filled bronchus against a background of consolidation in the alveoli) is evident in fewer than half of cases and is more common in bacteremic than in nonbacteremic disease. In rare instances, pneumococcal pneumonia leads to a lung abscess; a malignancy or a mixture of anaerobic and microaerophilic organisms is likely to be implicated as well. Although some pleural fluid may actually be present in half of cases, no more than 20% of patients have a sufficient volume of fluid to allow aspiration, and in only a minority of these patients is empyema documented.

General Laboratory Findings The peripheral-blood white blood cell (WBC) count exceeds 12,000/uL in the great majority of patients with pneumococcal pneumonia. However, the count is<6000/uL in 5 to 10% of persons hospitalized for pneumococcal pneumonia. Such a low count is strongly associated with lethal disease and is often but not always associated with bone marrow suppression due to alcohol ingestion. The serum bilirubin level may be modestly elevated; hypoxia, inflammatory changes in the liver, and breakdown of red blood cells in the lung are all thought to contribute to this increase. Levels of lactate dehydrogenase may be elevated. A variety of other abnormalities may be present, reflecting the contributory role of underlying diseases.**Abnormalities of pleural fluid in empyema are reviewed in Chap. 255.*

Differential Diagnosis Patients who present with community-acquired pneumonia may actually have infection of the lungs due to one of many organisms. The extensive list includes the following: *H. influenzae* or *Moraxella catarrhalis* in persons with little to predispose them other than chronic or acute inflammation of the airways; *Staphylococcus aureus* in persons who take glucocorticoids or who have major anatomic disruption of the airways; *Streptococcus pyogenes*; *Neisseria meningitidis*; anaerobic species in persons who have seizures or may have aspirated oropharyngeal or gastric secretions for some other reason; *Legionella*; *Pasteurella multocida* in dog or cat owners; gram-negative bacilli, especially in persons with severely damaged lungs who are taking glucocorticoids; viruses, especially influenza virus (in season), adenovirus, or respiratory syncytial virus; *Mycobacterium tuberculosis*; fungi, including *Pneumocystis carinii* (depending upon epidemiologic factors and the possible presence of HIV infection); *Mycoplasma*; *Chlamydia pneumoniae*, especially in older adults; and *Chlamydia psittaci* in bird owners. Many older men with lung cancer present with pneumonia, as do persons who have acute-onset inflammatory pulmonary conditions of uncertain etiology or those with pulmonary embolus and infarction. The breadth of this list vividly illustrates the difficulty of using empirical therapy for community-acquired pneumonia. Many of these diseases require evaluation, and specific therapy is available for an increasing number. Moreover, pneumococci -- perhaps the most common cause of community-acquired pneumonia -- are increasingly resistant to available antibiotics. Taken together, these factors favor precise determination of the etiology of a pneumonia syndrome whenever possible.

Diagnostic Microbiology An etiologic role for the pneumococcus in pneumonia is strongly suggested by the microscopic demonstration of large numbers ofPMNs and slightly elongated gram-positive cocci in pairs and chains in the sputum (Plate VI-2). Capsules may be seen surrounding the bacterial forms. Examined areas of the slide must be free of buccal epithelial cells, which indicate the admixture of saliva with sputum; saliva may contain 10^7viridans streptococci per milliliter. When characteristic microscopic findings are noted, the identification of *S. pneumoniae* in sputum culture strongly indicates pneumococcal infection of the lower respiratory tract. In the absence of such microscopic findings, the identification of pneumococci by culture may be nonspecific, reflecting colonization of the upper airways. Culture is also less sensitive than microscopic examination for identifying pneumococci. Since most pneumococci do not produce distinctively mucoid colonies, their identification in the laboratory depends on the ability to select putative pneumococcal colonies for further study from amonga-hemolytic streptococci of the mouth. In short, laboratory diagnosis by sputum culture relies on the quality of the specimen provided, the care with which the relevant

purulent component is separated for culture, and the assiduity with which a-hemolytic colonies are studied. These factors need to be considered when sputum cultures from patients who appear to have pneumococcal pneumonia are said to yield only "normal mouth flora" and when the medical literature describes what appear to be poor results of sputum culture. Because of the central role of microscopic examination in diagnosis, physicians may wish to view the slides with the microbiologist. Blood cultures yield *S. pneumoniae* in about 25% of cases of pneumococcal pneumonia. Modern, automated systems often yield positive blood cultures within 12 h after the sample is obtained.

Complications Empyema is the most common complication of pneumococcal pneumonia, occurring in about 2% of cases. As noted above, some fluid appears in the pleural space in a substantial proportion of cases of pneumococcal pneumonia, but this parapneumonic effusion usually reflects an inflammatory response to infection that has been contained within the lung, and its presence is self-limited. When bacteria reach the pleural space -- either hematogenously or as a result of contiguous spread, possibly across lymphatics of the visceral pleura -- empyema results. The finding of frank pus, a positive result on Gram's staining, or the presence of fluid with a pH of£7.1 indicates the need for aggressive and complete drainage, preferably by prompt insertion of a chest tube, with verification byCT that fluid has been removed. If there is no response, thoracotomy is indicated. Persistence of fever (even if low-grade) and leukocytosis after 4 or 5 days of appropriate antibiotic treatment for pneumococcal pneumonia suggests empyema. In this setting, the diagnosis is exceedingly likely if the x-ray shows the persistence of pleural fluid. At this stage, thoracotomy is often needed for cure. Aggressive drainage is likely to reduce morbidity and mortality from empyema (Chap. 262).

Other Syndromes The appearance of pneumococcal infection at other, usually sterile body sites indicates hematogenous spread, either during frank pneumonia or, in a smaller proportion of cases, from an inapparent focus of infection. A case of pneumococcal endocarditis is seen every few years at large tertiary-care hospitals. Purulent pericarditis due to this organism, occurring as a separate entity or together with endocarditis, is even rarer. Most cases of spontaneous bacterial peritonitis in children and some cases in adults are caused by *S. pneumoniae*. Peritonitis in women may be related to the use of an intrauterine contraceptive device, and pneumococcal infections of the female reproductive organs continue to be described. Septic arthritis can arise spontaneously in a natural or prosthetic joint or as a complication of rheumatoid arthritis. Osteomyelitis in adults tends to involve vertebral bones. Epidural and brain abscesses are rarely described. Cellulitis can develop and does so most often in persons who have connective tissue diseases or HIV infection. The appearance of any of these unusual pneumococcal infections in a young adult may suggest that tests for HIV infection should be undertaken.

TREATMENT

Antibiotic Susceptibility b-Lactam antibiotics, the cornerstone of therapy for serious pneumococcal infection, bind covalently to the active site and thereby block the action of the cell-membrane enzymes (endo-, trans-, and carboxypeptidases) that are responsible for cell-wall synthesis. These enzymes were identified by their reaction with radiolabeled penicillin and thus are called *penicillin-binding proteins*. In the 1960s,

virtually all clinical isolates of *S. pneumoniae* were susceptible to penicillin (i.e., were inhibited in vitro by concentrations of<0.06 ug/mL). During the past 20 years in Europe and the past 10 years or so in the United States, a steadily increasing number of pneumococcal isolates have shown some degree of resistance to penicillin. Resistance results when spontaneous mutation or acquisition of new genetic material alters penicillin-binding proteins in a manner that reduces their affinity for penicillin, thereby necessitating a higher concentration of penicillin for their saturation. The genetic information acquired also conveys resistance to other antibiotics. Mutation and selection of strains in communities in the United States -- especially in areas of high antibiotic use, such as day-care centers -- and spread of identifiable strains from other countries where antibiotics are available without prescription have contributed to the prevalence of resistance.

For most of the antibiotic era, pneumococcal susceptibility was not studied in vitro because of the organism's high degree of susceptibility to virtually all recommended antibiotics. Clearly, the situation has changed, and it seems important to study pneumococcal isolates, especially those causing invasive disease, for antibiotic susceptibility. In 1997, about 20% of pneumococcal isolates in the United States were intermediately susceptible to penicillin [minimal inhibitory concentration (MIC), 0.1 to 1.0 ug/mL] and 15% were resistant (MIC,³ 2.0 ug/mL;Table 138-3). The clinical significance of the MIC varies with the infection being treated. An intermediately resistant strain (e.g., MIC = 0.5 ug/mL) behaves as a susceptible organism when it causes pneumonia, but probably not when it causes otitis and certainly not when it causes meningitis. As a result, susceptibility may eventually be redefined on the basis of the site infected -- a concept supported by pharmacokinetic considerations and validated by outcome studies. Amoxicillin, with two- and fourfold lower MICs, appears to be more active against *S. pneumoniae* than penicillin -- thus the emerging preference for amoxicillin. Penicillin-susceptible pneumococci are susceptible to all commonly used cephalosporins. Penicillin-intermediate strains are resistant to all first- and many second-generation cephalosporins (of which cefuroxime retains the best efficacy) but are susceptible to some third-generation cephalosporins, including cefotaxime, ceftriaxone, cefepime, and cefpodoxime. One-half of highly penicillin-resistant pneumococci are also resistant to cefotaxime and ceftriaxone, a higher proportion are resistant to cefepime, and nearly all are resistant to cefpodoxime. Pneumonia caused by intermediately penicillin-resistant strains responds well to b-lactam antibiotics. Pneumonia due to fully resistant strains also responds, but probably not as reliably; data that address this issue are currently being examined. Sinusitis and otitis media caused by intermediately resistant *S. pneumoniae* do not reliably respond to therapy, and failure of therapy may be common when these conditions are caused by highly resistant pneumococcal strains.

Resistance to erythromycin extends to the new macrolides, including azithromycin and clarithromycin. This resistance will certainly affect empirical therapy for bronchitis, sinusitis, and pneumonia. In the United States, the majority of macrolide-resistant pneumococci bear the so-called M phenotype (erythromycinMIC= 1 to 8 ug/mL) and are susceptible to clindamycin. In this case, resistance is mediated by an efflux pump mechanism; it is not yet known whether M-type resistance can be overcome by clinically achievable levels of macrolides. In Europe, most macrolide resistance is due to a mutation in *ermB*, which confers high-level resistance not only to macrolides but also to

clindamycin. Rates of resistance to doxycycline among pneumococci of varying susceptibility to penicillin are similar to those observed for macrolides, whereas the overall rate of pneumococcal resistance to trimethoprim-sulfamethoxazole (25%) is sufficiently high to discourage therapy with this agent unless an isolate is known to be susceptible.

The newer fluoroquinolones remain highly effective against pneumococci, with equal efficacy against penicillin-susceptible and -resistant strains. All pneumococci are susceptible to vancomycin, although it is feared that the acquisition of vancomycin resistance by enterococci and other gram-positive bacteria may eventually lead to pneumococcal transformation to resistance. Of drugs under study, the oxazolidinones and glycopeptides appear to be most promising, withMICs for drug-resistant *S. pneumoniae* strains no higher than for penicillin-susceptible strains. Resistance to streptogramins parallels that to macrolides and limits the usefulness of these drugs for the treatment of pneumonia.

Pneumococcal susceptibility patterns vary greatly between and even within individual communities and the data are in a state of flux. It does appear, however, that the constant trend is toward more widespread resistance.

General Therapy There has been increased emphasis on outpatient therapy in patients who are at low risk (as determined by PORT score according to criteria described by the Pneumonia Outcomes Research Team; Chap. 255). This approach appears to be safe. However, if the physician is in doubt about the severity of illness, the social circumstances, or the likelihood of compliance with the prescribed antibiotic regimen, it may be best to hospitalize the patient, at least briefly.

Specific Antibiotic Therapy

Pneumonia This section will deal primarily with the treatment of pneumonia that is known to be due to *S. pneumoniae*. The broader issue of empirical therapy for community-acquired pneumonia is covered in detail elsewhere (Chap. 255). However, a few general comments on empirical therapy apply. An important problem in treating pneumonia is that, without a good sputum sample that can be Gram-stained and examined microscopically, the etiologic agent is not known at the time when treatment needs to be initiated and is not likely to become known later. Empirical therapy in such cases must be effective against *S. pneumoniae*, which remains the most likely causative agent of community-acquired pneumonia, unless epidemiologic, clinical, and radiologic findings strongly favor another etiologic entity. If a good sputum sample is obtained and only *S. pneumoniae* is visible, therapy can be focused on this organism, although additional treatment may be added for organisms that are not visualized microscopically -- e.g., influenza virus in a patient hospitalized during an influenza outbreak. Even if the pneumococcus is suspected, a certain degree of empiricism is required, because the antibiotic susceptibility of the strain involved will not be known for 1 or 2 days.

OUTPATIENT THERAPY Amoxicillin (500 mg four times daily) effectively treats all cases of pneumococcal pneumonia except those caused by the most highly penicillin-resistant isolates. Neither cefuroxime nor cefpodoxime offers any advantages

over amoxicillin since these drugs are less likely, even at high dosages, to be active against highly resistant pneumococcal strains. One of the newer fluoroquinolones in an accepted dosage for pneumonia is highly likely to be effective. Doxycycline, azithromycin, or clarithromycin will be effective in 85 to 90% of cases and clindamycin in a higher proportion. The trend toward increasing resistance to all these drugs is worrisome. Because one-fourth of all isolates are now resistant to trimethoprim-sulfamethoxazole, this agent can no longer be recommended. Since none of these therapies ensures the kind of antibiotic coverage that it would have in the past, patients should be instructed to remain in close contact with the prescribing physician, especially if there is any deterioration in their condition. It is worth noting that an outcomes study using data from the mid-1990s, when the rate of resistance was lower, showed that treatment with any of the above-mentioned antibiotics was associated with a good outcome; the majority of cases in which an etiologic agent was identified were due to *S. pneumoniae*.

INPATIENT THERAPY Pneumonia caused by penicillin-susceptible or intermediately penicillin-resistant pneumococcal isolates is readily treatable with penicillin. The dosages that follow are acceptable against intermediately resistant strains and against many or most fully resistant isolates, although they are excessive for use against susceptible isolates. Lower doses, however, cannot be recommended initially because susceptibility is not known until 24 to 72 h after treatment is begun. Patients who are sick enough to be hospitalized should be treated promptly. Most physicians favor parenteral antibiotics, although oral administration of well-absorbed drugs may be acceptable if the patient is not vomiting or hypotensive. Recommended regimens include ceftriaxone (1 to 2 g/d) or cefotaxime (1 to 2 g every 6 to 8 h). Ampicillin (1 to 2 g every 6 h) is also widely used. A quinolone or azithromycin can be given parenterally or orally. About 10 to 15% of all pneumococci are resistant to macrolides, and 1 to 2% are resistant to quinolones. Much of the resistance to macrolides among pneumococcal isolates may be overcome by the administration of azithromycin at a dosage of 500 mg on the first day and 250 mg/d thereafter. Clindamycin is effective against a higher proportion of resistant pneumococci than are the macrolides. Vancomycin is uniformly effective against pneumococci and should be used for initial therapy if there is reason to believe that a patient is infected with a strain that is resistant to the drugs listed above. As antimicrobial resistance among pneumococci evolves, updated recommendations will be issued by the Infectious Diseases Society of America, the American Thoracic Society, and the Centers for Disease Control and Prevention (CDC).

Patients with severe allergic reactions to b-lactam antibiotics should receive vancomycin (500 mg intravenously every 6 h) or a quinolone. As noted above, there have always been treatment failures unrelated to the antimicrobial susceptibility of the organism; nevertheless, the failure of a patient to respond promptly should raise the question of resistance, and vancomycin should be given until the susceptibility of the infecting strain to other drugs has been documented. Of course, evidence for loculated infections (such as empyema) and/or other causes of fever should be sought.

DURATION OF THERAPY The optimal duration of treatment for pneumococcal pneumonia is uncertain. Penicillin-susceptible strains disappear from the sputum within several hours of the first dose of penicillin, and a single dose of procaine penicillin, which results in the maintenance of an effective antimicrobial level for 24 h, was said to

cure pneumococcal pneumonia in otherwise-healthy young adults at the time when all isolates were susceptible. Most older physicians treat pneumococcal pneumonia for 5 to 10 days. In the absence of reports of therapy failure, younger physicians have tended to treat the infection for 10 to 14 days. Prolongation of therapy is a two-edged sword, especially in debilitated patients, because the risk of complications increases with each day of antibiotic treatment, particularly in the hospital setting. A few days of close observation and parenteral therapy followed by an oral antibiotic -- with the entire course of treatment continuing for no more than 5 days after the patient becomes afebrile -- may be the best approach.

Otitis Media and Acute Sinusitis Current treatment recommendations for otitis media and acute sinusitis -- conditions whose pathogenesis and microbial etiology are similar -- are based on the following points: (1) Acute otitis media is the most common infection for which antibiotics are prescribed in the United States. (2) As noted above, *S. pneumoniae* is the most likely treatable cause; taken together, *H. influenzae* and *M. catarrhalis*, many strains of which produceb-lactamases, are implicated nearly as frequently as pneumococci. (3) In the absence of diagnostic tympanocentesis, the etiologic diagnosis is nearly always presumptive. (4) Because penetration into a closed space is required, high serum levels of an effective antibiotic are required to treat otitis caused by intermediately or fully resistant pneumococci. (5) Otitis due to *S. pneumoniae* is more likely to fail to respond and to produce complications without specific therapy. (6) Antibiotics that are effective against pneumococci and yet resist b-lactamases tend to be very expensive compared with amoxicillin.

As a result of these considerations, theCDC's Otitis Media Working Group recommends that initial therapy be amoxicillin in a high dosage -- e.g., 80 mg/kg for infants and toddlers or 500 mg four times daily for adults. If this regimen fails, highly penicillin-resistant pneumococci orb-lactamase-producing bacteria may be responsible, and a course of cefpodoxime, perhaps preceded by a single parenteral dose of ceftriaxone, is recommended. Once therapy has begun, patients must be monitored closely for a response. Despite the detection (by molecular analysis) of pneumococcal DNA in middle-ear fluid, chronic serous otitis ("glue ear") is probably not due to active infection and does not require antibiotic therapy.

Meningitis A reasonable recommendation is that pneumococcal meningitis be treated initially with cefotaxime (2 g every 6 h) or ceftriaxone (1 to 2 g every 12 h) plus vancomycin (500 mg every 6 h or 1 g every 12 h). Two drugs are given initially because the cephalosporin is likely to be effective against most isolates and readily penetrates the blood-brain barrier, whereas vancomycin is uniformly effective but has a somewhat unpredictable capacity to cross the blood-brain barrier. If the isolate is shown to be penicillin-susceptible, treatment can be continued with 24 million units of penicillin every 24 h, given every 4 h in divided doses or continuously. If the isolate exhibits reduced susceptibility to penicillin but is susceptible to cefotaxime or ceftriaxone, the administration of vancomycin may be discontinued. Rifampin inhibits the bactericidal activity ofb-lactam antibiotics and probably should not be added to the regimen. The total duration of therapy for pneumococcal meningitis is 10 to 14 days. Despite the central pathogenic role of inflammation in meningitis, the use of glucocorticoids or other anti-inflammatory agents is controversial, even in children, in whom most of the relevant studies have been done. Data simply do not exist on which to base an informed

decision regarding the administration of glucocorticoids or cyclooxygenase inhibitors to adults with pneumococcal meningitis (Chap. 372). Meningitis should be treated in an intensive care unit and with the participation of appropriate consultants, generally including a neurologist and a specialist in infectious diseases.

Endocarditis Pneumococcal endocarditis is associated with rapid destruction of heart valves. Vancomycin should be given pending assays for the minimal bactericidal concentrations of b-lactam antibiotics. There is no clear evidence that the addition of another antibiotic to the regimen is beneficial; aminoglycosides are somewhat synergistic and rifampin or quinolones are antagonistic with b-lactams. Endocarditis and meningitis should be treated initially in an intensive care unit, with the participation of appropriate consultants. Patients with endocarditis should probably be treated in collaboration with an infectious disease consultant, a cardiologist, and a cardiovascular surgeon.

Other Therapeutic Modalities A variety of agents that block the action ofTNF-a,IL-1, or platelet-activating factor have conferred no benefit in and may have had a detrimental effect on pneumococcal sepsis. Similar results have been obtained with glucocorticoids.

PREVENTION

Pneumococcal vaccine contains 25 ug of capsular polysaccharide from the 23 most prevalent serotypes of *S. pneumoniae*; vaccination stimulates antibody to most serotypes in most recipients. In adults under 55 years old, protection rates are at least 85%, even 5 years or longer after vaccination. The level and duration of protection decrease with advancing age, perhaps because of a diminished avidity of the antibody for the capsular polysaccharide. As a result, persons in their eighties have 50% protection for 3 years and very little or no protection thereafter. In subgroups of the population at high risk (e.g., debilitated elderly persons and individuals with severe chronic lung disease), vaccine has not been shown conclusively to be effective. Persons who most need the vaccine because of poor IgG responses are not likely to respond to immunization with significant increases in antibody level. Nevertheless, the poor average rate of response should not deter the physician from administering vaccine to individual patients who are at increased risk of pneumococcal infection. In light of the safety, low cost, and efficacy of vaccine and the emergence of antibiotic-resistant strains, the failure to vaccinate elderly persons and individuals who have conditions predisposing to pneumococcal disease is viewed by some authorities as a missed opportunity in public health policy.

TheCDC's Immunization Practices Advisory Committee has broadened its recommendations for pneumococcal vaccination to include all persons over the age of 2 years who are at substantially increased risk of developing pneumococcal infection and/or a serious complication of such an infection. General categories included within these recommendations are as follows: (1) persons over the age of 65; (2) persons with anatomic or functional asplenia,CSFleak, diabetes mellitus, alcoholism, cirrhosis, chronic renal insufficiency, chronic pulmonary disease, or advanced cardiovascular disease; (3) persons who have an immunocompromising condition associated with increased risk of pneumococcal disease, such as multiple myeloma, lymphoma, Hodgkin's disease, HIV infection, organ transplantation, or chronic use of

glucocorticoids; (4) persons who are genetically at increased risk, such as Native Americans and Alaskans; and (5) persons who live in special environments where outbreaks are particularly likely to occur, such as nursing homes. This list should not be regarded as all-inclusive.

Recommendations regarding revaccination seem to be somewhat inconsistent. A single revaccination is advocated for persons over the age of 65. Since antibody levels decline and there is no anamnestic response, it seems more reasonable simply to recommend revaccination at 5-year intervals, especially in persons over the age of 65, who tend to have almost no local reaction, and in splenectomized patients, who are most in need. If penicillin-resistant pneumococci continue to increase in prevalence, routine immunization of children over the age of 2 years should be considered. Pneumococcal vaccine has not been useful in children<2 years of age, who do not respond well to polysaccharide antigens. In a recent field trial, a heptavalent protein-conjugate pneumococcal polysaccharide vaccine protected infants and children against pneumococcal pneumonia, bacteremia, and meningitis; this vaccine is likely to be released for administration to young children in the next few years.

139. STAPHYLOCOCCAL INFECTIONS - *Jeffrey Parsonnet*, *Robert L. Deresiewicz*

The staphylococci are hardy and ubiquitous colonizers of human skin and mucous membranes and were among the first human pathogens identified. They cause a variety of syndromes, including superficial and deep pyogenic infections, systemic intoxications, and urinary tract infections. Staphylococci are the leading cause of bacteremia, surgical wound infections, and infections of bioprosthetic materials in the United States; in addition, they are the second leading cause of nosocomial infections. Organisms of this genus are also a significant cause of bacterial food poisoning.

Staphylococcus aureus is the most important human pathogen in the genus. It remains a major public health concern due to its tenacity, potential destructiveness, and increasing resistance to antimicrobial agents. Although less virulent, the coagulase-negative staphylococci (CoNS), especially *S. epidermidis*, adhere avidly to prosthetic materials and are important nosocomial pathogens, especially of compromised hosts. Another CoNS species, *S. saprophyticus*, is a common cause of urinary tract infections.

TAXONOMY AND MICROBIOLOGY

Members of the genus *Staphylococcus* are nonmotile, nonsporulating gram-positive cocci, 0.5 to 1.5 um in diameter, that occur singly and in pairs, short chains, and the irregular three-dimensional clusters from which their name is derived (Greek *staphule,* "grape-like"). Staphylococci can grow over a wide range of environmental conditions, but they grow best at temperatures between 30°C and 37°C and at a pH around neutrality. They are resistant to desiccation and to chemical disinfectants, and they tolerate NaCl concentrations up to 12%. With rare exceptions, the staphylococci are facultatively anaerobic. The more virulent staphylococci can clot plasma (coagulase-positive), while the less virulent cannot (coagulase-negative). Of the six recognized coagulase-positive staphylococcal species, the only important human pathogen is *S. aureus*, whose colonies are larger than those of *S. epidermidis*, are often pigmented (golden yellow), and are usuallyb-hemolytic on sheep blood agar. Twenty-eight species of CoNSare recognized. Of these, *S. epidermidis* is by far the most common nonurinary human isolate. Strains of *S. epidermidis* are typically white and nonhemolytic and may be tenaciously adherent as a result of their production of polysaccharide adhesin. *S. epidermidis* is followed in frequency by *S. hominis*, *S. haemolyticus*, and *S. warneri*. *S. lugdunensis* is increasingly recognized as a cause of serious human infection. *S. saprophyticus* is the most common staphylococcal urinary isolate.

STAPHYLOCOCCUS AUREUS

EPIDEMIOLOGY

Humans constitute the major reservoir of *S. aureus* in nature. The mucous membranes of the anterior nasopharynx are the principal site of carriage, with roughly 30% of healthy adults being so colonized at any point in time. Other common sites of colonization include the axillae, the vagina, damaged skin, and the perineum. Among postmenarcheal U.S. women, the rate of vaginal colonization by *S. aureus* ranges from

5 to 15% but rises to 30% during menses -- a change that is relevant to the pathogenesis of the toxic shock syndrome (TSS). Most adults are colonized by *S. aureus* intermittently, whereas 10 to 20%have persistent colonization and about the same percentage are never found to harbor the organism. Colonization is influenced by both microbial and host factors as well as by the nature of the competing nonstaphylococcal flora. Carriage is more common among persons with frequent staphylococcal exposure and those with habitual or chronic disruption of cutaneous epithelial integrity. Thus, colonization rates are higher among health care workers, dialysis patients, patients with type 1 diabetes, injection drug users, persons infected with HIV, and individuals with chronic dermatologic conditions. After 2 weeks in a hospital, colonization rates rise to 30 to 50%, and colonizing strains are more likely to be resistant to antibiotics.

Colonization of mucocutaneous sites is an important risk factor for staphylococcal infection. For example, surgical wound infection following cardiothoracic surgery is up to 10 times more likely among patients who harbor *S. aureus* in the nares preoperatively than among those who do not. The vast majority of postoperative wound infections of all types are caused by a strain of *S. aureus* that was present in the nares before surgery. Furthermore, presurgical clearance of carriage with topical and systemic antibiotics decreases the incidence of postoperative staphylococcal infection, but it is not yet standard practice to screen and treat patients before surgery.

PATHOGENESIS AND HOST DEFENSE

S. aureus causes two types of syndrome: *intoxications* and *infections*. The clinical manifestations of intoxications are attributable to the action of one or a few secreted products of the microorganism (toxins), and these clinical features can be reproduced by administration of the toxin(s) in the absence of the microorganism. The toxin can be produced either in vivo (as inTSS or staphylococcal scalded skin syndrome) or in a suitable vector that subsequently delivers it to the host (as in staphylococcal food poisoning). Infections, in contrast, involve bacterial proliferation, invasion or destruction of host tissues, and -- in most cases -- local and systemic inflammatory responses by the host to these events. The ability of a microorganism to infect is predicated on its ability to produce certain products that enable it to survive and prosper in the host (*virulence factors*), and *S. aureus* is particularly well-armed in this regard.

Steps in Pathogenesis The pathogenesis of staphylococcal intoxications is straightforward and involves four steps: colonization by a toxigenic strain of the bacterium, toxin production, toxin absorption, and intoxication. The pathogenesis of invasive infections is more complex and the steps are less discrete. They include colonization, invasion of the bacterium across epithelial or mucosal barriers, adherence to materials in the extracellular matrix, evasion or neutralization of host defenses, and destruction of host tissues. For both intoxications and infections, the entire process is carefully orchestrated by the bacterium in response to specific environmental conditions.

Physical Preservation of Cellular Integrity Staphylococci are robust and adaptable organisms that can survive under relatively harsh environmental conditions. A rigid cell wall confers shape and strength to the organisms. The major component of the cell wall, *peptidoglycan*, is responsible for its physical properties. Disruption of peptidoglycan

cross-linking by cell wall-active antibiotics (b-lactams or glycopeptides) renders staphylococci susceptible to lysis mediated by endogenous peptidoglycan hydrolases (*autolysins*). The osmotolerance exhibited by *S. aureus* enables the organism to grow without microbial competition in foods of low water activity and so sets the stage for contamination of food by staphylococcal enterotoxins (SEs), which cause food poisoning.

Colonization Staphylococcal colonization of the nasal mucosa is mediated by adherence of cell-surface components to host molecules (e.g., mucin carbohydrate). Factors contributing to colonization of other surfaces, such as the vaginal mucosa, are poorly understood. After colonization, the production of certain staphylococcal toxins [toxic shock syndrome toxin 1 (TSST-1), exfoliative toxins, orSEs] can ensue under the appropriate environmental conditions. Colonization may be transient or persistent; the latter condition increases the likelihood that organisms will gain access to deeper tissues, beginning the process of infection.

Invasion and Adherence to the Extracellular Matrix Staphylococci generally cannot invade through intact epithelial surfaces, which represent the primary line of antistaphylococcal defense. Invasion is facilitated by a mechanical break in the epithelium or by plugging of a gland or hair follicle. Once the epithelial barrier is breached, colonization of host tissues is facilitated by adherence of *S. aureus* to molecules present either on host cell surfaces or in the extracellular matrix. Several staphylococcal surface proteins, including protein A, function as adhesins by binding extracellular matrix molecules. These proteins have been designated "microbial-surface components recognizing adhesive matrix molecules" and may adhere to fibrinogen, fibronectin, collagen, elastin, and other serum constituents.

Destruction of Host Cells and Alteration of the Host Microenvironment A number of products of *S. aureus* alter the host environment in a way that benefits the bacterium. *Coagulase* is a secreted enzyme that binds prothrombin and thereby causes the conversion of fibrinogen to fibrin; it may aid in the establishment of an environment within host tissues that is protected from cells of the immune system or from antibiotics. *S. aureus* produces a number of *lipases*, which may enhance the organism's survival in sebaceous areas of the human body. *Hyaluronidase* hydrolyzes hyaluronic acid, a mucopolysaccharide present in extracellular ground substance; its action may facilitate the spread of the organism through the extracellular matrix to adjoining tissues. *Staphylokinase*, *thermonuclease*, and *serine protease* are other extracellular enzymatic products that may play roles in pathogenesis.

S. aureus produces a number of membrane-active toxins that probably contribute to pathogenesis by damaging host cells, although their exact role in pathogenesis remains uncertain. These toxins include a-,b-, and d-hemolysins and the synergohymenotropic toxins (g-hemolysin and Panton-Valentine leukocidin).*a-Hemolysin* (a-toxin) is the prototypic pore-forming toxin; it inserts into the cell membrane, creating ion-conductive channels that destroy membrane integrity. The toxin is dermonecrotic on subcutaneous injection, induces proinflammatory changes in mammalian cells, and -- in animal models -- induces many findings seen in sepsis, including hypotension and thrombocytopenia. The *synergohymenotropic toxins* are a family of bicomponent toxins. Their name derives from the fact that their two components are tropic for cell membranes and are

synergistically active against them. Like a-toxin, the synergohymenotropic toxins are pore-forming toxins. *Panton-Valentine leukocidin* is most active against polymorphonuclear cells, monocytes, and macrophages. It is dermonecrotic to rabbit skin, and strains producing it are strongly associated with human furunculosis.

Evasion of Host Defense Once staphylococci have breached mucosal or epithelial barriers, the host's immune response is directed at containing and eliminating them, principally by polymorphonuclear recruitment and phagocytic killing. The bacteria fight back by cloaking antigenic determinants on their surface, by interfering with the function of opsonins, by directly killing the phagocytes, and by developing strategies to survive within them. The pyogenic abscess, the histologic hallmark of staphylococcal infection, represents the battlefield for this encounter, in which the microorganism survives in an environment in which leukocyte function is impaired and into which antibiotics penetrate poorly. Although the abscess may contain the spread of the bacteria, patients with abscesses are symptomatic and usually require surgical drainage for relief.

Some staphylococcal components and products are direct chemoattractants for polymorphonuclear leukocytes; others provoke the release of chemoattractant cytokines that recruit phagocytic cells to the infected area. Histologic sections of early lesions typically reveal a central focus of organisms surrounded by a zone of necrotic debris, which in turn is surrounded by a zone of viable inflammatory cells. The toxic action of staphylococcal leukocidin may in part explain the zone of necrosis. After several days, fibroblasts populate the margin of the abscess and there elaborate collagen, which creates a true capsule around the abscess.

Staphylococcal cell-wall peptidoglycan activates complement, which is an important opsonin in persons lacking antibody to staphylococcal surface components. Peptidoglycan also acts as a general stimulator of inflammatory cytokine release and may thereby contribute to sepsis, but it is weaker in this regard than gram-negative lipopolysaccharide. Opsonic antibodies specific for peptidoglycan or capsule mediate phagocytosis by polymorphonuclear leukocytes and macrophages in vitro, although the role of antibody in vivo is less certain. There is considerable interstrain variation in susceptibility to opsonization, and acquired protective immunity to staphylococcal infection is generally thought *not* to develop. (In contrast, acquired antibody-mediated immunity to systemic staphylococcal intoxications does occur; e.g.,>90% of healthy adults have protective antibody to the most commonTSStoxin,TSST-1.) Mitigating against opsonization is *protein A*, an important cell-surface component; protein A binds the Fc portion of IgG subclasses 1, 2, and 4 and thereby interferes with antibody-mediated opsonization. Polysaccharide capsule, which is produced by most clinical isolates, may also interfere with opsonization.

S. aureus has numerous defenses against killing after phagocytosis. Intracellular bacteria are usually killed rapidly by the oxidative burst within the phagosome, but staphylococcal catalase, which converts hydrogen peroxide to oxygen and water, detoxifies oxygen radicals and potentiates intracellular survival. Staphylococci are also taken up by nondedicated phagocytes, such as endothelial cells and osteoblasts, and may survive within them. One strategy for intracellular survival is the genesis of small-colony variants (SCVs). These slow-growing cells exhibit alterations in electron transport and generally produce reduced amounts of virulence determinants such as

a-toxin and coagulase. They are relatively resistant to cell wall-active antibiotics and aminoglycosides and are capable of persisting intracellularly for extended periods, thereby evading host defenses. Their slow growth also makes them less likely to be recovered in the clinical laboratory and then targeted for treatment. Their existence may in part explain the startling capacity of certain *S. aureus* infections (e.g., chronic osteomyelitis) to recrudesce after years of dormancy and the difficulty of curing infections in intravascular sites and bone. Prolonged exposure to aminoglycosides or to trimethoprim-sulfamethoxazole appears to be a risk factor for the development of SCVs.

Hosts at particular risk for staphylococcal infection include those with frequent or chronic disruptions in epithelial or mucosal integrity; those with disordered leukocyte chemotaxis, such as patients with the Chediak-Higashi or Wiskott-Aldrich syndrome; those whose phagocytes are defective in oxidative killing, as in chronic granulomatous disease; those with neutropenia or acquired functional deficiencies (e.g., deficiencies induced by exogenous glucocorticoids); and those with indwelling foreign bodies, which provide a matrix for staphylococcal adherence and biofilm formation and seriously impair phagocytic function. Patients with disorders of immunoglobulin or complement (especially C1-C4 deficiencies) are also at increased risk for *S. aureus* infection.

Superantigens The superantigens are V_b-restricted T cell mitogens: they bind directly and without prior processing to major histocompatibility class II molecules on the surface of antigen-presenting cells, thereby stimulating T cells on the basis of the sequence of the variable region of the b chain of the T cell receptor rather than on the basis of the epitope specified by this receptor. Accordingly, a superantigen may be able to stimulate>10% of the T cells in a given individual -- a percentage much higher than the ~1 in 10_6cells stimulated by conventional antigens. This massive T cell stimulation provokes an exuberant and dysregulated immune response characterized by the release of the cytokines interleukins 1 and 2, tumor necrosis factor, and interferon g.TSS is a manifestation of this process, as some aspects of septic shock may be as well. *S. aureus* produces a number of superantigens, including theSEs,TSST-1, and possibly the exfoliative toxins (ETs). Ten SEs have been identified to date, several of which are common causative agents of staphylococcal food poisoning. The mechanism by which the SEs cause vomiting is uncertain but may involve direct neural stimulation of the autonomic nervous system rather than a local effect on the gastrointestinal mucosa. The superantigenic properties of TSST-1 and the SEs are thought to explain their ability to cause TSS, although the exact mechanism by which they craft the various clinical manifestations of TSS is uncertain. There is conflicting evidence as to whether theETs, which cause scalded skin syndrome, are superantigens; structural data suggest that they may instead be related to the serine proteases.

Genetic Regulation of Virulence Genes The production of virulence factors by bacteria is typically tightly and coordinately regulated by genetic apparatuses that sense and respond to environmental cues. Such coordinate regulation enables an organism to rapidly tailor its repertoire of proteins to suit its changing needs, either as it passes between microenvironments or as the environment evolves around it. Many of the staphylococcal exoproteins are typical virulence factors in this regard. For example, a-, b-, andd-hemolysins,TSST-1, staphylococcal enterotoxin B, serine protease, and thermonuclease are all produced during the late logarithmic phase of growth in batch culture, at a time when nutrients become scarce and cell density reaches saturation.

Their production is coordinately regulated and occurs reciprocally to that of the cell wall-associated staphylococcal proteins protein A and coagulase. Several genetic regulatory loci modulate these events, as do specific environmental conditions that presumably operate through those genetic loci. Foreign materials that increase the risk ofTSS and conditions in food that predispose to staphylococcal food poisoning probably do so by presenting microenvironments that stimulate production of the relevant toxins. Similar events are undoubtedly operative within the environment of host tissues during infection, even in the absence of a foreign body.

Several distinct genetic loci regulate exoprotein production in *S. aureus*, the best-studied of which are *agr* (accessory gene regulator) and *sar* (staphylococcal accessory regulator). Both affect gene expression primarily at the level of transcription, and both activate the expression of secreted proteins and diminish the expression of cell wall-associated proteins during the late logarithmic phase of bacterial growth. Data suggest that *agr* may function primarily as a "quorum sensor," an apparatus that informs the bacterium of the density of staphylococci in its environment. Exoprotein regulation in *S. aureus* apparently results from a complex interplay of environmental factors and gene products.

STAPHYLOCOCCAL INTOXICATIONS

Toxic Shock Syndrome TSS is an acute, life-threatening intoxication characterized by fever, hypotension, rash, multiorgan dysfunction, and desquamation during the early convalescent period (Fig. 139-1,Fig. 139-CD6). The disease was first characterized in 1978 but gained notoriety in 1980 upon the recognition of many cases among menstruating women. It is a relatively uncommon illness, with a reported annual incidence (among menstruating women) of 1 case per 100,000; it is likely, however, that the disease is substantially underreported, especially nonmenstrual cases. About half of all cases occur in settings other than menstruation and are distributed among individuals of both sexes and all ages. Menstrual and nonmenstrual cases are clinically indistinguishable. Among cases reported to the Centers for Disease Control and Prevention between 1985 and 1994, the minimum case-fatality rate was 2.5% for menstrual cases and 6.4% for nonmenstrual cases.

TSSis caused by any of several related exoproteins produced by *S. aureus*.TSST-1is the toxin most frequently implicated (causing virtually all menstrual cases), and staphylococcal enterotoxin B is the second most frequent. For illness to develop, an individual must be colonized or infected with a toxigenic strain of *S. aureus* and must lack a protective level of antibody to the toxin made by that strain. That TSS is primarily a disease of the young reflects the fact that >90% of adults have antibodies to TSS toxins.

Menstruation remains the most common setting forTSS, but the disease can also complicate the use of barrier contraceptives and childbirth. Moreover, nonmenstrual TSS can ensue after superinfection of skin lesions of many types, including burns, insect bites, varicella lesions, and surgical wounds. Postoperative disease can develop from hours to weeks after any surgical procedure. Staphylococcal superinfection after influenza is a common setting for TSS, as is acute sinusitis. Overt infection with *S. aureus* is not required for the development of TSS; mere colonization with a toxigenic

strain may suffice. Accordingly, the primary site of toxin production in TSS may appear entirely benign.

TSSremains a clinically defined syndrome (Table 139-1). Patients meeting the case definition are severely ill, although milder forms of "staphylococcal toxin-mediated disease" do occur. The illness usually begins precipitously, with high fever and a complex of symptoms that may include nausea, vomiting, abdominal pain, diarrhea, muscular pain, sore throat, and headache. Dizziness is common as a manifestation of orthostatic or frank hypotension. The characteristic macular erythroderma develops over the first 2 days of illness. It is usually generalized but is sometimes locally confined; it can be evanescent or persistent. The patient's mental status is often abnormal to a degree that is out of proportion to the degree of hypotension. Conjunctival suffusion (Fig. 18-CD3), pharyngeal injection, and peripheral edema are evident in many cases; a so-called strawberry tongue develops in up to half of patients. In menstrual disease, the vaginal mucosa may be erythematous and a purulent vaginal discharge may be present, but these findings are not universal. Common laboratory abnormalities include azotemia, hypoalbuminemia, hypocalcemia, hypophosphatemia, creatine phosphokinase elevation, leukocytosis or leukopenia with a left shift, thrombocytopenia, and pyuria.

The early signs and symptoms ofTSSresolve within the first few days of illness, after which complications of organ hypoperfusion, such as renal and myocardial dysfunction, fluid overload, and adult respiratory distress syndrome, dominate the picture. After about a week of illness, desquamation begins with superficial flaking of the skin of the torso, face, and extremities, which may be followed by full-thickness desquamation of the palms, soles, and digits. Common late sequelae include peripheral gangrene, reversible nail and hair loss, muscle weakness, and lingering asthenia and neuropsychiatric dysfunction.

The differential diagnosis ofTSS is that of a severe febrile exanthem with hypotension. In the setting of menstruation accompanied by purulent vaginal discharge, the diagnosis may be obvious. The challenge is to recognize the less obvious cases, in which the exanthem may be fleeting, multiorgan dysfunction may be subtle, or (in nonmenstrual cases) a primary site of infection may be inapparent. Recovery of *S. aureus* supports the diagnosis, as does demonstration of toxin production by the strain and serologic susceptibility to the toxin. Other diagnoses to consider include streptococcal TSS, staphylococcal scalded skin syndrome, Kawasaki syndrome, Rocky Mountain spotted fever, leptospirosis, meningococcemia, gram-negative sepsis, exanthematous viral syndromes, and severe drug reactions. Staphylococcal TSS and streptococcal TSS (Chap. 140) can be clinically indistinguishable.

Treatment ofTSSinvolves drainage of the site of toxin production, aggressive fluid resuscitation, and administration of antistaphylococcal antibiotics. Recent surgical wounds should be explored and irrigated, even when signs of inflammation are lacking; foreign bodies should be removed. Pressors should be used for sustained hypotension that is unresponsive to fluids. Electrolyte abnormalities, particularly hypocalcemia and hypomagnesemia, must be corrected. Penicillinase-resistant penicillins (nafcillin, oxacillin) and first-generation cephalosporins have been widely used in TSS. A growing body of clinical and laboratory evidence indicates, however, that a protein synthesis

inhibitor, such as clindamycin, might be superior to b-lactam agents. The authors recommend therapy with clindamycin (900 mg intravenously every 8 h), either alone or in combination with a b-lactam antibiotic [or vancomycin for patients perceived to be at risk for infection with methicillin-resistant *S. aureus* (MRSA)]. For a seriously ill patient in whom the diagnosis of TSS is uncertain, broad-spectrum antibiotics may be appropriate until the diagnosis is confirmed. A 14-day course of therapy -- some of which may be administered perorally -- is reasonable. Patients whose illness is severe enough to warrant vasopressors, who require mechanical ventilation, who have worsening renal function, or who have an undrainable focus of infection should be treated with intravenous immunoglobulin, which contains high levels of neutralizing antibody to TSS toxins. A single infusion of 400 mg/kg generates a protective level of antibody toTSST-1that persists for weeks. Glucocorticoids have not been shown to be of significant benefit.

Because vaginal staphylococcal carriage can be persistent or recurrent and because in more than half of all casesTSS does not elicit immunity, recurrent menstrual TSS is a concern; recurrent nonmenstrual TSS has also been reported. The risk of recurrent illness can be assessed by tests for seroconversion toTSST-1. Women who do not seroconvert after acute illness (or who are not tested for antibody) should refrain indefinitely from using tampons or barrier contraceptives.

Staphylococcal Scalded Skin Syndrome This syndrome encompasses a range of cutaneous diseases of varying severity caused byET-producing strains of *S. aureus*. The most severe form of staphylococcal scalded skin syndrome is termed *Ritter's disease* in newborns and *toxic epidermal necrolysis* (TEN) (Fig. 18-CD5) in older individuals. Milder and more common forms include *pemphigus neonatorum* and (in children and adults) *bullous impetigo* (see "Skin and Soft Tissue Infections," below). Persons>5 years old rarely develop staphylococcal TEN; those who do almost invariably have underlying disease (renal insufficiency, systemic immunosuppression). The rarity of the syndrome in adults has been ascribed to acquired immunity to the inciting toxins, to enhanced renal clearance of the toxins, and perhaps to diminished sensitivity to the action of the toxins.

StaphylococcalTEN, or Ritter's disease, often begins with a nonspecific prodrome. The acute phase starts with the onset of an erythematous rash. The erythema begins in the periorbital and perioral areas and spreads to the trunk and centrifugally to the limbs. Pastia's lines may be apparent. The skin has a sandpaper texture and is often tender. Periorbital edema is common. In infants and children, fever and irritability or lethargy are common, but systemic toxicity is not. Within hours or days, wrinkling and sloughing of the epidermis begin; sloughing can be provoked by gentle stroking of the skin (Nikolsky's sign), even in areas that appear uninvolved. The denuded areas are red and glistening but not purulent, and staphylococci are not present. Exfoliation may continue in large sheets or in ragged snippets of tissue. Large, flaccid bullae may develop. As in thermal burns, significant fluid and electrolyte loss can occur at this stage, as can secondary infection. Within about 48 h, the exfoliated areas dry and secondary desquamation begins. The entire illness resolves within about 10 days. Mortality (from hypovolemia or sepsis) is ~3% among children but approaches 50% among adults. Treatment includes the administration of antistaphylococcal agents, fluid and electrolyte management, and local care to the denuded skin.

Staphylococcal Food Poisoning Between 2 and 6 h after ingestion of contaminated food, staphylococcal food poisoning begins abruptly with nausea, vomiting, crampy abdominal pain, and diarrhea. The diarrhea is usually noninflammatory and is of lower volume than that in cholera or toxigenic *Escherichia coli* infection. Fever and rash are absent, and the patient is neurologically normal. The majority of cases are self-limited and resolve between 8 and 24 h after onset. In severe cases, hypovolemia and hypotension can develop. Although most cases probably do not come to medical attention and are not diagnosed, staphylococcal intoxication is the second or third leading cause of diagnosed food poisoning in the United States.

Food poisoning is caused by the ingestion of any of theSEs, which are produced by *S. aureus* in contaminated food before it is eaten. The presence of SEs in the food vector before its consumption accounts for the short incubation period of this illness. The SEs are heat stable, thus tolerating cooking conditions that kill the organisms that produced them. The disease has a high attack rate and is somewhat more common during the summer than at other times of the year. Processed meats and custard-filled baked goods are common food vectors, perhaps because staphylococci can tolerate conditions of high protein, salt, or sugar and so grow without competition in these environments. The most important epidemiologic risk factor in outbreaks of this disease is the ingestion of food that has been left at warm temperatures for prolonged periods, thereby allowing toxin production to occur before consumption. Contaminated preparation equipment and poor personal hygiene of food handlers are frequently implicated as well.

STAPHYLOCOCCAL INFECTIONS

S. aureus causes invasive disease by breaching host defense barriers, often after disruption or dysfunction of such barriers. The most common portals of entry leading to staphylococcal invasion are the skin and associated structures. A nidus for staphylococcal colonization and subsequent invasion is provided by chronic skin conditions, such as eczema and psoriasis; acute breaks in the skin, such as puncture wounds (Fig. 139-CD1), abrasions, and lacerations; and abnormalities of skin appendages, such as hair follicles and nails (Fig. 139-CD2). Colonization of the nasopharynx predisposes to respiratory tract infection after aspiration, obstruction (e.g., of a bronchus by carcinoma or of sinus ostia by trauma, edema, or polyps), or impaired ciliary function (e.g., in chronic bronchitis or acute viral infection). Intubation of the trachea provides a conduit by which upper respiratory flora, including pathogens such as *S. aureus*, can reach the lower respiratory tract.

Skin and Soft Tissue Infections *S. aureus* is the most common etiologic agent of skin and soft tissue infections (Chap. 128). Such infections are usually caused by endogenous flora -- i.e., strains of *S. aureus* that are harbored in the nares or other sites of colonization. Infection may represent a primary pathologic process, with direct invasion of skin and adjacent tissues, or a secondary process complicating preexisting lesions.

Staphylococcal infections originating in hair follicles range in severity from trivial to life-threatening. *Folliculitis* (Fig. 128-CD3) is an infection of follicular ostia; the

appearance is that of a domed yellow pustule with a narrow red margin. Infection is often self-limited, although healing may be hastened by topical antiseptics and more severe cases may benefit from topical or systemic antibiotics. A *furuncle* (often called a *boil*;Fig. 139-CD3) is a deep-seated necrotic infection of a hair follicle, most often located on the buttocks, face, or neck. Furuncles are painful and tender, and their appearance is often accompanied by fever and constitutional symptoms. Surgical drainage and systemic antibiotic treatment may hasten recovery and limit scar formation. Deep infection of a group of contiguous follicles is called a *carbuncle* (Fig. 139-CD4). This type of painful necrotic lesion occurs most commonly on the back of the neck, shoulders, hips, and thighs, typically in middle-aged or elderly men. There is intense inflammation of surrounding and underlying connective tissue, and the infection may be complicated by bacteremia. Surgical drainage and systemic antibiotic administration are indicated. *S. aureus* is also the most common cause of acute *paronychia*, infection of the lateral nail folds.

S. aureus causes *bullous impetigo* (Fig. 128-CD1), a superficial cutaneous disorder occurring predominantly in children. An epidermal split caused byETresults in the formation of 1- to 2-cm bullae containing neutrophils and organisms. *Nonbullous impetigo* is most often caused byb-hemolytic streptococci, but *S. aureus* can secondarily infect impetiginous lesions. Treatment of impetigo with a topical antibiotic, such as mupirocin, may suffice for mild and localized infection, whereas systemic therapy is indicated for widespread or severe disease or for infection accompanied by lymphadenopathy.

Cellulitis, a spreading infection of subcutaneous tissue, is occasionally caused by *S. aureus* (Fig. 139-CD5), butb-hemolytic streptococci are more common agents of this disease (Chap. 140). Secondary infection of surgical and traumatic wounds is more likely to be staphylococcal in etiology than is cellulitis arising from minor or inapparent breaks in the skin, and empiric treatment directed against both *S. aureus* and streptococci is reasonable in these settings. *Erysipelas*, the hallmark of which is a well-demarcated raised border, is a more superficial infection of the dermis and subcutaneous tissue; it is usually caused by group A streptococci and only rarely, if ever, by *S. aureus*.

Respiratory Tract Infections *S. aureus* can gain access to the lung parenchyma by two routes: aspiration of upper respiratory flora and hematogenous spread. Staphylococcal pneumonia is a relatively uncommon but severe infection, characterized clinically by chest pain, systemic toxicity, and dyspnea and pathologically by intense neutrophilic infiltration, necrosis, and abscess formation. *Pleural empyema* is a common complication and increases the already-considerable morbidity associated with this infection. Only rarely does *S. aureus* cause pneumonia without predisposing epidemiologic or host factors that favor colonization of the respiratory tract and/or that impair defense mechanisms. Residence in a chronic care facility, recent use of antibiotics, and hospitalization favor colonization -- and hence respiratory tract infection -- with *S. aureus*. Staphylococcal pneumonia most commonly follows tracheal intubation of a hospitalized patient or viral infection of the respiratory tract. Influenza virus is known both to increase respiratory colonization by *S. aureus* and to impair ciliary function (and therefore clearance of staphylococci). In a classic scenario, a patient (often elderly and/or institutionalized) develops a flulike respiratory illness and then, after several

days, deteriorates rapidly, with high fever, dyspnea, productive cough, and obtundation. The diagnosis of staphylococcal pneumonia is readily established by Gram's staining of expectorated sputum, which reveals abundant clusters of gram-positive cocci.

Hematogenous seeding of the lungs with *S. aureus* follows embolization from an intravascular nidus of infection. Common settings for septic pulmonary embolization are right-sided endocarditis (especially common among injection drug users) and septic thrombophlebitis, which is most often a complication of an indwelling venous catheter. Pneumonia is heralded by the acute onset of pleuritic chest pain and dyspnea; although diagnostic sputum may be lacking, a chest radiograph typically shows multiple nodular infiltrates, providing an important clue to both the diagnosis and the pathogenesis of disease.

Although not typically considered in the differential diagnosis of sore throat, *S. aureus* is occasionally isolated as the dominant organism from patients (especially children) with exudative *pharyngitis*. The illness may be accompanied by a scarlatiniform rash and may result in systemic toxicity (like that seen inTSS). Staphylococcal *tracheitis* may be diagnosed in children who have systemic toxicity and positive respiratory cultures but who lack pulmonary infiltrates. *S. aureus* is a prominent cause of *chronic sinusitis*, typically following the selection pressure of antimicrobial regimens that lack activity against this organism. Finally, *S. aureus* is a major etiologic agent of *sphenoid sinusitis*.

Infections of the Central Nervous System *S. aureus* gains access to structures of the central nervous system by hematogenous spread or by direct extension from contiguous structures. This organism is a prominent cause of *brain abscess*, especially as a result of embolization during mitral or aortic valve endocarditis. Such abscesses are often multiple, small, and scattered diffusely throughout the brain. Brain abscess can also develop by direct extension from frontoethmoid or sphenoid sinuses or from infected soft tissue after surgery or penetrating trauma. Patients with staphylococcal brain abscesses are more likely to have fever, meningismus, and other signs of infection than are patients with anaerobic bacterial or mixed-etiology brain abscesses. Purulent *meningitis* may accompany staphylococcal brain abscess or may develop during bacteremia in the absence of demonstrable abscesses.

S. aureus is the organism most likely to cause a variety of other space-occupying, suppurative intracranial infections. *Subdural empyema* usually develops by direct extension of osteomyelitis of the skull, after surgery or trauma, or in the setting of sinusitis. This condition may be accompanied by meningitis, epidural abscess, or intracranial phlebitis. The cardinal features of subdural empyema are fever, headache, vomiting, and signs of meningeal irritation. As the infection progresses, cerebral edema, often with infarction, may ensue and may be accompanied by alteration in mental status, seizures, and focal neurologic signs, which sometimes progress rapidly. The diagnosis should be suspected in any patient with meningeal signs and focal neurologic findings. Magnetic resonance imaging (MRI) is the diagnostic procedure of choice; lumbar puncture is contraindicated because of the danger of brainstem herniation. Early surgical drainage and treatment with an antibiotic that penetrates well into the central nervous system may be curative, although neurologic sequelae are not uncommon.

S. aureus is the most common cause of *spinal epidural abscess*, which develops most

often in association with vertebral osteomyelitis or diskitis. The diagnosis is suggested by some combination of fever, back pain, radicular pain, lower-extremity weakness, and bowel or bladder dysfunction, but the presentation is often subtle, resulting in delayed diagnosis. Patients may report only difficulty in walking or weakness, and objective findings may initially be lacking. The principal danger is the potential for necrosis of the spinal cord by compression and/or venous involvement. Early recognition of this condition is critical if long-term sequelae, such as paraplegia, are to be averted. AnMRI scan of the spine establishes whether or not an epidural collection is present. Fluoroscopy- or computed tomography (CT)-guided needle aspiration may confirm the diagnosis, but an open procedure offers a higher yield. Prompt surgical decompression by laminectomy is often required for preservation of neurologic function, although a trial of antibiotic therapy alone may be considered if no focal neurologic deficits are detected at the time of diagnosis. Any deterioration in neurologic status should prompt urgent surgical intervention. The pathogenesis of *intracerebral epidural abscess* is similar to that of subdural empyema, with staphylococcal infection usually following sinusitis, craniotomy, or trauma. Clinical manifestations reflect the anatomy of the underlying osteomyelitis plus the mass effect of the abscess, cerebral edema, and (often) secondary involvement of the subdural space. Emergent surgical drainage is usually required for cure.

Finally, *S. aureus* is the most common cause of *septic intracranial thrombophlebitis*, typically following sinusitis, mastoiditis, or soft tissue infection of the face. Clinical manifestations reflect the underlying condition and the anatomic structures in contiguity with the infected vein or sinus. Focal neurologic deficits, particularly of cranial nerve function, are characteristic of cavernous sinus thrombosis. Sagittal sinus thrombosis may be manifested by leg and arm weakness and by altered mental status; infections of the lateral and petrosal sinuses also produce characteristic clinical syndromes. Intracranial phlebitis may accompany epidural abscess, subdural empyema, and meningitis and is sometimes clinically indistinguishable from other types of intracranial infection.MRI is the diagnostic procedure of choice.

Urinary Tract Infections *S. aureus* is an uncommon cause of urinary tract infection. Ascending infection almost exclusively follows instrumentation of the bladder (e.g., cystoscopy or placement of an indwelling catheter). Under other circumstances, the presence of *S. aureus* in the urine, even in low numbers, suggests staphylococcal bacteremia and hematogenous seeding of the kidneys, with or without abscess formation; staphylococcal endocarditis should be considered in this setting.

Endovascular Infections *S. aureus* is the most common cause of acute bacterial *endocarditis* of both native and prosthetic valves (Chap. 126). The organism may infect previously normal valves. Staphylococcal endocarditis presents as an acute febrile illness, rarely of more than a few weeks' duration; complications such as meningitis, brain or visceral abscess, peripheral vascular embolization, valvular incompetence with heart failure, myocardial abscess, and purulent pericarditis have often developed by the time a patient seeks medical attention. The valves most commonly involved are the mitral and/or the aortic except among injection drug users, in whom infection of the tricuspid valve is most common.

The diagnosis of endocarditis is suggested by a heart murmur and the presence of

conjunctival hemorrhages, subungual petechiae, or purpuric lesions on the distal extremities; it is readily confirmed by demonstration of high-grade bacteremia and echocardiography showing valvular vegetations. Echocardiography also helps establish which valve(s) are infected, the degree of valvular dysfunction or destruction, the quality of left ventricular function, and the presence or absence of annular or myocardial abscess. Transesophageal echocardiography (TEE) is more sensitive than transthoracic echocardiography (TTE) in detecting vegetations and abscesses, but it is also more invasive. TEE need not be performed in all cases of proven or suspected endocarditis. This approach is useful, however, in the setting of persistent bacteremia or fever (to evaluate for abscess) and in anticipation of surgery if TTE has not been sufficiently informative.

Native valve staphylococcal endocarditis carries a high mortality rate (on the order of 40%) and mandates prompt initiation of antimicrobial therapy. In addition to blood cultures and echocardiography, evaluation may includeCT of the head and lumbar puncture if brain abscess or meningitis is suspected; a radionucleotide study if osteomyelitis is suspected; and abdominal CT if visceral abscess is suggested by abdominal pain or persistent fever or bacteremia. Indications for valve replacement are the same as those in endocarditis caused by other organisms: persistent bacteremia (beyond 5 to 7 days of therapy), valvular dysfunction resulting in heart failure, perivalvular or myocardial abscess, or recurrent embolization. Early consultation with a cardiothoracic surgeon is advisable in all cases because of the high proportion of patients with *S. aureus* endocarditis (around half) who develop one of these complications and therefore require valve replacement, often urgently. Once there is an indication for removal of an infected valve, nothing is gained and much can be lost by delaying surgery. *S. aureus* infection of a prosthetic valve (as an early or a late complication of valve replacement) almost always requires surgery for one of the above indications.

Right-sided endocarditis, which most often develops in association with injection drug use or venous catheterization, is frequently complicated by septic pulmonary emboli but otherwise carries a lower rate of serious complications than left-sided disease. Surgery is rarely required for right-sided infection. A relatively short course of parenteral combination therapy (2 weeks) may be curative, and the prognosis is relatively good.

The propensity of *S. aureus* to adhere to and infect damaged tissues makes it the foremost cause of endovascular infections other than endocarditis. Vascular infection is a consequence of hematogenous seeding of damaged vessels, especially large arteries with atheromatous plaques, resulting in the development of a mycotic aneurysm. It may also develop by spread from a contiguous focus of infection (e.g., after vascular surgery), often resulting in an infected pseudoaneurysm, or by contamination of an intravascular device, resulting in septic phlebitis. Staphylococcal infection of an atherosclerotic artery (most commonly the abdominal aorta or iliac arteries), which may be aneurysmal to begin with, is a potentially catastrophic event. Such infections are associated with high-grade bacteremia, may result in rupture and massive hemorrhage, and require surgical resection and bypass of the infected vessel. Septic phlebitis is also associated with high-grade bacteremia and systemic toxicity but is less likely than arteritis to result in rupture. Persistent bacteremia suggests the need for surgical removal of infected thrombus or vein, but the technical difficulty of such surgery may

warrant an attempt at cure with antibiotics and anticoagulants alone.

Bacteremia A classic clinical scenario is that of a patient presenting with *S. aureus* bacteremia but without a demonstrable primary site of infection. Even in the absence of a changing murmur, peripheral embolic lesions, or a diagnostic echocardiogram, the possibility of endocarditis must be considered carefully in this situation. It is often hard to differentiate between endocarditis and bacteremia arising from another primary site; in addition, *S. aureus* may secondarily seed endovascular sites, such as heart valves or atheromatous plaques. Several criteria increase the likelihood that a patient has endocarditis as opposed to simple bacteremia: community (vs. nosocomial) acquisition of infection, absence of an apparent primary site of infection, and evidence of metastatic infection. The evaluation of a bacteremic patient should be tailored to the individual but may include an abdominalCT scan and a bone scan or gallium scan to detect an occult visceral abscess or osteomyelitis.TEE has demonstrated valvular abnormalities suggestive of endocarditis in up to one-fourth of bacteremic patients who lack clinical orTTEevidence of endocarditis. This finding has prompted some authorities to recommend TEE for all patients with staphylococcal bacteremia. The authors favor performance of this test for patients with persistent fever or bacteremia.

Complications of *S. aureus* bacteremia include abscesses of abdominal viscera, brain abscess, meningitis, septic arthritis, osteomyelitis, epidural abscess, and mycotic aneurysm. High-grade or persistent bacteremia mandates a thorough evaluation for these complications, even if a primary site of infection has been identified. The reported mortality rate for staphylococcal bacteremia ranges from 11 to 43%, with catheter-related infections carrying lower rates of complications and mortality than noncatheter infections.

Musculoskeletal Infections *S. aureus* is the most common cause of *acute osteomyelitis* (Chap. 129) in adults and one of the leading causes in children. Acute osteomyelitis develops as a result of either hematogenous seeding of bone (especially damaged bone) or direct extension from a contiguous focus of infection. The most common sites of hematogenous staphylococcal osteomyelitis in adults are the vertebral bodies; in children, the highly vascular metaphyses of long bones are most often affected. Acute osteomyelitis in adults usually presents with constitutional symptoms and pain over the affected area, often developing over several weeks or months. Leukocytosis and an elevated erythrocyte sedimentation rate or C-reactive protein level are laboratory clues to the diagnosis. Bacteremia may or may not be demonstrable. Four weeks of parenteral antibiotic therapy is usually curative.

S. aureus is also a prominent cause of *chronic osteomyelitis*, which develops at sites of previous surgery, trauma, or devascularization. In light of the hectic pace of many infections caused by *S. aureus*, chronic staphylococcal osteomyelitis can be impressively indolent; the infection may be asymptomatic for years or even decades, only to reawaken spontaneously and cause pain, sinus tract formation, and purulent drainage. A plain film of the affected area reveals bony destruction. The staphylococcal etiology of infection is best established by biopsy and culture of bone, as cultures of superficial or sinus tract drainage may yield misleading results. Cure requires surgical debridement of necrotic bone followed by a prolonged course of antibiotics.**For consensus definitions of acute and chronic osteomyelitis, see Chap. 129.*

A special form of osteomyelitis is that associated with prosthetic joints or with internal or external fixation devices. Pain, fever, swelling, and decreased range of motion are cardinal features of an infected prosthesis. A plain film may suggest loosening of the prosthesis, often as radiolucency at the interface between bone and cement. *S. aureus* osteomyelitis associated with a prosthesis is infrequently cured by antibiotics alone. Persistent sepsis, persistent bacteremia, and clinical or radiologic evidence of loosening are absolute indications for removal of the prosthesis. *S. aureus* infection of fixation devices requires their removal, although this procedure may occasionally be delayed long enough to allow healing of the underlying fracture. Late relapses after apparent medical cure are not uncommon. A strategy of microbial suppression with oral antibiotics after a course of high-dose parenteral therapy is occasionally employed when removal of hardware is deemed too aggressive a measure for a particular patient.

S. aureus is a major cause of *septic arthritis* in adults (Chap. 323). Predisposing factors include injection drug use, rheumatoid arthritis, use of systemic or intraarticular steroids, penetrating trauma, and joints previously damaged by trauma or disease. Knees, hips, and sacroiliac joints are most frequently infected. In addition to parenteral antibiotics, cure requires either repeated joint aspirations -- the end points being sterilization of the joint space, a decrease in the number of leukocytes in the joint aspirate, and no reaccumulation of fluid -- or open or arthroscopic debridement and drainage. Failure to adequately drain joints infected with *S. aureus* poses a risk of permanent loss of function. *S. aureus* is also the most common cause of *septic bursitis* (Chap. 325), which most often involves bursae of the elbows, knees, and shoulders. As in arthritis, adequate drainage (via repeat aspiration, placement of a drain, or open debridement) hastens recovery and minimizes loss of function.

S. aureus infection of muscle (*pyomyositis*;Chap. 128) is relatively uncommon in temperate climates; *psoas abscess* is the most common such infection. The psoas muscle is seeded either hematogenously or by direct extension from the site of vertebral osteomyelitis; the results are pain upon extension of the hip and fever. Although formerly a cause of fever of unknown origin, psoas abscess is now relatively easy to diagnose by abdominalCT orMRI. Psoas abscesses are occasionally amenable to drainage via a percutaneous catheter; if not, then surgical drainage is indicated. For reasons that are not well understood, most other cases of staphylococcal pyomyositis occur in the tropics (tropical pyomyositis); in the United States, pyomyositis is seen most often in patients with underlying conditions such as diabetes mellitus, alcoholism, immunosuppressive therapy, and hematologic malignancy.

DIAGNOSIS

The diagnosis of *S. aureus* infection is generally straightforward and is based on the isolation of the organism either from purulent material or from a normally sterile body fluid. Rarely should *S. aureus* growing from even a single blood culture be considered a contaminant. Clinical samples require no special transport media to preserve the viability of the organisms. Gram's staining of purulent material from a staphylococcal abscess invariably reveals abundant neutrophils and intra- and extracellular gram-positive cocci, which may be found singly or in pairs, tetrads, or clusters. *S. aureus* grows readily on standard laboratory media. Colonies that are catalase-positive

and coagulase- or thermonuclease-positive are identified presumptively as *S. aureus*. Commercial kits are also available for the identification of gram-positive cocci and are generally reliable for identification of *S. aureus*.

The diagnosis of staphylococcal intoxications (such asTSS) may be more difficult and may in fact rely entirely on clinical data. The contribution of the laboratory may be confirmatory -- for example, the demonstration of seroconversion toTSST-1following a compatible illness, the demonstration of toxin production in vitro by a strain isolated from a patient, or the detection ofSE in a food sample.

TREATMENT

The essential elements of therapy for staphylococcal infections are drainage of purulent collections of pus, debridement of necrotic tissue, removal of foreign bodies, and administration of antimicrobial agents. The importance of adequate drainage cannot be overemphasized; all but the smallest of staphylococcal abscesses require drainage for cure. In skin and soft tissue infections, surgical drainage is occasionally all that is required for cure. It is very difficult to eradicate *S. aureus* infection in the presence of a foreign body, such as a piece of orthopedic hardware, an intravascular catheter or other device, or a pacemaker. For example, patients with catheter-associated bacteremia who are treated with antibiotics but do not have their catheters removed have been found to be six times more likely to experience a relapse or to die of their infection than are patients whose catheters are removed. Only under extraordinary circumstances should an attempt be made to cure such infections without removal of foreign material or debridement of necrotic tissue.

Antimicrobial Resistance The relentless spread of antibiotic resistance among strains of *S. aureus* is one of the great challenges facing clinicians today. Within 4 years of the introduction of penicillin G into clinical practice in 1941,b-lactamase-mediated resistance to penicillin was reported. As additional antibiotics became available in the 1950s, resistance rapidly emerged to them as well. Bacterial killing byb-lactam antibiotics depends on binding of the drugs to penicillin-binding proteins (PBPs), a group of transpeptidases that catalyze the terminal steps in peptidoglycan assembly. *S. aureus* normally produces four PBPs, all of which are inhibited by b-lactam antibiotics and several of which are essential for bacterial integrity and multiplication. Penicillin resistance in *S. aureus* is largely due to bacterial production of b-lactamase, a serine peptidase that enzymatically degrades the b-lactam ring of penicillin, thereby inactivating the drug before it can interact with the PBPs. In most communities,>90% of *S. aureus* strains produce b-lactamase and hence are resistant to penicillin.

Methicillin, the firstb-lactamase-stable semisynthetic penicillin, was introduced in 1960; it took only 1 year, however, for anMRSAstrain to be isolated. Classic methicillin resistance is encoded by the methicillin resistance determinant (*mec*), a 30- to 50-kb transposon-like segment of DNA that is present in MRSA strains and absent from sensitive strains. The *mecA* gene encodes a variantPBPcalled *PBP2¢* or *PBP2a*. PBP2¢ has reduced affinity forb-lactam antibiotics and can substitute for the essential PBPs if they have been inactivated byb-lactams. MRSA strains are resistant to the action of all b-lactam antibiotics, including penicillins, cephalosporins, and carbapenems. Since the early 1980s, these strains have tended to be resistant to most

other antibiotics as well, including chloramphenicol, tetracyclines, and macrolides, through other resistance mechanisms. Nosocomial (as opposed to community-acquired) isolates of MRSA are especially likely to be multidrug-resistant. Classic methicillin resistance can be detected readily in the clinical microbiology laboratory by a variety of techniques. An additional mechanism of relative resistance to methicillin -- hyperproduction ofb-lactamase -- has been described, but the clinical significance of this form of resistance is uncertain.

Until recently, all strains ofMRSAremained susceptible to vancomycin (if nothing else), making this the drug of choice for the treatment of infections caused by suspected or proven MRSA. Unfortunately, the efficacy of vancomycin for serious *S. aureus* infections, regardless of susceptibility to other agents, is suboptimal (see "Selection of Antibiotics," below). Furthermore, resistance of *S. aureus* to vancomycin has now emerged as well (see below), making the search for new antistaphylococcal agents all the more urgent. If isolates are shown to be susceptible to clindamycin or trimethoprim-sulfamethoxazole, these agents can be effective for treatment of MRSA infection -- but again, many strains are resistant. Two newly licensed antibiotics, representing the vanguard of two new classes of drugs, may prove to be useful for treatment of infections caused by MRSA. A new antibiotic that combines two streptogramins, quinupristin and dalfopristin, blocks protein synthesis at two ribosomal sites, resulting in a synergistic bactericidal effect on *S. aureus* and other gram-positive cocci. Linezolid, the first representative of the new oxazolidinone class of antibiotics, also demonstrates excellent activity against *S. aureus*, including multidrug-resistant strains of MRSA. Oxazolidinones are bacteriostatic, but resistance to them is unusual and there is no cross-resistance with other classes of compounds. Until data reveal the relative efficacies and toxicities of vancomycin and these new compounds, however, vancomycin remains the drug of choice for treatment of MRSA infections.

In 1996, a long-predicted monster -- *S. aureus* with decreased susceptibility to vancomycin -- finally emerged from the theoretical nightmares of microbiologists into the clinical realm. The term *vancomycin-intermediate S. aureus* (VISA) has been widely used to describe these strains, whose minimum inhibitory concentrations (MICs) of vancomycin (8 to 16 ug/mL) should theoretically confer only intermediate resistance to this agent. The clinical experience has been one of treatment failure, however. In 1997, four patients with VISA infection were reported from Japan and the United States; all died, although only one death was a direct result of the VISA infection. As of this writing, about a dozen additional cases have been reported from Asia, North America, and Europe, and the VISA genotype is already widespread in Japan. The risk factors for infection with VISA are uncertain because of the small number of reported cases, but they appear to include a history of dialysis, multiple prior courses of antibiotics (including vancomycin), admission to an intensive care unit, and prior infection withMRSA.

The mechanism for decreased susceptibility to vancomycin in *S. aureus* appears to be novel and unrelated to the mechanism of resistance of vancomycin-resistant enterococci (VRE).VISAstrains have unusually thick extracellular matrices that make it more difficult for vancomycin to reach its binding site at the level of the murein monomer of the cell wall. In addition, peptidoglycan from VISA appears to bind more vancomycin than does peptidoglycan from susceptible strains of *S. aureus*. These two factors create a "vancomycin sink," resulting in an increase in theMIC of vancomycin. VISA strains

may also be characterized by increased expression ofPBPs, slower growth, and decreased autolysis, all potentially contributing to antimicrobial resistance. Vancomycin resistance within a population of organisms is expressed in a heterogeneous manner, which may lead to difficulty in detection of the phenotype by usual susceptibility testing and may explain the failure of antimicrobial therapy in some cases. Therefore, infection with VISA should be suspected in any patient for whom seemingly appropriate therapy with vancomycin is ineffective. Removal of prosthetic material associated with infection is even more critical than usual in treating a patient infected withMRSA or VISA. Antimicrobial therapy for infections caused by VISA is discussed below (see "Selection of antibiotics").

In recent years, the percentage of staphylococcal isolates that are methicillin-resistant has risen substantially in U.S. hospitals; this trend has been driven by widespread (and often indiscriminate) antibiotic use. In some tertiary care institutions, up to 40% of *S. aureus* isolates are now resistant to methicillin, although rates of 5 to 15% are more typical. This situation is problematic for several reasons. Hospitalized patients colonized withMRSA are at increased risk (up to fourfold higher) of developing staphylococcal bacteremia than are patients colonized with methicillin-sensitive strains. The extent to which this difference reflects differences in bacterial virulence (as opposed to host factors or appropriateness of therapy) remains unclear; MRSA strains have not been shown consistently to be more virulent than sensitive strains, but the breadth of their resistance renders colonization more persistent, which in turn increases the rate of infection. In addition, higher rates of MRSA infection within an institution cause increased use of vancomycin, which contributes to the emergence ofVRE and apparently puts additional pressure on MRSA to develop resistance to vancomycin as well.

A second development over the past decade has been an apparent increase in the incidence in some communities ofMRSAinfection among individuals without apparent risk factors for MRSA. Previously identified risk factors for MRSA include residence in a long-term-care facility; hospitalization; chronic liver, lung, or vascular disease; dialysis; malignancy; and prolonged exposure to antibiotics. An increase in community-acquired cases of MRSA infection has been reported in several locations in the United States and suggests a change in the epidemiology of infection with this organism. It is hypothesized that strains of MRSA spread from the hospital to the community, where continued exposure to antibiotics (both appropriate and unnecessary) leads to their survival advantage and persistence. These reports have been based on retrospective observations, however, and have not yet been confirmed by prospective studies. The obvious question is whetherb-lactam antibiotics should continue to be used as the empirical agents of choice for community-acquired staphylococcal infections. For the time being, the incidence of MRSA infection in the community seems too low to justify more widespread use of vancomycin in this setting. There are situations, however, in which empirical use of vancomycin for community-acquired infections is justifiable and even advisable, as discussed below.

Selection of Antibiotics (Table 139-2) Although most pathogenic strains of *S. aureus* are resistant to penicillin, the development of penicillins and cephalosporins that are resistant tob-lactamase has allowed these classes of antibiotics to remain useful for treatment of most *S. aureus* infections. Nafcillin and oxacillin, both of which are

b-lactamase-resistant penicillins, are the drugs of choice for parenteral treatment of serious staphylococcal infections. Penicillin remains the drug of choice for infections caused by susceptible organisms. Drug combinations consisting of a penicillin plus a b-lactamase inhibitor are also effective but are best reserved for treatment of polymicrobial infections. Penicillin-allergic patients can usually be given a cephalosporin, although caution should be exercised if the prior adverse reaction to penicillin was anaphylaxis. Of the cephalosporins, the first-generation agents (e.g., cefazolin) are preferred for reasons related to cost and breadth of spectrum. For patients who are intolerant of all b-lactam agents, the best alternatives for parenteral administration are vancomycin and clindamycin. Dicloxacillin and cephalexin are recommended for oral treatment of minor infections or for continuation therapy; clindamycin is an alternative oral agent for most strains. Routine use of quinolones is not recommended because of the possibility of emergent resistance during therapy.

Use of vancomycin has increased dramatically over the past 20 years in response to the emergence ofMRSA, for which it has often been the sole therapeutic option, and the increasing number of infections caused byCoNS and other gram-positive cocci. Vancomycin's favorable pharmacokinetic properties and relatively low toxicity profile have also contributed to its widespread use. Unfortunately, increased use of vancomycin has resulted in the emergence of bothVRE andVISA, which are now poised to be the microbial scourges of the next decade. Equally important, however, is the fact -- often not recognized by practitioners -- that vancomycin is *less effective* than numerous other agents at our disposal. Vancomycin is generally only weakly bactericidal or even bacteriostatic for many strains of *S. aureus*. Studies of animal models have repeatedly shown vancomycin to be inferior to b-lactam agents for treatment of serious staphylococcal infections. Bacteremia is cleared more slowly in patients treated with vancomycin than in those treated withb-lactams, and clinical cure rates with vancomycin are significantly lower than with b-lactams as well. For all of these reasons, use of vancomycin should be reserved for situations in which there are no suitable alternative agents. It should not be used routinely for prophylaxis of staphylococcal infections, for empirical therapy in patients with fever and neutropenia (unless staphylococcal infection is especially likely), for decontamination of the digestive tract, for clearance of MRSA colonization, or for treatment of established gram-positive infections not due to resistant organisms. It is hoped that judicious use of vancomycin will help limit the spread of VRE and VISA and ensure that patients receive the most potent therapeutic agents.

Vancomycin remains the drug of choice for treatment of infections caused byMRSA, although sensitive strains may be amenable to therapy with clindamycin or trimethoprim-sulfamethoxazole. As discussed above, two new agents, quinupristin/dalfopristin and linezolid, offer promise for treatment of MRSA, but further studies are needed before they can be recommended for routine or preferential use. Optimal therapy for infections caused byVISA is unknown. To date, all isolates of VISA have been susceptible to alternative agents. Therapeutic options include the combination of vancomycin plus ab-lactam (based largely on in vitro data), quinupristin/dalfopristin, linezolid, or one of the new quinolone antibiotics, although the potential for development of resistance to the quinolones during therapy makes their use a questionable approach for infections requiring a prolonged course of antibiotic.

In most clinical settings, no significant benefit is attained by treating *S. aureus* infections with more than one drug to which the organism is known to be susceptible. Synergy has been demonstrated in vitro forb-lactam/aminoglycoside combinations, which hasten sterilization of the blood in endocarditis. Accordingly, therapy for *S. aureus* bacteremia is often initiated with such a combination for a brief period (e.g., 5 to 7 days) -- a strategy that seems reasonable when rapid clearance of bacteremia is deemed to be critical, as in prosthetic valve endocarditis. Thereafter, the toxicity of an aminoglycoside cannot be justified. Use of rifampin in conjunction with ab-lactam antibiotic (or vancomycin) occasionally results in microbial eradication and clinical cure of otherwise refractory infections, particularly those involving foreign bodies that are judged to be unremovable or those involving avascular tissue. These successes may relate to the high level of activity of rifampin against intracellular organisms, includingSCVs. Chronic osteomyelitis, parameningeal infections, and septic phlebitis have all been successfully treated with rifampin plus a cell wall-active agent. Nevertheless, routine use of rifampin for serious *S. aureus* infections is not recommended because of potential added toxicity, drug interactions, and theoretical antimicrobial antagonism. Rifampin should be reserved for refractory, relapsing, or inoperable infections and should never be administered as monotherapy, which rapidly leads to resistance.

Route and Duration of Therapy Because of poor bioavailability of most oral antistaphylococcal agents, parenteral therapy should be used for infections that require high concentrations of antibiotic, such as endovascular infections, infections of poorly vascularized tissue (including abscesses), and infections of the central nervous system. Given the propensity of *S. aureus* to adhere to endovascular and devitalized or damaged tissues, high doses of antibiotics (e.g., 12 g/d of nafcillin) should be used for bacteremic infections. When high serum levels of antibiotic are required to produce adequate tissue levels (e.g., in endocarditis or osteomyelitis), the parenteral route should be used for the duration of therapy. Oral agents may suffice for the treatment of nonbacteremic infections in which high serum levels of antibiotic are not requisite (e.g., skin, soft tissue, and upper respiratory tract infections).

With the notable exceptions of bacteremia (including endocarditis) and osteomyelitis, the duration of therapy for *S. aureus* infections can be tailored to the severity of illness, the immunologic status of the host, and the response to treatment. Because antibiotics penetrate bone poorly, treatment of acute osteomyelitis in adults requires at least 4 weeks of parenteral therapy. Chronic osteomyelitis is often treated with 6 to 8 weeks of parenterally administered antibiotics followed by several months of oral therapy, especially if the adequacy of debridement is uncertain.

Acute endocarditis and other endovascular infections caused by *S. aureus* should be treated with parenteral antibiotics for 4 weeks (6 weeks in the case of prosthetic valves). Simple bacteremia, as might occur with a removable or drainable focus of infection, is curable with a shorter duration of therapy, but a 2-week course of *parenteral* therapy has traditionally been recommended *for all patients* with *S. aureus* bacteremia, even under these circumstances. The costs and effort implicit in this recommendation are apparent, but shorter courses of therapy are associated with an unacceptable rate of secondary complications. Data suggest that a 7-day course of parenteral therapy may be adequate for simple bacteremia if the clinical response to therapy is prompt, if cultures of blood obtained after 2 days of therapy are negative, and ifTEE is negative for

vegetations. These data require confirmation, however. One of the more challenging aspects of treating staphylococcal bacteremia is deciding whether to administer parenteral therapy for 2 or 4 weeks. A conservative approach (one that is supported by numerous studies) dictates that *4 weeks* should be standard unless specific criteria are met (Fig. 139-2).

PREVENTION AND CONTROL

Nosocomial staphylococcal outbreaks and the spread of resistant strains of *S. aureus* are serious global problems. Within an institution, the most important vector of transmission of *S. aureus* is the hands of health care workers. Patients with exposed wounds or with nasal colonization are important reservoirs of the organisms. Transmission of *S. aureus* -- and hence the incidence of staphylococcal infection within an institution -- can be reduced most effectively by meticulous hand washing before and after contact with patients. The incidence of postoperative staphylococcal infection can be reduced by perioperative administration of an antibiotic with a favorable spectrum of activity and favorable pharmacokinetic properties, such as cefazolin, cefuroxime, or vancomycin. Elimination of nasal carriage before surgery (see below) may also prove to be effective in this regard.

More stringent infection-control measures must be taken to prevent the nosocomial spread ofMRSA. Such measures include assigning patients colonized or infected with MRSA to private rooms, wearing gloves for contact with contaminated wounds and mucous membranes as well as a gown if contamination of clothing is likely, and hand washing with an antiseptic soap after patient contact. Patients who are colonized but not infected with MRSA should not be treated with vancomycin merely for the sake of eliminating carriage of this organism.

Staphylococcal skin and soft tissue infections may recur once a person has been colonized with a virulent strain. In this context, therapy directed at the elimination of staphylococcal colonization may be warranted, especially for patients at particular risk for complications of infection. Use of an oral b-lactam antibiotic alone is ineffective, but combination therapy for 10 to 14 days with dicloxacillin or cephalexin (500 mg four times a day) plus rifampin (300 mg twice a day) plus mupirocin (2% ointment applied topically to both nares twice a day) is usually effective at clearing the carrier state, at least for a period of months.

COAGULASE-NEGATIVE STAPHYLOCOCCI

CoNSare a major cause of nosocomial infection and are the organisms most frequently isolated from the blood of hospitalized patients. The frequency with which they cause opportunistic infection in immunocompromised hosts attests more to the increased vulnerability of such hosts in modern medical practice than to the intrinsic virulence of the organisms. Despite the weak pathogenicity of these bacteria, the global impact of CoNS infection is considerable, including increased length and cost of hospital stay; increased use of antibiotics in general; and increased use of vancomycin in particular, which has contributed to the recent emergence of vancomycin-resistant gram-positive bacteria.

Although the variety of clinical syndromes caused byCoNS is impressive, several characteristics apply to most such infections. First, they tend to be *indolent*. There is often a long latent period between the time of contamination (e.g., of a medical device) and the onset of clinical illness; bacteremia in neutropenic patients can be an exception to this rule. Second, most CoNS infections are nosocomial in origin; important exceptions are prosthetic valve endocarditis and *S. saprophyticus* infections of the urinary tract. Third, most clinically significant infections are caused by strains of CoNS that are resistant to multiple antibiotics, including penicillins and cephalosporins. Finally, most CoNS infections are associated with a medical device of some kind, and removal of such devices is often required for cure.

EPIDEMIOLOGY AND PATHOGENESIS

CoNS, particularly *S. epidermidis*, are invariable and prominent constituents of the normal human skin flora. Infection most often results from direct inoculation of a foreign body at the time it is inserted, although hematogenous seeding can also occur.

CoNSare the quintessential pathogens of medical devices. The array of virulence factors produced by CoNS is meager compared with that of the virulence factors produced by *S. aureus*, but among these few factors are substances that promote bacterial adherence to and persistence on foreign bodies. A variety of surface antigens that promote colonization of medical devices by CoNS (particularly *S. epidermidis*) have been proposed; the best-studied of these is capsular polysaccharide adhesin, which serves as the organism's capsule and promotes the initial interaction of the bacteria and a foreign body. This polysaccharide is a major component of the *S. epidermidis* biofilm, which is important in the persistence of infection; the biofilm thwarts host defenses by coating staphylococcal cells onto foreign materials and impairing phagocytic killing. CoNS appear not to make toxic exoproteins or toxins; rather, they cause disease by tenaciously persisting on foreign materials, resulting in a local and occasionally a systemic inflammatory response.

The most important risk factor for infection withCoNS is the presence of a foreign body, especially an indwelling catheter. A second major risk factor for infection is deficient phagocyte function -- especially neutropenia, which is most often an iatrogenic complication of chemotherapy for cancer but may also reflect an underlying disease process (such as leukemia). The likelihood of catheter-related infection depends upon a number of variables, including the experience and skill of the person who inserts the catheter, the length of time that a catheter is left in place, and the quality of postinsertion care of the catheter site. CoNS only rarely cause infections (other than urinary tract infections) in immunologically normal hosts and typically do so only under extenuating circumstances.

CLINICAL SYNDROMES

BecauseCoNS can adhere to a variety of materials, virtually all *foreign bodies* are susceptible to colonization by these organisms. CoNS are the most common pathogens complicating the use of intravenous catheters, hemodialysis shunts and grafts, cerebrospinal fluid (CSF) shunts, peritoneal dialysis catheters, pacemaker wires and electrodes, prosthetic joints, vascular grafts, and prosthetic valves. CoNS infection of

intravenous catheters may or may not be accompanied by signs of inflammation at the site of catheter insertion, and the degree of systemic toxicity (including fever) ranges from minimal to moderately severe. The diagnosis can be established by the culturing of blood drawn from the catheter and by venipuncture. Infection of CSF shunts is usually evident within several weeks of implantation. Signs of meningitis are sometimes readily apparent but more often are subtle or absent; malfunction of the shunt may be the only manifestation of shunt infection. CoNS infection of a prosthetic joint often does not become evident until long after implantation, although the inciting contamination usually occurs at the time of implantation. Infection of vascular grafts may result in the development of an aneurysm or a pseudoaneurysm, with catastrophic consequences.

CoNSare a prominent cause of *bacteremia* in immunosuppressed patients. While such infections in immunocompetent hosts are relatively benign, patients with neutropenia may have high-grade bacteremia that results in significant systemic toxicity. A serious consequence of bacteremia is the seeding of a secondary foreign body, such as a prosthetic heart valve or joint or a pacemaker.

CoNSare the organisms most commonly responsible for *prosthetic valve endocarditis*, causing the majority of infections that develop within several months of implantation as well as a substantial percentage of late infections. The syndrome is one of subacute endocarditis (thus contrasting with the syndrome produced by *S. aureus*), with an illness that is clinically indistinguishable from that caused by viridans streptococci. Infection of prosthetic valves is often complicated by valvular dysfunction secondary either to dehiscence of the sewing ring or obstruction of the valve's orifice by bulky vegetations. CoNS are a less frequent but important cause of *native valve endocarditis*, accounting for<5% of such infections and usually affecting abnormal valves.

S. saprophyticus is a common cause of *urinary tract infection* among sexually active young women, in whom it is second only to *E. coli* in frequency. Exposure to spermicide-coated condoms may increase the incidence of infection. *S. saprophyticus* produces a syndrome indistinguishable from that caused by other etiologic agents, with pyuria and symptoms of dysuria, frequency, and abdominal pain. Infection with *S. saprophyticus* is readily amenable to therapy with most agents commonly used to treat urinary tract infections.CoNS can also cause urinary tract infection in hospitalized patients who have undergone invasive procedures; such infections are especially likely to be asymptomatic and may be difficult to treat because of antimicrobial resistance.

DIAGNOSIS

AlthoughCoNS are the most common cause of nosocomial bacteremia, they are also the most common contaminants of blood cultures; differentiation between infection and contamination often poses a challenge, with major therapeutic implications. Positive blood cultures are more likely to be "true positives" when there is a clinical illness suggestive of infection, when there is an indwelling catheter or some other risk factor for CoNS infection, and when cultures of blood drawn from multiple sites are positive for phenotypically identical organisms with the same antimicrobial susceptibility patterns. Except in the setting of neutropenia, physicians often have the luxury of awaiting the results of repeat cultures when the significance of CoNS growing from a blood culture is questionable.

TREATMENT

Removal of the foreign body (especially when it is an intravenous catheter) often constitutes adequate therapy forCoNSinfection related to that device. Most infections involving a foreign body require the removal of the device -- whether a prosthetic valve, prosthetic joint,CSFshunt, vascular graft, pacemaker or defibrillator and associated hardware, or hemodialysis shunt. Cures of all such infections with antibiotics alone have been reported, however, and a patient's poor medical condition or the hazards of surgery occasionally warrant an attempt at medical cure without extirpation of the device (see below). Infections of peritoneal dialysis catheters can be cured with antibiotics alone often enough that an attempt should be made to do so. CoNS infections of central venous catheters are also amenable to medical therapy, although relapses are common. Persistent bacteremia during therapy is an absolute indication for removal of a catheter, and bacteremia after a catheter's removal suggests seeding of a secondary site.

It is difficult to make generalizations about the optimal duration of therapy forCoNSinfections. In general, the duration of treatment is the same as for infection syndromes caused by other bacteria. For example, native valve endocarditis should be treated for 4 weeks, prosthetic valve endocarditis for 6. Transient bacteremia in an immunocompetent host may require no antimicrobial therapy after removal of an offending catheter. The efficacy of therapy can occasionally be enhanced by the delivery of antibiotics directly to the site of infection -- e.g., by intraventricular administration of vancomycin for central nervous system infections or by intraperitoneal administration of antibiotic for infections of peritoneal dialysis catheters.

Despite the low degree of pathogenicity ofCoNS, treatment of serious infections due to these organisms is often problematic because of the high percentage of strains that are resistant to commonly used antibiotics, including most oral agents. Most strains of CoNS isolated from patients in U.S. hospitals are resistant not only to penicillin but also to the penicillinase-resistant penicillins and cephalosporins. Nosocomial isolates are usually resistant to other classes of antibiotics as well. Vancomycin, to which the vast majority of CoNS remain susceptible, is of necessity the drug of choice for *empirical* therapy for serious CoNS infections. Strains proved to be susceptible to nafcillin (oxacillin) or penicillin should be treated with one of these agents or with a first-generation cephalosporin.

Synergistic combinations of antibiotics are often useful in the treatment ofCoNSinfections. Rifampin plays a unique role in this endeavor by virtue of its potency against most staphylococci, its excellent penetration into tissues (including those that are poorly vascularized), and the high levels it reaches within human cells and biofilm. Rifampin must be used in combination with other antibiotics because of the frequent and rapid emergence of microbial resistance to the drug when it is used alone. If an effort must be made to eradicate infection of a medical device without its removal, the concomitant use of ab-lactam antibiotic to which the organism is susceptible plus rifampin (300 mg twice daily by mouth) plus gentamicin affords the best chance for success. Vancomycin can be substituted for theb-lactam agent if so dictated by an organism's susceptibility pattern or by a patient's drug allergy.

140. STREPTOCOCCAL AND ENTEROCOCCAL INFECTIONS - *Michael R. Wessels*

Many varieties of streptococci are found as part of the normal human flora colonizing the respiratory, gastrointestinal, and genitourinary tracts. Several species are important causes of human disease. Group A *Streptococcus*, or *S. pyogenes*, is responsible for streptococcal pharyngitis, one of the most common bacterial infections of school-age children, and for the postinfectious syndromes of acute rheumatic fever and poststreptococcal glomerulonephritis. Group B *Streptococcus*, or *S. agalactiae*, is the leading cause of bacterial sepsis and meningitis in newborns and a major cause of endometritis and fever in parturient women. Enterococci are important causes of urinary tract infection, nosocomial bacteremia, and endocarditis. Viridans streptococci are the most common cause of bacterial endocarditis.

Streptococci are gram-positive bacteria of spherical to ovoid shape that characteristically form chains when grown in liquid media. Most streptococci that cause human infections are facultative anaerobes, although some are strict anaerobes. Streptococci are relatively fastidious organisms, requiring enriched media for growth in the laboratory. No single scheme for classification of streptococci is entirely satisfactory. Consequently, clinicians and clinical microbiologists often identify streptococci by any of several classification systems, including hemolytic pattern, Lancefield group, species name, and common or trivial name. Many of the streptococci associated with human infection produce a zone of complete hemolysis around the bacterial colony when cultured on blood agar, a pattern known as *b hemolysis*. Theb-hemolytic streptococci can be classified by the Lancefield system, a serologic grouping based on the reaction of specific antisera with cell-wall carbohydrate antigens of the bacteria. With rare exceptions, organisms belonging to Lancefield groups A, B, C, and G are allb-hemolytic streptococci, and each is associated with characteristic patterns of human infection. Other streptococci produce a zone of partial (a) hemolysis, often imparting a greenish appearance to the agar. These a-hemolytic streptococci are further identified by biochemical testing and include *S. pneumoniae*, an important cause of pneumonia, meningitis, and other infections, and several species of streptococci referred to collectively as the *viridans streptococci*, which are part of the normal oral flora and are important as agents of subacute bacterial endocarditis. Finally, some streptococci are nonhemolytic, a pattern sometimes called *ghemolysis*. The classification of the major groups of streptococci responsible for human infections is outlined inTable 140-1. Among the organisms classified serologically as group D streptococci, the enterococci are now considered to constitute a separate genus on the basis of DNA homology studies. Thus, species previously designated as *S. faecalis* and *S. faecium* have been renamed *Enterococcus faecalis* and *E. faecium*, respectively.**For further discussion of pneumococcal infections, see Chap. 138.*

GROUP A STREPTOCOCCI

Lancefield's group A consists of a single species, *S. pyogenes*. As its species name implies, this organism is associated with a variety of suppurative infections. In addition, group A streptococci can trigger the postinfectious syndromes of acute rheumatic fever (which is uniquely associated with *S. pyogenes* infection;Chap. 235) and poststreptococcal glomerulonephritis (Chap. 274).

PATHOGENESIS

Group A streptococci elaborate a number of cell-surface components and extracellular products important both in the pathogenesis of infection and in the immune response of the human host. The cell wall contains a carbohydrate antigen that may be released by treatment with acid. The reaction of such acid extracts with group A-specific antiserum is the basis for the definitive identification of a streptococcal strain as *S. pyogenes*. The major surface protein of group A streptococci is M protein, which occurs in more than 100 antigenically distinct types and is the basis for the serotyping of strains with specific antisera. The M protein molecules are fibrillar structures anchored in the cell wall of the organism and extending as hairlike projections away from the cell surface. The amino acid sequence of the distal or amino-terminal portion of the M protein molecule is quite variable, accounting for the antigenic variation of the different M types, while more proximal regions of the protein are relatively conserved. A newer technique for assignment of M type to group A streptococcal isolates uses the polymerase chain reaction to amplify the variable region of the M protein gene. DNA sequence analysis of the amplified gene segment can be compared with an extensive data base [developed at the Centers for Disease Control and Prevention (CDC)] for assignment of M type. This method eliminates the need for typing sera, which are available in only a few reference laboratories. The presence of M protein on a group A streptococcal isolate correlates with its capacity to resist phagocytic killing in fresh human blood; this phenomenon appears to be due, at least in part, to the binding of plasma fibrinogen to M protein molecules on the streptococcal surface, which interferes with complement activation and deposition of opsonic complement fragments on the bacterial cell. This resistance to phagocytosis may be overcome by M protein-specific antibodies, and thus individuals with antibodies to a given M type acquired as a result of prior infection are protected against subsequent infection with organisms of the same M type but not against that with different M types.

Group A streptococci also elaborate, to varying degrees, a polysaccharide capsule composed of hyaluronic acid. The production of large amounts of hyaluronic acid capsule by certain strains lends a characteristic mucoid appearance to the bacterial colonies. The capsular polysaccharide also plays an important role in protecting the organisms from ingestion and killing by phagocytes. In contrast to M protein, the hyaluronic acid capsule is a weak immunogen, and antibodies to hyaluronate have not been shown to be important in protective immunity; the presumed explanation is the apparent structural identity between streptococcal hyaluronic acid and the hyaluronic acid of mammalian connective tissues. The capsular polysaccharide may also play a role in group A streptococcal colonization of the pharynx by binding to CD44, a hyaluronic acid-binding protein expressed on human pharyngeal epithelial cells.

Group A streptococci produce a large number of extracellular products that may be important in local and systemic toxicity and in the spread of infection through tissues. These products include streptolysins S and O, toxins that damage cell membranes and account for the hemolysis produced by the organisms; streptokinase; DNases; protease; and pyrogenic exotoxins A, B, and C. The pyrogenic exotoxins, previously known as erythrogenic toxins, cause the rash of scarlet fever. Since the mid-1980s, pyrogenic exotoxin-producing strains of group A *Streptococcus* have been linked to unusually severe invasive infections, including necrotizing fasciitis and a systemic syndrome

termed the *streptococcal toxic shock syndrome*. Several extracellular products stimulate specific antibody responses useful in the serodiagnosis of recent streptococcal infection. Tests for these antibodies are used primarily for the detection of preceding streptococcal infection in cases of suspected acute rheumatic fever or poststreptococcal glomerulonephritis.

CLINICAL MANIFESTATIONS

Pharyngitis Although seen in patients of all ages, group A streptococcal pharyngitis is one of the most common bacterial infections of childhood, accounting for 20 to 40% of all cases of exudative pharyngitis in children. It is rare among those under the age of 3. Younger children may manifest streptococcal infection with a syndrome of fever, malaise, and lymphadenopathy without exudative pharyngitis. Infection is acquired through contact with another individual carrying the organism. Respiratory droplets are the usual mechanism of spread, although other routes, including food-borne outbreaks, have been well described.

The incubation period is 1 to 4 days. Symptoms include sore throat, fever and chills, malaise, and sometimes abdominal complaints and vomiting, particularly in children. Both symptoms and signs are quite variable, ranging from mild throat discomfort with minimal physical findings to high fever and severe sore throat associated with intense erythema and swelling of the pharyngeal mucosa and the presence of purulent exudate over the posterior pharyngeal wall and tonsillar pillars. Enlarged, tender anterior cervical lymph nodes commonly accompany exudative pharyngitis.

The differential diagnosis of streptococcal pharyngitis includes the many other bacterial and viral causes of pharyngitis. Streptococcal infection is unlikely to be the cause of pharyngitis when symptoms and signs suggestive of viral infection are prominent (conjunctivitis, coryza, cough, hoarseness, or discrete ulcerative lesions of the buccal or pharyngeal mucosa). Other infections commonly producing exudative pharyngitis include infectious mononucleosis and adenovirus infection. Now rare in the United States, the pseudomembrane of diphtheria may give a similar appearance. The coryneform organism *Arcanobacterium haemolyticum* may cause pharyngitis, often in association with a scarlet fever-like rash (Chap. 141). Other causes of pharyngitis, usually without a purulent exudate, include coxsackievirus, influenza virus, mycoplasmas, and *Neisseria gonorrhoeae* and acute infection with HIV. Because of the range of clinical presentations of streptococcal pharyngitis and the large number of other agents that can produce the same clinical picture, diagnosis of streptococcal pharyngitis on clinical grounds alone is not reliable.

The throat culture remains the diagnostic "gold standard." Culture of a throat specimen that is properly collected (i.e., by vigorous rubbing of a sterile swab over both tonsillar pillars) and properly processed is the most sensitive and specific means available to make a definitive diagnosis. A rapid diagnostic kit using latex agglutination or enzyme immunoassay of swab specimens can serve as a useful adjunct to the throat culture. While precise figures on sensitivity and specificity vary among studies, the rapid diagnostic kits generally are>95% specific. Thus a positive result can be relied upon for definitive diagnosis and eliminates the need for a throat culture. However, because the rapid diagnostic tests are less sensitive than throat culture (with a relative sensitivity

ranging from 55 to 90% in comparative studies), a negative result should be confirmed with a throat culture.

TREATMENT

In the usual course of uncomplicated streptococcal pharyngitis, symptoms resolve after 3 to 5 days. The course is shortened little by treatment, which is given primarily to prevent suppurative complications and rheumatic fever. Prevention of rheumatic fever depends on eradication of the organism from the pharynx, not simply on resolution of symptoms, and requires 10 days of penicillin treatment -- either a single intramuscular dose of benzathine penicillin G or a 10-day course of oral penicillin (Table 140-2). Erythromycin may be substituted for penicillin in the treatment of individuals allergic to penicillin. Follow-up culture after treatment is no longer routinely recommended but may be warranted in selected cases, such as those involving patients or families with frequent streptococcal infections or those occurring in situations in which the risk of rheumatic fever is thought to be high (e.g., when cases of rheumatic fever have recently been reported in the community).

Complications Suppurative complications of streptococcal pharyngitis have become uncommon with the widespread use of antibiotics for most cases of symptomatic streptococcal infection. The complications result from the spread of infection from the pharyngeal mucosa to deeper tissues by direct extension or by the hematogenous or lymphatic route and may include cervical lymphadenitis, peritonsillar or retropharyngeal abscess, sinusitis, otitis media, meningitis, bacteremia, endocarditis, and pneumonia. Local complications, such as abscess formation in the peritonsillar or parapharyngeal space, should be considered in a patient with unusually severe or prolonged symptoms or localized pain associated with high fever and a toxic appearance.

Asymptomatic Carrier State Surveillance cultures have shown that up to 20% of individuals in certain populations may have asymptomatic pharyngeal colonization with group A streptococci. There are no definitive guidelines for management of these asymptomatic carriers or of asymptomatic individuals who still have a positive throat culture after a full course of treatment for symptomatic pharyngitis. A reasonable course of action is to give a single 10-day course of penicillin for symptomatic pharyngitis and, if positive cultures persist, not to re-treat unless symptoms recur. Studies of the natural history of streptococcal carriage and infection have shown that the risk both of developing rheumatic fever and of transmitting infection to others is substantially lower among asymptomatic carriers than among individuals with symptomatic pharyngitis. Therefore, overly aggressive attempts to eradicate carriage are probably not justified under most circumstances. An exception is the situation in which an asymptomatic carrier is a potential source of infection to others. Outbreaks of food-borne infection and nosocomial puerperal infection have been traced to asymptomatic carriers who may harbor the organisms in the throat, on the skin, or in the vagina or anus.

TREATMENT

In cases in which a carrier is transmitting infection to others, attempts to eradicate carriage are warranted, although data are limited on the best regimen to use to clear the organism after penicillin alone has failed. The combination of penicillin V (500 mg four

times daily for 10 days) and rifampin (600 mg twice daily for the last 4 days) has been used to eliminate pharyngeal carriage. A 10-day course of oral vancomycin (250 mg four times daily) and rifampin (600 mg twice daily) has eradicated rectal colonization. However, experience is not extensive with any regimen.

Scarlet Fever Scarlet fever consists of streptococcal infection, usually pharyngitis, accompanied by a characteristic rash. The rash arises from the effects of one of three toxins, currently designated streptococcal pyrogenic exotoxins A, B, and C and previously known as erythrogenic or scarlet fever toxins. In the past, scarlet fever was thought to reflect infection of an individual lacking toxin-specific immunity with a toxin-producing strain of group A *Streptococcus*. Susceptibility to scarlet fever was correlated with results of the Dick test. A small amount of erythrogenic toxin injected intradermally produced local erythema in susceptible individuals but elicited no reaction in those with specific immunity. Subsequent studies have suggested that development of the scarlet fever rash may reflect a hypersensitivity reaction requiring prior exposure to the toxin. For reasons that are not clear, scarlet fever has become less common in recent years, although strains of group A streptococci that produce pyrogenic exotoxins continue to be prevalent in the population.

The symptoms of scarlet fever are the same as those of pharyngitis alone (Fig. 140-CD1). The (Fig. 140-CD2) rash typically begins on the first or second day of illness over the upper trunk, spreading to involve the extremities but sparing the palms and soles. The rash is made up of minute papules, giving a characteristic "sandpaper" feel to the skin. Associated findings include circumoral pallor, "strawberry tongue" (Fig. 140-CD3) (enlarged papillae on a coated tongue, which later may become denuded), and accentuation of the rash in the skin folds (Pastia's lines). Subsidence of the rash in 6 to 9 days is followed after several days by desquamation of the palms and soles. The differential diagnosis of scarlet fever includes other causes of fever and generalized rash, such as measles and other viral exanthems, Kawasaki disease, toxic shock syndrome, and systemic allergic reactions (e.g., drug eruptions).

Skin and Soft Tissue Infections Group A streptococci -- and occasionally other streptococcal species -- cause a variety of infections involving the skin (Fig. 140-CD4), subcutaneous tissues, muscles, and fascia (Fig. 140-CD5). While several clinical syndromes, recognized according to the tissues involved, offer a useful means for classification of skin and soft tissue infections, not all cases fit exactly into a single category. The classic syndromes should be considered as general guides to predicting the level of tissue involvement in a particular patient, the probable clinical course, and the likelihood that surgical intervention or aggressive life-support will be required.

Impetigo (Pyoderma) Impetigo is a superficial infection of the skin caused primarily by group A streptococci and occasionally by other streptococci or by *Staphylococcus aureus*. Impetigo is seen most often in young children, tends to occur during the warmer months, and is more common in semitropical or tropical climates than in cooler regions. Infection is more common among children living under conditions of poor hygiene. Prospective studies have shown that colonization of unbroken skin with group A streptococci precedes the development of clinical infection. Minor trauma, such as a scratch or an insect bite, may then serve to inoculate organisms into the skin. Impetigo is best prevented, therefore, by attention to adequate hygiene. The usual sites of

involvement are the face (particularly around the nose and mouth) and the legs, although lesions may occur at other locations. Individual lesions begin as red papules, which evolve quickly into vesicular and then pustular lesions that break down and coalesce to form characteristic honeycomb-like crusts (Plate IID-38). Lesions are generally not painful, and patients do not appear ill. Fever is not a feature of impetigo and, if present, suggests either infection extending to deeper tissues or another diagnosis.

The classic presentation of impetigo usually poses little diagnostic difficulty. Cultures of impetiginous lesions often yield *S. aureus* as well as group A streptococci, but longitudinal studies have shown that, in almost all cases, streptococci can be isolated initially, with staphylococci appearing later, presumably as secondary colonizing flora. In the past, penicillin was nearly always effective against these infections; in recent years, however, penicillin treatment failures have become more common, an observation suggesting that *S. aureus* infection may have become more prominent as a cause of impetigo. *Bullous impetigo* due to *S. aureus* is distinguished from typical streptococcal infection by the presence of more extensive, bullous lesions that break down and leave thin paper-like crusts instead of the thick amber crusts of streptococcal impetigo. Other skin lesions that may be confused with impetigo include herpetic lesions -- either those of orolabial herpes simplex or those of chickenpox or zoster. Herpetic lesions can generally be distinguished by their appearance as more discrete, grouped vesicles and by a positive Tzanck test. In difficult cases, cultures of vesicular fluid should yield group A streptococci in impetigo and the responsible virus in *Herpesvirus* infections.

TREATMENT

Treatment of streptococcal impetigo is the same as that for streptococcal pharyngitis. In view of evidence that *S. aureus* has become a relatively frequent cause of impetigo, empirical regimens should cover both streptococci and *S. aureus*. For example, either dicloxacillin or cephalexin can be given at a dose of 250 mg four times daily for 10 days. Topical mupirocin ointment is also effective. Rheumatic fever (unlike pharyngitis) is not a sequela to streptococcal skin infections, although poststreptococcal glomerulonephritis may follow either skin or throat infection. The reason for this difference is not known. One hypothesis is that the immune response necessary for development of rheumatic fever occurs only after infection of the pharyngeal mucosa. In addition, the strains of group A streptococci that cause pharyngitis are generally of different M protein types than those associated with skin infections; thus the strains that cause pharyngitis may have rheumatogenic potential, while the skin-infecting strains may not.

Cellulitis Inoculation of organisms into the skin may lead to infection involving the skin and subcutaneous tissues, or *cellulitis*. The portal of entry may be a traumatic or surgical wound, an insect bite, or any other break in skin integrity. Often, no entry site is apparent.

One form of streptococcal cellulitis, *erysipelas*, is characterized by a bright red appearance of the involved skin, which forms a plateau sharply demarcated from surrounding normal skin (Plate IID-34). The lesion is warm to the touch, may be tender, and appears shiny and swollen. The skin often has a *peau d'orange* texture, which is

thought to reflect involvement of superficial lymphatics; superficial blebs or bullae may form, usually 2 or 3 days after onset. The lesion typically develops over a few hours and is associated with fever and chills. Erysipelas tends to occur in certain characteristic locations: the malar area of the face (often with extension over the bridge of the nose to the contralateral malar region) and the lower extremities. After one episode, recurrence at the same site -- sometimes years later -- is not uncommon.

Classic cases of erysipelas, with the typical features described above, are almost always due tob-hemolytic streptococci, usually those of group A and occasionally those of group C or G. Often, however, the appearance of streptococcal cellulitis is not sufficiently distinctive to permit a specific diagnosis on clinical grounds. The area of involvement may not be one of the typical sites for erysipelas, the lesion may be less intensely red than usual and may fade into surrounding skin, and/or the patient may appear only mildly ill. In such cases, it is prudent to broaden the spectrum of empiric antimicrobial therapy to include other pathogens, particularly *S. aureus*, that can produce cellulitis with the same appearance. Staphylococcal infection should be suspected if cellulitis develops around a wound or ulcer.

Streptococcal cellulitis tends to develop at anatomic sites in which normal lymphatic drainage has been disrupted, such as sites of prior episodes of cellulitis, the arm ipsilateral to a mastectomy and axillary lymph node dissection, a lower extremity previously involved in deep venous thrombosis or chronic lymphedema, and the leg from which a saphenous vein has been harvested for coronary artery bypass grafting. The organism may enter via a breach in the dermal barrier at a location some distance from the eventual site of clinical cellulitis. For example, some patients with recurrent episodes of leg cellulitis following saphenous vein removal stop having recurrent episodes only after treatment of tinea pedis on the affected extremity, fissures in the skin presumably having served as a portal of entry for streptococci, which then produced infection more proximally in the leg at the site of previous injury. Streptococcal cellulitis may also involve recent surgical wounds. Group A streptococci are among the few bacterial pathogens that typically produce signs of wound infection and surrounding cellulitis within the first 24 h after surgery. These wound infections are usually associated with a thin exudate and may spread rapidly, either as cellulitis in the skin and subcutaneous tissue or as a deeper tissue infection (see below). Streptococcal wound infection or localized cellulitis may also be associated with *lymphangitis*, manifested by red streaks extending proximally along superficial lymphatics from the site of infection.

TREATMENT

SeeTable 140-2 andChap. 128.

Deep Soft Tissue Infections Necrotizing fasciitis (Fig. 18-CD4), also referred to as *hemolytic streptococcal gangrene*, is an infection involving the superficial and/or deep fascia investing the muscles of an extremity or the trunk. The source of the infection is either the skin, with organisms introduced into the tissue as a result of trauma (sometimes trivial), or the bowel flora, with organisms released during abdominal surgery or from an occult enteric source, such as a diverticular or appendiceal abscess. The site of inoculation in both forms of necrotizing fasciitis may be inapparent and is often some distance from the site of clinical involvement; e.g., the introduction of

organisms via minor trauma to the hand may be associated with clinical infection of the tissues overlying the shoulder or chest. In cases associated with the bowel flora, the infection is usually polymicrobial, involving a mixture of anaerobic bacteria (such as *Bacteroides fragilis* or anaerobic streptococci) and facultative organisms (usually gram-negative bacilli). Cases unrelated to contamination from bowel organisms are most commonly caused by group A streptococci, either alone or in combination with other organisms (most often *S. aureus*). Overall, group A streptococci are implicated in about 60% of cases of necrotizing fasciitis. The onset of symptoms is usually quite acute and is marked by severe pain at the site of involvement, malaise, fever, chills, and a toxic appearance. The physical findings, particularly early in the illness, may not be striking, with only minimal erythema of the overlying skin. Pain and tenderness are usually severe; in contrast, in more superficial cellulitis, the skin appearance is more abnormal, but pain and tenderness are only mild or moderate. As the infection progresses (often in a matter of several hours), the severity and extent of symptoms worsen, and skin changes become more evident, with the appearance of dusky or mottled erythema and edema. The marked tenderness of the involved area may evolve into anesthesia as the spreading inflammatory process produces infarction of cutaneous nerves.

Although myositis is more commonly due to *S. aureus* infection, group A streptococci occasionally produce abscesses in skeletal muscles (*streptococcal myositis*), with little or no involvement of the surrounding fascia or overlying skin. The presentation is usually subacute, but a fulminant form has been described in association with severe systemic toxicity, bacteremia, and a high mortality rate. The fulminant form may reflect the same basic disease process as that seen in necrotizing fasciitis, but with the necrotizing inflammatory process extending into the muscles themselves rather than remaining limited to the fascial layers.

TREATMENT

Once necrotizing fasciitis is suspected, early surgical exploration is both diagnostically and therapeutically indicated. Surgery reveals necrosis and inflammatory fluid tracking along the fascial planes above and between muscle groups, without involvement of the muscles themselves. The process usually extends beyond the area of clinical involvement, and extensive debridement is required. Drainage and debridement are central to the management of necrotizing fasciitis; antibiotic treatment is a useful adjunct (Table 140-2), but surgery is life-saving.

Treatment for streptococcal myositis consists of surgical drainage -- usually by an open procedure that permits evaluation of the extent of the infection and ensures adequate debridement of involved tissues -- and high-dose penicillin (Table 140-2).

Pneumonia and Empyema Group A streptococci are an occasional cause of pneumonia, generally in previously healthy individuals. The onset of symptoms may be abrupt or gradual. Pleuritic chest pain, fever, chills, and dyspnea are the characteristic symptoms. Cough is usually present but may not be prominent. Approximately one-half of patients with group A streptococcal pneumonia have an accompanying pleural effusion. In contrast to the sterile parapneumonic effusions typical of pneumococcal pneumonia, those complicating streptococcal pneumonia are almost always infected.

The empyema fluid is usually visible by chest radiography on initial presentation and may enlarge rapidly. These pleural collections should be drained early, as they tend to become loculated rapidly, resulting in a chronic fibrotic reaction that may require thoracotomy for removal.

Bacteremia, Puerperal Sepsis, and Streptococcal Toxic Shock Syndrome Group A streptococcal bacteremia is usually associated with an identifiable local infection. Bacteremia occurs rarely with otherwise uncomplicated pharyngitis, occasionally with cellulitis or pneumonia, and relatively frequently with necrotizing fasciitis. Bacteremia without an identified source raises the possibility of endocarditis, an occult abscess, or osteomyelitis. A variety of focal infections may arise secondarily from streptococcal bacteremia, including endocarditis, meningitis, septic arthritis, osteomyelitis, peritonitis, and visceral abscesses.

Group A streptococci are occasionally implicated in infectious complications of childbirth, usually endometritis and associated bacteremia. In the preantibiotic era, puerperal sepsis was commonly caused by group A streptococci, but currently it is more often caused by group B streptococci. Several nosocomial outbreaks of puerperal infection due to group A streptococci have been traced to an asymptomatic carrier, usually an individual present at the delivery of the infant. The site of carriage may be the skin, throat, anus, or vagina.

Beginning in the late 1980s, several reports described patients who had group A streptococcal infections associated with shock and multisystem organ failure. This syndrome has been called the streptococcal toxic shock syndrome because it shares certain features with staphylococcal toxic shock syndrome. In 1993, a case definition for group A streptococcal toxic shock syndrome was formulated by a group of clinicians, microbiologists, and epidemiologists in conjunction with theCDC(Table 140-3). The general features of the illness include fever, hypotension, renal impairment, and respiratory distress syndrome. Various types of rash have been described, but rash usually does not develop. Laboratory abnormalities include a marked shift to the left in the white blood cell differential, with many immature granulocytes; hypocalcemia; hypoalbuminemia; and thrombocytopenia, which usually becomes more pronounced on the second or third day of illness. In contrast to those with staphylococcal toxic shock, the majority of patients with the streptococcal syndrome are bacteremic. The most common associated infection is a soft tissue infection -- necrotizing fasciitis, myositis, or cellulitis -- although a variety of other associated local infections have been described, including pneumonia, peritonitis, osteomyelitis, and myometritis. Streptococcal toxic shock syndrome is associated with a mortality rate of 30%, with most deaths secondary to shock and respiratory failure. Because of its rapidly progressive and lethal course, early recognition of the syndrome is essential. Patients should be given aggressive supportive care in the form of fluid resuscitation, pressors, and mechanical ventilation in addition to antimicrobial therapy and, in cases associated with necrotizing fasciitis, surgical debridement. Exactly why certain patients develop this fulminant syndrome is not known; however, early studies of the streptococcal strains isolated from these patients demonstrated a strong association with the production of pyrogenic exotoxin A. In subsequent case series, particularly from Europe, the syndrome was also associated with strains producing exotoxin B or C.

TREATMENT

In light of the possible role of exotoxins or other streptococcal toxins in streptococcal toxic shock syndrome, treatment of the affected patients with clindamycin has been advocated by some authorities, who argue that, through its direct action on protein synthesis, clindamycin is more effective in rapidly terminating toxin production than penicillin -- a cell-wall agent. Support for this view comes from studies of an experimental model of streptococcal myositis, in which mice treated with clindamycin had a higher rate of survival than those given penicillin. Comparable data on the treatment of human infections are not available. Although clindamycin resistance in group A streptococci is uncommon (<2% among U.S. isolates), it has been documented. Thus, if clindamycin is used for initial treatment of a critically ill patient, penicillin should be given as well until the antibiotic susceptibility of the streptococcal isolate is known.

Intravenous immunoglobulin has been suggested as adjunctive therapy for streptococcal toxic shock; pooled immunoglobulin preparations are likely to contain antibodies capable of neutralizing the effects of streptococcal toxins. Anecdotal reports have suggested favorable clinical responses to intravenous immunoglobulin, but no controlled trials of this modality of therapy have yet been reported.

STREPTOCOCCI OF GROUPS C AND G

Group C and group G streptococci are b-hemolytic bacteria that occasionally cause human infections similar to those caused by group A streptococci, including pharyngitis, cellulitis and soft-tissue infections, pneumonia, bacteremia, endocarditis, and septic arthritis. Puerperal sepsis, meningitis, epidural abscess, intraabdominal abscess, urinary tract infection, and neonatal sepsis have also been reported. Group C streptococci are a common cause of infection in domesticated animals, especially horses and cattle, and some human infections have been acquired through contact with animals or through consumption of unpasteurized milk. Bacteremia and septic arthritis more frequently involve group G than group C streptococci. Group C or G streptococcal bacteremia occurs most often in patients who are elderly or chronically ill and, in the absence of an obvious local infection, is likely to reflect endocarditis. Septic arthritis, sometimes involving multiple joints, may complicate endocarditis or develop in its absence.

TREATMENT

Penicillin is the drug of choice for therapy of infections due to group C or G streptococci. Antibiotic treatment is the same as for patients with similar syndromes due to group A *Streptococcus* (Table 140-2). Patients with bacteremia or septic arthritis should receive intravenous penicillin (2 to 4 mU every 4 h). All group C and G streptococci are sensitive to penicillin; nearly all are inhibited in vitro by concentrations of £0.03 ug/mL. Occasional isolates exhibit tolerance: although inhibited by low concentrations of penicillin, they are killed only by significantly higher concentrations. The clinical significance of tolerance is unknown. Because of the poor clinical response of some patients to penicillin alone, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) is recommended by some authors for treatment of endocarditis or septic arthritis due to group C or G streptococci; however, combination therapy has not been shown to be

superior to treatment with penicillin alone.

Patients with joint infections often require repeated aspiration or open drainage and debridement for cure; the response to treatment may be slow, particularly in debilitated patients and those with involvement of more than one joint. Infection of prosthetic joints almost always requires removal of the prosthesis in addition to antibiotic therapy.

GROUP B STREPTOCOCCI

Identified first as a cause of mastitis in cows, streptococci belonging to Lancefield's group B have since been recognized as a major cause of sepsis and meningitis in human neonates. Group B streptococci are also a frequent cause of peripartum fever in women and an occasional cause of serious infection in nonpregnant adults. Lancefield group B consists of a single species, *S. agalactiae*, which is definitively identified with specific antiserum to the group B cell wall-associated carbohydrate antigen. A streptococcal isolate can be classified presumptively as belonging to group B on the basis of biochemical tests, including hydrolysis of sodium hippurate (in which 99% of isolates are positive), hydrolysis of bile esculin agar (in which 99 to 100% are negative), bacitracin susceptibility (in which 92% are resistant), and production of CAMP factor (in which 98 to 100% are positive). CAMP factor is a phospholipase produced by group B streptococci that results in synergistic hemolysis with b lysin produced by certain strains of *S. aureus*. Its presence can be demonstrated by cross-streaking of the test isolate and an appropriate staphylococcal strain on a blood agar plate. Group B streptococci causing human infections are encapsulated by one of nine antigenically distinct polysaccharides. The capsular polysaccharide has been shown experimentally to be important in the virulence of the organism. Antibodies to the capsular polysaccharide afford protection against group B streptococci of the same (but not of a different) capsular type.

INFECTION IN NEONATES

Two general types of group B streptococcal infection in infants are defined by the age of the patient at presentation. *Early-onset infections* occur within the first week of life, with a median age of 20 h at the onset of illness. Approximately half of these infants have signs of group B streptococcal disease at birth. The infection is acquired during or shortly before birth from organisms colonizing the maternal genital tract. Surveillance studies have shown that 5 to 40% of women are vaginal or rectal carriers of group B streptococci. Approximately 50% of infants delivered vaginally by carrier mothers become colonized, although only 1 to 2% of those colonized develop clinically evident infection. Prematurity and maternal risk factors (prolonged labor, obstetric complications, and maternal fever) are often involved. The presentation of early-onset infection is the same as that of other forms of neonatal sepsis. Typical findings include respiratory distress, lethargy, and hypotension. Essentially all infants with early-onset disease are bacteremic, one-third to one-half have pneumonia and/or respiratory distress syndrome, and one-third have meningitis.

Late-onset infections occur in infants between 1 week and 3 months of age, with a mean age at onset of 3 to 4 weeks. The infecting organism may be acquired during delivery (as in early-onset cases) or during later contact with a colonized mother,

nursery personnel, or another source. Meningitis is the most common manifestation of late-onset infection and in most cases is associated with a strain of capsular type III. Infants present with fever, lethargy or irritability, poor feeding, and seizures. The various other types of late-onset infection include bacteremia without an identified source, osteomyelitis, septic arthritis, and facial cellulitis associated with submandibular or preauricular adenitis.

TREATMENT

Penicillin is the treatment of choice for all group B streptococcal infections. Empirical broad-spectrum therapy for suspected bacterial sepsis, consisting of ampicillin and gentamicin, is generally administered until culture results become available. If cultures yield group B streptococci, many pediatricians continue to administer gentamicin, along with ampicillin or penicillin, for a few days until clinical improvement becomes evident. Infants with bacteremia or soft-tissue infection should receive penicillin at a dosage of 200,000 units/kg per day in divided doses; those with meningitis should receive 400,000 units/kg per day. Meningitis should be treated for at least 14 days because of the risk of relapse with shorter courses.

Prevention The incidence of group B streptococcal infection is unusually high among infants of women with risk factors: preterm delivery, early rupture of membranes (>24 h before delivery), prolonged labor, fever, or chorioamnionitis. Because the usual source of the organisms infecting a neonate is the mother's birth canal, efforts have been made to prevent group B streptococcal infections by the identification of high-risk carrier mothers and their treatment with various forms of antibiotic or immunoprophylaxis. Prophylactic administration of ampicillin or penicillin to such patients during delivery has been shown to reduce the risk of infection in the newborn. This approach has been hampered by the logistical difficulties of identifying colonized women before delivery, since the results of vaginal cultures early in pregnancy are poor predictors of carrier status at delivery. TheCDC has suggested two alternative approaches to the prevention of neonatal group B streptococcal infection: In the first approach, women are screened for anogenital colonization at 35 to 37 weeks of pregnancy by means of a swab culture of the lower vagina and anorectum; intrapartum chemoprophylaxis is offered to carriers and is *recommended* for those carriers with any of the risk factors noted above, those anticipating multiple births, and those who have previously given birth to an infant with group B streptococcal infection. In the second approach, screening cultures need not be performed, but intrapartum chemoprophylaxis is recommended for *all* women with one or more of the risk factors noted above. The recommended regimen for chemoprophylaxis is 5 million units of penicillin G followed by 2.5 million units every 4 h until delivery. Clindamycin or erythromycin may be substituted in women allergic to penicillin.

Treatment of all pregnant women who are colonized or who have risk factors for neonatal infection will result in exposure of 15 to 25% of pregnant women and newborns to antibiotics, with the attendant risks of allergic reactions and selection for resistant organisms. Although still in the developmental stages, a group B streptococcal vaccine may ultimately offer a better solution to prevention. Because transplacental passage of maternal antibodies produces protective antibody levels in the newborn, efforts are under way to develop a vaccine against group B streptococci that can be given to

childbearing women before or during pregnancy. Results of phase 1 clinical trials of group B streptococcal capsular polysaccharide-protein conjugate vaccines suggest that a multivalent conjugate vaccine would be safe and highly immunogenic.

INFECTION IN ADULTS

The majority of group B streptococcal infections in adults are related to pregnancy and parturition. Peripartum fever, the most common manifestation, is sometimes accompanied by symptoms and signs of endometritis or chorioamnionitis (abdominal distention and uterine or adnexal tenderness). Blood cultures are often positive, as are cultures of vaginal swabs. Bacteremia is usually transitory but occasionally results in meningitis or endocarditis. Infections in adults that are not associated with the peripartum period generally involve individuals who are elderly or have some underlying chronic illness, such as diabetes mellitus or a malignancy. Among the infections that develop with some frequency in adults are cellulitis and soft tissue infection (including infected diabetic skin ulcers), urinary tract infection, pneumonia, endocarditis, and septic arthritis. Other reported infections include meningitis, osteomyelitis, and intraabdominal or pelvic abscesses.

TREATMENT

Group B streptococci are less sensitive to penicillin than group A organisms, requiring somewhat higher doses. Adults with serious localized infections (pneumonia, pyelonephritis, abscess) should receive doses in the range of 12 million units of penicillin G daily, while patients with endocarditis or meningitis should receive 18 to 24 million units per day in divided doses. Vancomycin is an acceptable alternative for patients allergic to penicillin.

ENTEROCOCCI, GROUP D STREPTOCOCCI

ENTEROCOCCI

Lancefield group D includes the enterococci, organisms now classified in a separate genus from other streptococci, and nonenterococcal group D streptococci. Enterococci are distinguished from nonenterococcal group D streptococci by their ability to grow in the presence of 6.5% sodium chloride and by the results of other biochemical tests. The enterococcal species that are significant pathogens for humans are *E. faecalis* and *E. faecium*. These organisms tend to produce infection in patients who are elderly or debilitated or in whom mucosal or epithelial barriers have been disrupted or the balance of the normal flora altered by antibiotic treatment. Urinary tract infections due to enterococci are quite common, particularly among patients who have received antibiotic treatment or undergone instrumentation of the urinary tract. Enterococci are a frequent cause of nosocomial bacteremia in patients with intravascular catheters. These organisms account for 10 to 20% of cases of bacterial endocarditis on both native and prosthetic valves. The presentation of enterococcal endocarditis is usually subacute but may be acute, with rapidly progressive valve destruction. Enterococci are frequently cultured from bile and are involved in infectious complications of biliary surgery and in liver abscesses. Moreover, enterococci are often isolated from polymicrobial infections arising from the bowel flora (e.g., intraabdominal abscesses), from abdominal surgical

wounds, and from diabetic foot ulcers. While such mixed infections are frequently cured by antimicrobials not active against enterococci, specific therapy directed against enterococci is warranted when these organisms are the predominant species or are isolated from blood cultures.

TREATMENT

Unlike other streptococci, enterococci are not reliably killed by penicillin or ampicillin alone at concentrations achieved clinically in the blood or tissues. Ampicillin reaches sufficiently high urinary concentrations to constitute adequate monotherapy for uncomplicated urinary tract infections. Because in vitro testing has shown evidence of synergistic killing of most enterococcal strains by the combination of penicillin or ampicillin with an aminoglycoside, combined therapy is recommended for enterococcal endocarditis and meningitis; the regimen is penicillin (3 to 4 million units every 4 h) or ampicillin (2 g every 4 h) plus moderate-dose gentamicin (1 mg/kg every 8 h for patients with normal renal function). Enterococcal endocarditis should be treated for a minimum of 4 weeks and for 6 weeks if symptoms have been present for³3 months or if the infection involves a prosthetic heart valve. For nonendocarditis bacteremia and other serious enterococcal infections, it is not known whether the efficacy of single-agentb-lactam therapy is improved by the addition of gentamicin, but many infectious disease specialists use combination therapy for such infections, especially in critically ill patients. Vancomycin, in combination with gentamicin, may be substituted for penicillin in allergic patients. Enterococci are resistant to all cephalosporins; therefore, this class of antibiotics should not be used for treatment of enterococcal infections.

Antimicrobial susceptibility testing should be performed routinely on enterococcal isolates from patients with serious infections, and therapy should be adjusted according to the results (Table 140-4). Most enterococci are resistant to streptomycin, and this drug should not be used for treatment of enterococcal infection unless in vitro testing of the strain indicates susceptibility. Though less widespread than streptomycin resistance, high-level resistance to gentamicin -- with a minimum inhibitory concentration (MIC) of >2000 ug/mL -- has become common. Gentamicin-resistant enterococci should be tested for susceptibility to streptomycin; occasional gentamicin-resistant enterococci are sensitive to streptomycin. If the isolate is resistant to all aminoglycosides, treatment with penicillin or ampicillin alone may be successful. The prolonged administration (i.e., for at least 6 weeks) of high-dose ampicillin (e.g., 12 g/d) is recommended for endocarditis due to these highly resistant enterococci.

Enterococci may be resistant to penicillins via two distinct mechanisms. The first is the production ofb-lactamase (mediating resistance to penicillin and ampicillin), which has been reported for *E. faecalis* isolates from several locations in the United States and other countries. Because the amount of b-lactamase produced by enterococci may be insufficient for detection by routine antibiotic susceptibility testing, isolates from serious infections should be screened specifically forb-lactamase production with use of a chromogenic cephalosporin or by another method. For the treatment ofb-lactamase-producing strains, vancomycin, ampicillin/sulbactam, amoxicillin/clavulanate, or imipenem may be used in combination with gentamicin.

The second mechanism of penicillin resistance is not mediated byb-lactamase and may

be due to altered penicillin-binding proteins. This intrinsic penicillin resistance is common among *E. faecium* isolates, which routinely are more resistant tob-lactam antibiotics than are isolates of *E. faecalis*. Moderately resistant enterococci (MICs of penicillin and ampicillin, 16 to 64 ug/mL) may be susceptible to high-dose penicillin or ampicillin plus gentamicin, but strains with MICs of³200 ug/mL must be considered resistant to clinically achievable levels of b-lactam antibiotics, including imipenem. Vancomycin plus gentamicin is the recommended regimen for infections due to enterococci with high-level intrinsic resistance tob-lactams.

Vancomycin-resistant enterococci, first reported from clinical sources in the late 1980s, have become common in many hospitals. Three major vancomycin resistance phenotypes have been described: VanA, VanB, and VanC. The VanA phenotype is associated with high-level resistance to vancomycin and to teicoplanin, a related glycopeptide antibiotic not currently available in the United States. VanB and VanC strains are resistant to vancomycin but susceptible to teicoplanin, although teicoplanin resistance may develop during treatment in VanB strains. For enterococci resistant to both vancomycin and b-lactams, there are no established therapies. Regimens that have been tried with some success in individual cases or experimentally include ciprofloxacin plus rifampin plus gentamicin; ampicillin plus vancomycin (particularly if in vitro testing shows synergistic bacteriostatic activity); and chloramphenicol or tetracycline (if the strain is susceptible in vitro). Quinupristin/dalfopristin (Synercid) is a streptogramin combination with in vitro activity against *E. faecium*, including vancomycin-resistant isolates, but not against *E. faecalis* or other enterococcal species. The evidence for clinical efficacy of this agent in serious enterococcal infections is limited, and, as of this writing, quinupristin/dalfopristin is not yet licensed for use in the United States.

OTHER GROUP D STREPTOCOCCI

The main nonenterococcal group D streptococcal species that causes human infections is *S. bovis*. *S. bovis* endocarditis is often associated with neoplasms of the gastrointestinal tract -- most frequently a colon carcinoma or polyp -- but is also reported in association with other bowel lesions. When occult gastrointestinal lesions are carefully sought, abnormalities are found in ³60% of patients with *S. bovis* endocarditis. In contrast to the enterococci, nonenterococcal group D streptococci like *S. bovis* are reliably killed by penicillin as a single agent, and penicillin is the treatment of choice for *S. bovis* infections.

VIRIDANS AND OTHER STREPTOCOCCI

VIRIDANS STREPTOCOCCI

Consisting of multiple species of a-hemolytic streptococci, the viridans streptococci are a heterogeneous group of organisms that are important as agents of bacterial endocarditis (Chap. 126). Several species of viridans streptococci, including *S. salivarius*, *S. mitis*, *S. sanguis*, and *S. mutans*, are part of the normal flora of the mouth, where they live in close association with the teeth and gingiva. Some species contribute to the development of dental caries. The transient viridans streptococcal bacteremia induced by eating, tooth-brushing, flossing, and other sources of minor trauma, together

with adherence to biologic surfaces, is thought to account for the predilection of these organisms to cause endocarditis. Viridans streptococci are also isolated, often as part of a mixed flora, from sites of sinusitis, brain abscess, and liver abscess.

Viridans streptococcal bacteremia occurs relatively frequently in neutropenic patients, particularly after bone marrow transplantation or high-dose chemotherapy for cancer. Some of these patients develop a sepsis syndrome with high fever and shock. Risk factors for viridans streptococcal bacteremia include chemotherapy with high-dose cytosine arabinoside, prior treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone, treatment with antacids or histamine antagonists, mucositis, and profound neutropenia.

The *S. milleri* group (also referred to as the *S. intermedius* or *S. anginosus* group) includes three species that cause human disease: *S. intermedius*, *S. anginosus*, and *S. constellatus*. These organisms are often are considered viridans streptococci, although they differ somewhat from other viridans streptococci in both their hemolytic pattern (they may bea-, b-, or nonhemolytic) and the disease syndromes they cause. This group commonly produces suppurative infections, particularly abscesses of brain and abdominal viscera, and infections related to the oral cavity or respiratory tract, such as peritonsillar abscess, lung abscess, and empyema.

TREATMENT

Isolates from neutropenic patients with bacteremia often are resistant to penicillin; thus these patients should be treated presumptively with vancomycin until the results of susceptibility testing become available. Viridans streptococci isolated in other clinical settings usually are sensitive to penicillin.

NUTRITIONALLY VARIANT STREPTOCOCCI

Occasional isolates cultured from the blood of patients with endocarditis fail to grow when subcultured on solid media. These *nutritionally variant streptococci* require supplemental thiol compounds or active forms of vitamin B_6(pyridoxal or pyridoxamine) for growth in the laboratory. The nutritionally variant streptococci are generally grouped with the viridans streptococci because they cause similar types of infections. However, they have been reclassified on the basis of 16S RNA sequence comparisons into a separate genus, *Abiotrophia*, with two species: *A. defectivus* and *A. adjacens*.

TREATMENT

Because treatment failure and relapse appear to be more common for cases of endocarditis due to nutritionally variant streptococci than for usual viridans streptococci, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) to the penicillin regimen is recommended in therapy for endocarditis due to these organisms.

OTHER STREPTOCOCCI

S. suis is an important pathogen in swine and has been reported to cause meningitis in

humans, usually in individuals with occupational exposure to pigs. Strains of *S. suis* associated with human infections have generally reacted with Lancefield group R typing serum and sometimes with group D typing serum as well. Isolates may bea- or b-hemolytic and are sensitive to penicillin. *S. iniae*, a pathogen of fish, has been associated with infections in humans who have handled live or freshly killed fish. Cellulitis of the hand is the most common form of human infection, although bacteremia and endocarditis have been reported. *Anaerobic streptococci*, or *peptostreptococci*, are part of the normal flora of the oral cavity, bowel, and vagina. Infections caused by the anaerobic streptococci are discussed in Chap. 167.

141. DIPHTHERIA, OTHER CORYNEBACTERIAL INFECTIONS, AND ANTHRAX - *Randall K. Holmes*

DIPHTHERIA

DEFINITION

Diphtheria is a localized infection of mucous membranes or skin caused by *Corynebacterium diphtheriae*. A characteristic pseudomembrane may be present at the site of infection (Fig. 141-CD1). Some strains of *C. diphtheriae* produce diphtheria toxin, a protein that can cause myocarditis, polyneuritis, and other systemic toxic effects. Respiratory diphtheria is usually caused by toxinogenic (*tox*$^+$) *C. diphtheriae*, but cutaneous diphtheria is frequently caused by nontoxinogenic (*tox*$^-$) strains.

ETIOLOGY

C. diphtheriae is an aerobic, nonmotile, nonsporulating, irregularly staining, gram-positive rod. The bacteria are club-shaped and are often arranged in clusters (*Chinese letters*) or parallel arrays (*palisades*). *C. diphtheriae* forms gray to black colonies on selective media containing tellurite. The gravis, mitis, and intermedius biotypes are distinguished by colonial morphology and laboratory tests. Both *tox*$^+$ and *tox*$^-$ strains cause infections, and *tox*$^+$ strains of all three biotypes can cause severe disease. The gene for diphtheria toxin is present in specific corynephages, and *tox*$^-$ *C. diphtheriae* can acquire the ability to produce diphtheria toxin by infection with *tox*$^+$phages (*phage conversion*). Growth of *C. diphtheriae* under low-iron conditions that mimic the environment of host tissues induces production of diphtheria toxin and expression of systems for siderophore-dependent iron uptake and utilization of iron from heme.

IMMUNOLOGY

Treatment of diphtheria toxin with formaldehyde converts it to a nontoxic but immunogenic product (*diphtheria toxoid*). Immunization with toxoid elicits antibody (*antitoxin*) that neutralizes the toxin and prevents diphtheria. The attack rate and mortality rate for diphtheria are low in immune individuals with antitoxin titers of >0.01 unit per milliliter. Antitoxin neither prevents colonization by *C. diphtheriae* nor eradicates the *carrier state*. When most individuals in a population have protective levels of antitoxin (*herd immunity*), the carrier rate for *tox*$^+$ strains of *C. diphtheriae* falls to a low level, and the risk that susceptible individuals will be exposed to *tox*$^+$ *C. diphtheriae* decreases dramatically. Susceptible individuals may contract diphtheria if they travel to regions where the disease is present or if *tox*$^+$ strains of *C. diphtheriae* are introduced into their community.

EPIDEMIOLOGY AND IMMUNITY

Humans are the principal reservoir for *C. diphtheriae*. Transmission occurs primarily by close personal contact. The risk is greater that *C. diphtheriae* will be transmitted to susceptible individuals from patients with diphtheria than from carriers. The incubation period for respiratory diphtheria is typically 2 to 5 days and rarely up to 8 days.

Cutaneous diphtheria is usually a secondary infection whose signs develop an average of 7 days (range, 1 to >21 days) after the appearance of primary dermatologic lesions of other etiologies.

In temperate climates, diphtheria primarily involves the respiratory tract; occurs throughout the year, with a peak incidence in colder months; and is usually caused by *tox*+ *C. diphtheriae*. Before immunization was introduced, diphtheria was primarily a disease of children; it affected up to 10% of individuals in this group and sometimes caused devastating epidemics. Most young infants were immune because of transplacental transfer of maternal IgG antitoxin, but children became susceptible by 6 to 12 months of age. Approximately 75% of individuals became immune by age 10 as a result of contact with *C. diphtheriae*. Mortality rates of 30 to 40% were common in untreated disease and were sometimes >50% in epidemics. Treatment with antitoxin reduced the case-fatality rate to 5 to 10%.

Routine immunization of children in the United States resulted in a progressive decrease of diphtheria from the peak of 206,939 cases (incidence rate, 191 cases per 100,000 population) in 1921 to <5 cases per year since 1980. Concomitantly, circulation of *tox*+ strains of *C. diphtheriae* among the population decreased dramatically, although an endemic focus for transmission of *tox*+ and *tox*- strains without clinical disease was recently identified in North Dakota. As the incidence rate of diphtheria decreased, a higher proportion of cases occurred in older persons (who were never immunized or whose immunity waned because it was not boosted by either booster doses of vaccine or contact with *C. diphtheriae*), but the case-fatality ratio remained unchanged at 5 to 10%. High rates of immunization are currently achieved by school entry (>96%), but immunization rates for younger children are substantially lower. Among adults >20 years of age, 19 to 77% are susceptible as a consequence of failure to receive periodic booster immunizations and lack of contact with *C. diphtheriae*. The most recent large diphtheria outbreak in the United States (about 1100 cases) occurred in Seattle, Washington, between 1972 and 1982. Alcoholism, low socioeconomic status, crowded living conditions, and Native-American ethnic background were significant risk factors in this outbreak.

A massive diphtheria epidemic (>157,000 cases and 5000 deaths) occurred recently in the states of the former Soviet Union and accounted for>80% of diphtheria cases reported worldwide during that interval. The epidemic began in 1990 with 1436 cases (0.49 per 100,000 population), peaked in 1995 with 50,425 cases (17.29 per 100,000 population), and waned by 1998 with 2720 cases (0.93 per 100,000 population) as the result of a mass immunization program. The progression of the epidemic was associated with emergence of a previously uncommon clonal group of *tox*+ *C. diphtheriae* strains that accounted for>80% of isolates by 1994; molecular analysis of the *tox* gene from these strains demonstrated that the existing diphtheria toxoid vaccine remained appropriate for control of the epidemic by vaccination.

A majority of cases throughout this epidemic occurred in persons ³15 years old, and adults from 40 to 49 years old had very high incidence and death rates. In 1994, case-fatality rates varied from 2.8%in the Russian Federation to 23% in Lithuania and Turkmenistan. Factors that facilitated the spread of this epidemic included large-scale population movements, socioeconomic instability, deteriorating health infrastructure,

delayed implementation of aggressive control measures in response to the epidemic, inadequate information for physicians and the public, and frequent shortages of supplies for prevention and treatment of the disease. The most important risk factor for diphtheria in the Republic of Georgia was lack of vaccination (matched odds ratio, 19.2), but household diphtheria exposure, exposure to skin lesions, the presence of tonsils, a history of eczema, preceding fever with myalgia, sharing a bed, sharing glasses and cups, and taking a bath less often than weekly were also significant risk factors. Although small numbers of imported cases from this epidemic occurred in western European countries, none resulted in secondary transmission of diphtheria, notwithstanding a high proportion of susceptible adults in countries with imported cases. Inadequate primary immunization of children in the states of the former Soviet Union in the years preceding the epidemic, along with failure to maintain adequate immunity in adults by booster immunization, may have synergistically facilitated transmission of diphtheria and emergence of the massive epidemic in this region.

In the tropics, cutaneous diphtheria is more common than respiratory diphtheria, occurs throughout the year, and often develops as a secondary infection complicating other dermatoses. Isolates of *C. diphtheriae* from skin lesions are more often *tox*$^-$than *tox*$^+$. Cutaneous diphtheria is increasingly recognized in temperate climates and accounted for 86% of the 1100 cases in the Seattle epidemic of 1972 to 1982. Since 1980, cutaneous diphtheria has not been a reportable disease in the United States, and recent health statistics include only respiratory diphtheria.

During the 1990s, *tox*$^-$ strains of *C. diphtheriae* were associated with new types of infections. In the United Kingdom, these strains caused symptomatic pharyngitis, predominantly among homosexual men, that was sometimes accompanied by tonsillar exudate. In Switzerland, strains with a high potential for invasiveness were isolated from 38 intravenous drug users and shown by ribotyping to be clonally related. The latter strains caused infections of the skin (15 cases), respiratory tract (10 cases), and blood (13 cases). Among the patients with bloodstream infections, 9 had endocarditis, and 4 of these 9 patients died.

PATHOLOGY AND PATHOGENESIS

C. diphtheriae infects mucous membranes, most commonly in the respiratory tract, and also invades open skin lesions resulting from insect bites or trauma. In infections caused by *tox*$^+$ *C. diphtheriae*, initial edema and hyperemia are often followed by epithelial necrosis and acute inflammation. Coagulation of the dense fibrinopurulent exudate produces a pseudomembrane, and the inflammatory reaction accompanied by vascular congestion extends into the underlying tissues. The pseudomembrane contains large numbers of *C. diphtheriae* organisms, but the bacteria are rarely isolated from the blood or internal organs.

Diphtheria toxin acts both locally and systemically, and the lethal dose for humans is ~0.1 ug/kg. Toxin contributes locally to pseudomembrane formation; systemically, it can cause myocarditis, neuritis, and focal necrosis in various organs, including the kidneys, liver, and adrenal glands. Changes in the myocardium include cloudy swelling of muscle fibers and interstitial edema. These changes are followed within weeks by hyaline and granular degeneration (sometimes with fatty degeneration), progressing to myolysis and

finally to the replacement of lost muscle by fibrosis. Thus, diphtheria can cause permanent cardiac damage. In diphtheritic polyneuritis, pathologic changes include patchy breakdown of myelin sheaths in peripheral and autonomic nerves, but recovery of nerve damage is the rule if the patient survives.

Diphtheria toxin is produced by *C. diphtheriae* as an extracellular polypeptide. Proteolytic cleavage forms nicked toxin consisting of fragments A and B. Fragment B binds to a plasma-membrane receptor (a precursor of a heparin-binding growth factor resembling epidermal growth factor), and the bound toxin is internalized by receptor-mediated endocytosis. Fragment A is translocated across the endosomal membrane and released into the cytoplasm, where it catalyzes the transfer of the adenosine diphosphate ribose moiety from nicotinamide adenine dinucleotide (NAD) to a modified histidine residue (diphthamide) on elongation factor 2 (EF-2), thereby inactivating EF-2 and inhibiting protein synthesis. One molecule of fragment A in the cytoplasm can kill a cell. Other metabolic alterations are secondary to inhibition of protein synthesis.

CLINICAL MANIFESTATIONS

Patients with *C. diphtheriae* in the respiratory tract are classified as diphtheria cases if pseudomembranes are present and as diphtheria carriers if pseudomembranes are absent. The disease is graded as *tonsillar* if pseudomembranes are localized to the tonsils, as *combined types* or *delayed diagnosis* if more extensive pseudomembranes are present, and as *severe* if cervical adenopathy or cervical edema is also present. Onset is often gradual, but most patients seek medical care within a few days of becoming ill. Fever of 37.8° to 38.9°C (100° to 102°F), sore throat, and weakness are the most common symptoms, while dysphagia, headache, and change of voice occur in fewer than half of patients. Neck edema and difficulty breathing are noted in£10% of patients and are associated with an increased risk of death. Systemic manifestations are due primarily to toxic effects of diphtheria toxin. Patients without toxicity exhibit discomfort and malaise associated with local infection, whereas severely toxic patients may develop listlessness, pallor, and tachycardia that can progress rapidly to vascular collapse.

Primary infection in the respiratory tract is most often tonsillopharyngeal but may also be (in decreasing order) laryngeal, nasal, and tracheobronchial. Multiple sites are frequently involved, and secondary spread of pharyngeal infection upward to the nasal mucosa or downward to the larynx and tracheobronchial tree is much more common than primary infection at those sites. Systemic toxicity is usually most severe when extensive pseudomembrane extends from the tonsils and pharynx into contiguous regions. A small percentage of patients present with malignant or "bull-neck" diphtheria, with extensive pseudomembrane formation, foul breath, massive swelling of the tonsils and uvula, thick speech, cervical lymphadenopathy, striking edematous swelling of the submandibular region and anterior neck, and severe toxicity.

In tonsillopharyngeal diphtheria, isolated spots of gray or white exudate may appear first. These spots often extend and coalesce within a day to form a confluent, sharply demarcated pseudomembrane that becomes progressively thicker, more tightly adherent to the underlying tissue, and darker gray in color. Unlike the exudate in

streptococcal pharyngitis, the diphtheritic pseudomembrane often extends beyond the margin of the tonsils onto the tonsillar pillars, palate, or uvula. Dislodging the membrane is likely to cause bleeding. Laryngeal diphtheria often presents as hoarseness and cough. Demonstration of laryngeal pseudomembrane by laryngoscopy helps distinguish diphtheria from other infectious forms of laryngitis. Patients with nasal diphtheria may present with unilateral or bilateral serosanguineous nasal discharge associated with irritation of the nares or lip. Primary or secondary diphtheritic infection occasionally involves other mucous membranes, including the conjunctiva and the membranes of the genitourinary and gastrointestinal tracts.

Cutaneous diphtheria usually presents as an infection by *C. diphtheriae* of preexisting dermatoses involving the lower extremities, upper extremities, head, or trunk. The clinical features are similar to those of other secondary cutaneous bacterial infections. In the tropics, cutaneous diphtheria may present as a primary cutaneous lesion, typically with morphologically distinct "punched-out" ulcers that are covered by necrotic slough or membrane and have well-demarcated edges.

C. diphtheriae is an occasional cause of invasive infections, including endocarditis and septic arthritis. Risk factors for such infections include preexisting cardiac abnormalities, abuse of intravenous drugs, and alcoholic cirrhosis.

COMPLICATIONS

Obstruction of the respiratory tract can be caused by extensive pseudomembrane formation and swelling early in the disease or by sloughed pseudomembrane that becomes lodged in the airways later in the disease. The risk is greater when infection involves the larynx or the tracheobronchial tree and in children because of the small size of the airways.

Myocarditis and polyneuritis are the most prominent toxic manifestations of diphtheria. The risk of each is proportional to the severity of local disease. Myocarditis occurred in 22% and neuritis in 5% of 656 hospitalized patients (54% female, 70% ³15 years old) with diphtheria in the Kyrgyz Republic in 1995; 7% of patients with myocarditis and 2% of patients without myocarditis died. The median interval from hospitalization to death was 4.5 days (range, 0 to 13 days).

Bulbar dysfunction in diphtheritic neuritis typically develops during the first 2 weeks. Palatal and pharyngeal paralysis usually develops first. Swallowing is difficult, the voice is nasal, and ingested fluids may be regurgitated through the nose. Additional bulbar signs may develop over several weeks, with oculomotor and ciliary paralysis more common than facial or laryngeal paralysis. Peripheral polyneuritis typically begins from 1 to 3 months after the onset of diphtheria with proximal weakness of the extremities, which spreads distally. Paresthesia may occur, most often in a glove-and-stocking distribution. Polyneuritis usually resolves completely, with the time needed for improvement approximately equal to that elapsing from exposure to the development of symptoms.

Pneumonia occurs in more than one-half of fatal cases of diphtheria. Less common complications include renal failure, encephalitis, cerebral infarction, pulmonary

embolism, and bacteremia or endocarditis due to invasive infection by *C. diphtheriae*. Serum sickness may result from antitoxin therapy.

COURSE AND PROGNOSIS

Most cases of diphtheria develop in nonimmunized patients. The attack rate, severity of disease, and risk of complications are much lower in immunized patients. The pseudomembrane may continue to increase in size during the first day after administration of antitoxin. During the next several days to a week, it becomes softer, less adherent, and nonconfluent and eventually disappears. In the preantibiotic era, *C. diphtheriae* persisted in the throat for ~2 weeks in one-half of patients and for ³1 month in about one-fifth. Mortality increases with the severity of local disease, the extent of pseudomembrane formation, and the delay between onset of local disease and administration of antitoxin. The death rate is highest during the first week of illness; among patients with bull-neck diphtheria; among patients with myocarditis who develop ventricular tachycardia, atrial fibrillation, or complete heart block; among patients with laryngeal or tracheobronchial involvement; among infants and patients >60 years of age; and among alcoholics. Both the mortality rate and the risk of myocarditis or peripheral neuropathy are significantly lower in cutaneous diphtheria than in respiratory diphtheria.

DIAGNOSIS

A characteristic pseudomembrane on the mucosa of the tonsils, palate, oropharynx, nasopharynx, nose, or larynx suggests diphtheria but is not uniformly present. Diphtheritic pseudomembrane must be distinguished from other pharyngeal exudates, including those of group A b-hemolytic streptococcal infections, infectious mononucleosis, viral pharyngitis, fusospirochetal infection, and candidiasis. Diphtheria should be considered in patients with sore throat, cervical adenopathy or swelling, and low-grade fever, especially when these manifestations are accompanied by systemic toxicity, hoarseness, stridor, palatal paralysis, or serosanguineous nasal discharge with or without demonstrable pseudomembrane. Treatment with diphtheria antitoxin should begin as soon as the clinical diagnosis of diphtheria is made.

Definitive diagnosis of diphtheria depends on the isolation of *C. diphtheriae* from local lesions. The laboratory should be notified that diphtheria is suspected to ensure the use of selective tellurite medium appropriate for the isolation of *C. diphtheriae*. All isolates of *C. diphtheriae* should be subjected to toxicity testing. Primary isolates can be screened rapidly for the presence of the *tox* gene by the polymerase chain reaction, although occasional strains of *C. diphtheriae* that carry an inactive toxin gene give false-positive results. Biochemical tests needed to differentiate *C. diphtheriae* from corynebacteria of the normal flora (diphtheroids) require several days. Group A b-hemolytic streptococci and *Staphylococcus aureus* are also isolated frequently from patients with diphtheria.

Cutaneous diphtheria may present as a characteristic "punched-out" ulcer with a membrane, but it is more often indistinguishable from other inflammatory dermatoses. Diagnosis depends on a high degree of suspicion and on culture of cutaneous lesions on laboratory media appropriate for isolation of *C. diphtheriae*. Throat samples from all patients with cutaneous diphtheria should be cultured for *C. diphtheriae*.

TREATMENT

The decision to administer diphtheria antitoxin must be based on the clinical diagnosis of diphtheria without definitive laboratory confirmation, since each day of delay in treatment is associated with increased mortality. Because diphtheria antitoxin is produced in horses, it is necessary to inquire about possible allergy to horse serum and to perform a conjunctival or intracutaneous test with diluted antitoxin for immediate hypersensitivity. Epinephrine must be available for immediate administration to patients with severe allergic reactions. Patients with immediate hypersensitivity should be desensitized before a full therapeutic dose of antitoxin is given. The dose of diphtheria antitoxin currently recommended by the Committee on Infectious Diseases of the American Academy of Pediatrics is based on the site of the primary infection and the duration and severity of disease: 20,000 to 40,000 units for disease that has been present for £48 h and involves the pharynx or larynx; 40,000 to 60,000 units for nasopharyngeal infections; and 80,000 to 100,000 units for disease that is extensive, has been present for³3 days, or is accompanied by diffuse swelling of the neck. Antitoxin is administered intravenously by infusion in saline over 60 min to neutralize unbound toxin rapidly. The ~10% risk of serum sickness is acceptable because of the established therapeutic value of antitoxin in decreasing mortality from respiratory diphtheria. The risk of systemic toxicity is lower in cutaneous diphtheria than in respiratory diphtheria and must be weighed against the potential adverse effects of antitoxin treatment; authorities are not unanimous in recommending antitoxin therapy for cutaneous diphtheria.

Antibiotics have little demonstrated effect on the healing of local infection in diphtheria patients treated with antitoxin. The primary goal of antibiotic therapy for patients or carriers is therefore to eradicate *C. diphtheriae* and prevent its transmission from the patient to susceptible contacts. Erythromycin, penicillin G, rifampin, or clindamycin is recommended by most authorities. Commonly recommended regimens for the treatment of adults with respiratory diphtheria are erythromycin (500 mg four times daily, given parenterally or orally) or intramuscular procaine penicillin G (600,000 units at 12-h intervals) for 14 days. Patients with cutaneous diphtheria and carriers can be treated orally with erythromycin (500 mg four times daily) or rifampin (600 mg once daily) for 7 days. If compliance is in question, a single dose of benzathine penicillin G (1.2 to 2.4 million units intramuscularly) can be substituted. Eradication of *C. diphtheriae* should be documented by negative cultures of samples taken on two or three successive days, beginning at least 24 h after the completion of antibiotic therapy. Some authorities also recommend a repeat throat culture 2 weeks later. The small percentage of patients who continue to be infected with *C. diphtheriae* after treatment should receive an additional 10-day course of oral erythromycin or rifampin. Plasmid-mediated resistance to erythromycin of the MLS type emerged transiently in *C. diphtheriae* during the Seattle epidemic, but its frequency declined dramatically after the routine use of erythromycin was discontinued.

Patients with respiratory or cutaneous diphtheria caused by *tox*+ *C. diphtheriae* or by strains of unknown toxinogenicity should be hospitalized, kept in bed initially, handled with isolation procedures appropriate for the site of infection, and given supportive care as needed. Respiratory and cardiac function must be monitored closely. Early intubation

or tracheostomy is recommended when the larynx is involved or signs of impending airway obstruction are detected. Tracheobronchial membrane can sometimes be removed mechanically via the endotracheal tube or tracheostomy. Primary or secondary pneumonia should be diagnosed and treated promptly. Sedative or hypnotic drugs that may mask respiratory symptoms are contraindicated. Close electrocardiographic monitoring, treatment of arrhythmias, and electrical pacing for heart block are essential. Congestive heart failure should be treated as described in Chap. 232. Glucocorticoids do not reduce the risk of diphtheritic myocarditis or polyneuritis. Ulcerative or ecthymatous cutaneous lesions should be treated with Burow's solution applied on wet compresses after debridement of necrotic areas, and treatment for associated conditions such as pediculosis, scabies, or underlying dermatoses should be instituted. Recovery from diphtheria does not always confer active immunity, and initiation of an immunization regimen for diphtheria that is appropriate for the patient's age should be an integral part of the treatment plan.

PREVENTION

Vaccines available in the United States for immunization against diphtheria include diphtheria and tetanus toxoids and pertussis vaccine adsorbed (DTP), diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed (DTaP), diphtheria and tetanus toxoids adsorbed (DT; for pediatric use), and tetanus and diphtheria toxoids adsorbed (Td; for adult use). DTaP is preferred over DTP for primary immunization of children without contraindications, and use of DTP is no longer recommended. Td contains less diphtheria toxoid than DTP, DTaP, or DT and causes fewer adverse reactions in adults. Current guidelines for primary immunization of children and adults against diphtheria and for maintaining immunity by periodic booster doses of appropriate vaccines throughout life are summarized in Chap. 122.

Close contacts of diphtheria patients should be cultured for *C. diphtheriae*, kept under surveillance for 1 week, and treated with appropriate antibiotics if cultures are positive. Previously immunized close contacts should receive an appropriate booster containing diphtheria toxoid if their last booster was given>5 years previously. If immunization status is uncertain, close contacts should receive an antibiotic regimen appropriate for carriers and a primary immunization series appropriate for their age.

OTHER CORYNEBACTERIAL INFECTIONS

DEFINITION

Medically important coryneform bacteria (formerly called *diphtheroids*) include members of the normal flora that cause opportunistic infections, human pathogens of relatively low virulence, and animal pathogens that cause occasional zoonotic infections. Reported infections caused by coryneform bacteria have increased substantially in number over the past two decades. Isolates of *C. jeikeium* and *C. urealyticum* are often resistant to multiple antibiotics.

ETIOLOGY AND LABORATORY DIAGNOSIS

Because coryneform bacteria are potential pathogens, it is important not to dismiss

them as constituents of the normal flora or as contaminants when they are found in clinical specimens. Laboratory differentiation of coryneform bacteria is important when they are isolated repeatedly, when they are recovered in pure culture or in large numbers, or when they form pigmented or hemolytic colonies.

The coryneform bacteria are a large, heterogeneous group of gram-positive, pleomorphic, irregularly staining bacilli or coccobacilli that superficially resemble *C. diphtheriae* and are difficult to identify and classify. The genus *Corynebacterium* is currently divided into three groups of species: the nonlipophilic, fermentative corynebacteria (including *C. diphtheriae*, *C. xerosis*, *C. striatum*, *C. minutissimum*, and others); the nonlipophilic, nonfermentative corynebacteria (including *C. pseudodiphtheriticum* and others); and the lipophilic corynebacteria (including *C. jeikeium*, *C. urealyticum*, and others). Coryneform bacteria also belong to many other genera (including *Actinomyces*, *Arcanobacterium*, and *Rhodococcus*) as well as to several groups that have not yet been assigned to genera and species by the U.S. Centers for Disease Control and Prevention (CDC).

ECOLOGY AND EPIDEMIOLOGY

Humans are the probable natural reservoir for *C. xerosis*, *C. pseudodiphtheriticum* (formerly *C. hofmannii*), *C. striatum*, *C. minutissimum*, *C. jeikeium* (formerlyCDCgroup JK), *C. urealyticum* (formerly CDC group D2), and *Arcanobacterium haemolyticum* (formerly *C. haemolyticum*). Animals are the probable natural reservoir for *Actinomyces pyogenes* (formerly *C. pyogenes*; cows, sheep, pigs), *C. ulcerans* (cows, horses), and *C. pseudotuberculosis* (sheep, horses, goats, cattle). The natural reservoir for *Rhodococcus equi* (formerly *C. equi*) is soil. The ecologic niches for many other coryneform bacteria of medical importance are not well defined.

The coryneform bacteria found most frequently as components of the normal flora include *C. pseudodiphtheriticum* (pharynx, skin), *C. xerosis* (conjunctival sac, nasopharynx, skin), and *C. striatum* (anterior nares, skin). Coryneform bacteria that commonly colonize the skin of hospitalized patients include *C. jeikeium* (axilla, groin, perineum) and *C. urealyticum*. *C. jeikeium* most often colonizes patients with malignancies or severe immunodeficiency; it is also isolated from environmental sources (surfaces, air) in hospitals and from the hands of ward staff. *C. ulcerans* infections are acquired by consumption of raw milk. *C. pseudotuberculosis* infections are acquired by contact with animals or animal products or by consumption of raw milk.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

C. jeikeium was recognized in 1976 as a cause of infections in immunocompromised hosts. This organism also causes infections in immunocompetent hosts, but severe infections continue to be most frequent in patients with hematologic malignancies and neutropenia. Skin colonization precedes clinical infection. Additional risk factors for nosocomial *C. jeikeium* sepsis include prolonged hospitalization, breaks in the integument, chronic intravascular catheterization, and prior treatment with broad-spectrum antibiotics. Other presentations of *C. jeikeium* infection include endocarditis, device-related infections, pulmonary infiltrates, cutaneous septic emboli, soft tissue infections, and rashes. Endocarditis due to *C. jeikeium* occurs primarily in

patients with prosthetic heart valves. *C. jeikeium* is a rare cause of central nervous system infections in patients with ventricular shunts.

C. urealyticum (formerlyCDCgroup D2) was identified in 1985 as a significant cause of nosocomial urinary tract infections, including acute and chronic cystitis and pyelonephritis. The organism closely resembles *C. jeikeium* but differs from the latter by producing urease and failing to convert glucose to acidic metabolites. Hydrolysis of urea by urease causes alkalinization of the urine and formation of ammonium magnesium phosphate (struvite) stones. *C. urealyticum* is a cause of alkaline-encrusted cystitis in patients with preexisting bladder lesions that serve as foci for precipitation of struvite crystals. Risk factors associated with symptomatic urinary tract infections include preexisting immunosuppression, recent urologic procedures (including renal transplantation), underlying disorders of the genitourinary tract, and a history of urinary tract infections.

A. haemolyticum causes pharyngitis and chronic skin ulcers; less frequently, it causes a variety of deep tissue infections, septicemia, and endocarditis. Some 90% of *A. haemolyticum* infections occur in patients between 10 and 30 years old. *A. haemolyticum* pharyngitis in this age group is 5 to 13% as frequent as *Streptococcus pyogenes* pharyngitis. An erythematous rash is present in 30 to 67% of cases. The rash is usually scarlatiniform and most pronounced on the trunk and proximal extremities, but it sometimes resembles urticaria or erythema multiforme. Because rash is more frequent in *A. haemolyticum* infections than in *S. pyogenes* infections, *A. haemolyticum* should be considered as a possible etiology in older children and adults who present with the scarlet fever syndrome. Infection due to *A. haemolyticum* can also present as extensive pharyngeal exudate and can mimic diphtheria. *A. haemolyticum* occasionally causes peritonsillar abscess, sepsis, endocarditis, or meningitis.

C. minutissimum is frequently isolated from the lesions of erythrasma (Fig. 141-CD2), a common superficial skin infection characterized by the presence in intertriginous areas of reddish-brown, scaly, pruritic, macular patches that exhibit coral-red fluorescence under a Wood's light. The etiology of erythrasma appears to be polymicrobial; infection of the skin by *C. minutissimum* has been shown to follow the onset of maceration and scaling. Deep infections caused by *C. minutissimum* are rare and include abscesses, bacteremia, endocarditis, peritonitis, pyelonephritis, and infection of central venous catheters.

Among coryneform bacteria that cause disease in animals and occasionally in humans, *R. equi* has emerged as an important intracellular opportunistic pathogen in immunocompromised patients. Most reported cases are necrotizing pulmonary infections that resemble tuberculosis or nocardiosis in patients with severely defective cell-mediated immunity. Cases of *R. equi* infection are being diagnosed with increasing frequency in patients with AIDS.

A. pyogenes causes bovine mastitis, a disease transmitted by flies. Yearly epidemics of leg ulcers infected with *A. pyogenes* occurred among schoolchildren in Thailand between 1979 and 1984 and were postulated to have resulted from introduction of the organism into traumatic skin lesions by flies. Reported *A. pyogenes* infections in adults in Denmark have included abscesses, cystitis, intraabdominal infections, and mastoiditis

with bacteremia.

C. ulcerans infections in humans usually present as pharyngitis and can mimic respiratory diphtheria, whereas infections caused by *C. pseudotuberculosis* typically present as suppurative granulomatous lymphadenitis. Some strains of *C. ulcerans* and *C. pseudotuberculosis* produce diphtheria toxin. Human infections by *tox*+ strains of *C. ulcerans* -- but not by *tox*+ strains of *C. pseudotuberculosis* -- have been reported, and administration of diphtheria antitoxin is therefore warranted in infections by *C. ulcerans* that are presumed on clinical grounds to be caused by toxinogenic strains.

C. pseudodiphtheriticum, a commensal of low virulence, is an uncommon cause of pneumonia in men with AIDS and of endocarditis, necrotizing tracheitis, tracheobronchitis, and urinary tract infection in patients without known immune deficiencies. Likewise, *C. xerosis* and *C. striatum* only occasionally cause human infections.

DIAGNOSIS

The clinical features of *C. jeikeium* infections are not pathognomonic. The diagnosis of these infections is based on a high index of suspicion, identification of the organism by culture in appropriate clinical specimens, and exclusion of other likely causes of infection.

C. urealyticum often goes undetected by routine urine cultures; rather, it is necessary to incubate the cultures for 24 to 48 h on blood agar or on special media. Cultivation should be prolonged in selected cases -- i.e., those involving patients (especially elderly men with preexisting genitourinary abnormalities) with alkaline urine, ammonium magnesium phosphate stones, gram-positive bacilli in the urine, or negative standard urine cultures despite clinical evidence of bacteriuria. Other microbes that can cause urinary tract infections with alkaline urine include *Proteus*, *Ureaplasma*, and some staphylococci and streptococci. Alkaline-encrusted cystitis is an anatomic diagnosis made by cystoscopy.

The differential diagnosis of *A. haemolyticum* pharyngitis with rash includes scarlet fever; rubella; staphylococcal and streptococcal toxic shock syndromes; infections caused by Epstein-Barr virus, cytomegalovirus, and enteroviruses (especially coxsackieviruses); disseminated gonococcal infection; secondary syphilis; and drug allergy. Routine diagnostic methods for throat cultures are not ideal for the detection of *A. haemolyticum*, nor is this organism detected by the rapid tests for *S. pyogenes* that are sometimes substituted for throat cultures. Pharyngitis caused by *A. haemolyticum* in adolescents and adults is likely to be underdiagnosed until improved tests for the organism are used by diagnostic laboratories.

Erythrasma is diagnosed clinically. Because of uncertainty about the etiologic role of *C. minutissimum*, culture of erythrasma lesions is not currently recommended. Pharyngitis caused by *tox*+ strains of *C. ulcerans* may be clinically indistinguishable from diphtheria. The presentations of infections caused by other coryneform bacteria are not usually diagnostic; cultures are required for identification of the causal organisms.

TREATMENT

Strains of *C. jeikeium* are typically resistant to most antibiotics. Vancomycin is the drug of choice for empirical treatment of infections caused by this organism, although antimicrobial susceptibility testing may reveal other antibiotic options for some isolates. For device-related *C. jeikeium* infections, removal of the infected device is usually required in addition to appropriate antibiotic therapy.

C. urealyticum is often resistant to the antibiotics used commonly for the treatment of urinary tract infections. Empirical treatment with vancomycin is appropriate pending the results of antimicrobial susceptibility testing. Several courses of antibiotic therapy may be necessary for bacteriologic cure. Patients with alkaline-encrusted cystitis require resection of the encrusted lesions in addition to antibiotic therapy.

No controlled trials of treatment for *A. haemolyticum* infections have been performed. In vitro tests usually demonstrate susceptibility to penicillins, erythromycin, azithromycin, clindamycin, doxycycline, ciprofloxacin, and vancomycin, but treatment failures have been reported with appropriate doses of penicillins. Limited data suggest that the clinical course of *A. haemolyticum* pharyngitis may be shortened by treatment with erythromycin.

Infections with *C. ulcerans* that present like diphtheria or are known to be caused by *tox*+ strains should be treated like diphtheria. Oral erythromycin is usually effective for treatment of erythrasma. For infections caused by *R. equi*, vancomycin is the drug of choice. Possible alternatives include erythromycin, rifampin, aminoglycosides, and chloramphenicol; the combination of erythromycin and rifampin is attractive because of possible synergy. Penicillins should not be used, because *R. equi* rapidly develops resistance. Many weeks of antibiotic treatment, sometimes supplemented by surgical intervention, are often needed for infections caused by *R. equi*. Suppressive therapy with antibiotics should be continued indefinitely in patients with AIDS after initial treatment of infections caused by *R. equi*. Initial treatment of infections caused by other coryneform bacteria should be based on the identity of the organism and published data regarding antibiotic susceptibility. Therapy should be modified, when necessary, in light of the results of antibiotic susceptibility tests.

ANTHRAX

DEFINITION

Anthrax is an infection caused by *Bacillus anthracis* that occurs primarily in herbivores. Humans become infected when *B. anthracis* spores are introduced into the body by contact with infected animals or contaminated animal products, insect bites, ingestion, or inhalation. Aerosolized spores of *B. anthracis* have the potential for use in biological warfare or bioterrorism. Cutaneous anthrax is most common and is characterized by the development of a localized skin lesion with a central eschar surrounded by marked nonpitting edema. Inhalation anthrax (woolsorters' disease) typically involves hemorrhagic mediastinitis, rapidly progressive systemic infection, and a very high mortality rate. Gastrointestinal anthrax is rare and is associated with a high mortality rate.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

B. anthracis is a large, aerobic, spore-forming, gram-positive rod that is encapsulated and nonmotile and grows in chains. Sporulation does not take place in living animals. The rectangular shape of the individual bacteria gives chains of *B. anthracis* a boxcar-like appearance. Virulent strains of *B. anthracis* are pathogenic for animals, including mice and guinea pigs. Spores of *B. anthracis* can survive for years in dry earth but are destroyed by boiling for 10 min, by treatment with oxidizing agents such as potassium permanganate or hydrogen peroxide, or by dilute formaldehyde. Most strains of *B. anthracis* are susceptible to penicillin.

Anthrax occurs worldwide and is most prevalent among domestic herbivores (including cattle, sheep, horses, and goats) and wild herbivores. Grazing animals become infected when they forage for food in areas contaminated with spores of *B. anthracis*. Anthrax in herbivores tends to be severe, with high mortality. Terminally ill animals with overwhelming bacteremic infections often bleed from the nose, mouth, and bowel, thereby contaminating soil or water with vegetative *B. anthracis* that can sporulate and persist in the environment. The carcasses of infected animals provide additional potential foci of contamination.

Humans are more resistant to anthrax than are herbivorous animals. The estimated number of human cases worldwide is 20,000 to 100,000 per year. Human cases are classified as agricultural or industrial. Agricultural cases result most often from contact with animals that have anthrax (e.g., during skinning, butchering, or dissecting), from bites of contaminated or infected flies, and (in rare instances) from consumption of contaminated meat. Industrial cases are associated with exposure to contaminated hides, goat hair, wool, or bones. Only three cases of cutaneous anthrax were reported to theCDC from 1984 through 1993, and gastrointestinal anthrax has never been documented in the United States. In an epidemic in the former Soviet Union at Sverdlovsk in 1979, cases were initially reported as cutaneous and gastrointestinal anthrax associated with contaminated meat; however, subsequent analysis of epidemiologic data and autopsy findings for most of the fatal cases established that the disease was inhalational anthrax associated with accidental airborne release of *B. anthracis* from a nearby military biological weapons facility. A massive outbreak in Zimbabwe between 1978 and the early 1980s involved more than 9700 cases of agricultural anthrax in humans. This outbreak occurred during wartime and was associated with disruption of the veterinary and medical infrastructure and cessation of veterinary anthrax vaccination programs.

PATHOGENESIS

B. anthracis can evade phagocytosis, invade the bloodstream, multiply rapidly to a high population density in vivo, and kill quickly. The poly-D-glutamic acid capsule of *B. anthracis* confers resistance to phagocytosis. Anthrax toxin consists of three different proteins called *protective antigen* (PA), *edema factor* (EF), and *lethal factor* (LF). The toxin was discovered in studies demonstrating that transfer of sterile blood from guinea pigs dying of anthrax to uninfected guinea pigs killed the recipients. PA binds to plasma membranes of target cells and is cleaved by a cellular protease into two fragments. The

larger fragment remains on the cell surface, displays a binding site for a domain that is present in both EF and LF, and serves as a specific receptor that mediates endocytic entry of EF or LF into the target cells. The catalytic activity of EF, a calmodulin-dependent adenylate cyclase, is expressed in the cytoplasm of human or animal cells that contain both calmodulin and ATP. The biologic effects of EF, which include formation of edema in anthrax lesions and inhibition of polymorphonuclear leukocyte functions, are mediated by the intracellular cyclic AMP that is produced by the enzymatic action of EF. In contrast, LF is a highly specific endopeptidase that cleaves several members of the MAP-kinase-kinase protein family and inactivates their functions in signal transduction pathways. Macrophages appear to be the principal targets of LF in animals, and intoxication of macrophages by LF is associated with production of reactive oxygen species, release of cytokines (including tumor necrosis factor a and interleukin 1b), shock, and death.

Cutaneous anthrax is initiated when spores of *B. anthracis* are introduced into the skin through cuts or abrasions or by biting flies. The spores germinate within hours, and the vegetative cells multiply and produce anthrax toxin. The cutaneous anthrax lesion is characterized by necrosis, vascular congestion, hemorrhage, and gelatinous edema, but few leukocytes are present.

In inhalational anthrax, *B. anthracis* spores in airborne particles <5 um in diameter are deposited directly into the alveoli or alveolar ducts. The spores are phagocytized by alveolar macrophages, and some are carried to and germinate in mediastinal nodes. Hemorrhagic necrosis of the nodes, associated with hemorrhagic mediastinitis and overwhelming *B. anthracis* bacteremia, may develop rapidly. Secondary pneumonia sometimes occurs.

Gastrointestinal anthrax usually results from ingestion of inadequately cooked meat from animals with anthrax. Primary infection can be initiated in the intestine by organisms that survive passage through the stomach. An oropharyngeal form of the disease has also been described. Lesions in the throat or intestine are usually accompanied by hemorrhagic lymphadenitis.

B. anthracis bacteremia occurs in almost all cases of anthrax that progress to a fatal outcome.

CLINICAL MANIFESTATIONS

Approximately 95% of human cases of anthrax are the cutaneous form, and ~5% are the inhalational form. Gastrointestinal anthrax is very rare. Anthrax meningitis can occur as a complication of overwhelming *B. anthracis* bacteremia.

Cutaneous Anthrax The cutaneous lesion in anthrax is most often found on exposed areas of skin. A small red macule develops within days after inoculation of *B. anthracis* spores into skin. During the next week, the lesion typically progresses through papular and vesicular or pustular stages to the formation of an ulcer with a blackened necrotic eschar surrounded by a highly characteristic expanding zone of brawny edema. The early lesion may be pruritic, and the fully developed lesion is painless. Small satellite vesicles may surround the original lesion, and painful nonspecific regional lymphadenitis

is common. Most patients are afebrile, with mild or no constitutional symptoms; in severe cases, edema may be extensive and associated with shock. Spontaneous healing occurs in 80 to 90% of untreated cases, but edema may persist for weeks. In the 10 to 20% of untreated patients who have progressive infection, bacteremia develops and is often associated with high fever and rapid death. The differential diagnosis includes staphylococcal skin infections, tularemia, plague, and orf. Cutaneous anthrax should be considered when patients have painless ulcers associated with vesicles and edema and have had contact with animals or animal products.

Inhalational Anthrax The presenting symptoms of inhalational anthrax (woolsorters' disease) resemble those of severe viral respiratory diseases. Early diagnosis of inhalational anthrax that occurs naturally or as a consequence of biological warfare or bioterrorism is difficult. After 1 to 3 days, an acute phase supervenes, with increasing fever, dyspnea, stridor, hypoxia, and hypotension usually leading to death within 24 h. Occasionally, patients present with fulminant disease. A characteristic radiologic finding associated with hemorrhagic mediastinitis is symmetric mediastinal widening, which may provide an early clue to the diagnosis of inhalational anthrax.

Gastrointestinal Anthrax Symptoms of gastrointestinal anthrax are variable and include fever, nausea and vomiting, abdominal pain, bloody diarrhea, and sometimes rapidly developing ascites. Diarrhea is occasionally massive in volume. The major features of oropharyngeal anthrax are fever, sore throat, dysphagia, painful regional lymphadenopathy, and toxemia; respiratory distress may be evident. The primary lesion is most often located on the tonsils.

LABORATORY DIAGNOSIS

B. anthracis is present in large numbers in cutaneous lesions of anthrax and can be demonstrated by Gram's staining, direct fluorescent antibody staining, or culture unless the patient has been treated with antibiotics. A small proportion of patients with anthrax have bacteremia. Patients with anthrax meningitis have bloody spinal fluid containing large numbers of *B. anthracis* demonstrable by staining or culture. Patients with mild disease usually have normal leukocyte counts, but those with disseminated disease typically have polymorphonuclear leukocytosis. Tests for antibody to *B. anthracis* are useful in confirming the diagnosis of anthrax.

TREATMENT

Viable *B. anthracis* disappears from the lesions of cutaneous anthrax within 5 h of the initiation of treatment with parenteral penicillin G. The recommended regimen for adults is 2 million units of penicillin G at intervals of 6 h until edema subsides, with the subsequent administration of oral penicillin to complete a 7- to 10-day course. For penicillin-sensitive adults, treatment with ciprofloxacin, erythromycin, tetracycline, or chloramphenicol can be substituted. Antibiotics decrease local edema and systemic toxicity in cutaneous anthrax but do not prevent eschar formation. Cutaneous lesions should be cleaned and covered, and used dressings should be decontaminated. For inhalational or gastrointestinal anthrax, high-dose penicillin (8 to 12 million units per day in divided doses at intervals of 4 to 6 h) is recommended. A rational case can be made for passive immunization with anthrax antitoxin in addition to antibiotic therapy in

severely ill patients with anthrax, but no appropriate antitoxin is commercially available.

PREVENTION

Inhalational anthrax was essentially eliminated in England before 1940 through the development of methods to decontaminate wool and goat hair and the improvement of working conditions for handlers of animal products.

Nonliving vaccines consisting of alum-precipitated or aluminum hydroxide-adsorbed extracellular components of unencapsulated *B. anthracis* are used in the United States for military personnel, agricultural workers, veterinary personnel, and others at risk of exposure to anthrax. The major active component of these vaccines is protective antigen. Live attenuated vaccines containing spores of *B. anthracis* are used in both developed and developing countries to immunize domestic herbivores; these preparations are also used to immunize humans in Russia but not in the United States. The probable basis for attenuation of the original Pasteur spore vaccine is partial loss of a plasmid that encodes anthrax toxin. The basis for attenuation of the current Sterne spore vaccine is loss of a plasmid that encodes capsular polypeptide.

Improved anthrax vaccines for humans are needed because the current vaccines are impure and chemically complex, elicit only slow onset of protective immunity, provide incomplete protection, and cause significant adverse reactions. In addition to agricultural and industrial anthrax, the possible use of *B. anthracis* as an agent of biological warfare or bioterrorism is a stimulus for the development of an improved vaccine. Current strategies for vaccine development include purification of candidate protective antigens, expression of protective antigens in recombinant microbial vaccines, and construction of improved live attenuated strains of *B. anthracis*.

Carcasses of animals that succumb to anthrax should be buried intact or cremated. Necropsy or butchering of infected animals should be avoided because sporulation of *B. anthracis* occurs only in the presence of oxygen.

PROGNOSIS

The mortality rate is 10 to 20% for untreated cutaneous anthrax but is very low with appropriate antibiotic therapy. In contrast, the mortality rate for inhalational anthrax approaches 100%, and therapy is usually unsuccessful. The mortality rate in treated gastrointestinal anthrax is ~50%. Anthrax meningitis is usually fatal.

142. INFECTIONS CAUSED BY *LISTERIA MONOCYTOGENES* - *Anne Schuchat*, *Claire V. Broome*

Listeria monocytogenes is a gram-positive rod that can be isolated from soil, vegetation, and many animal reservoirs. Human disease due to *L. monocytogenes* generally occurs in the setting of pregnancy or of immunosuppression caused by illness or medication. Increasing evidence suggests that a substantial portion of cases of human listeriosis are attributable to the food-borne transmission of *L. monocytogenes*. Unlike most food-borne pathogens, which cause primarily gastrointestinal illness, *L. monocytogenes* causes invasive syndromes, such as meningitis, sepsis, chorioamnionitis, and stillbirth.

ETIOLOGY

Listeriae are aerobic or facultatively anaerobic nonsporulating bacilli that grow at 1 to 45°C and typically have tumbling motility when cultured at 20 to 25°C. Characteristics that help distinguish *L. monocytogenes* from other *Listeria* spp. include the formation of a narrow zone of b hemolysis on sheep blood agar and the production of acid from glucose, maltose, L-rhamnose, anda-methyl-D-mannoside but not from D-xylose. Determination of the serotype of *L. monocytogenes* is based on somatic (O) and flagellar (H) antigens. Most cases of human disease are caused by serotypes 1/2a, 1/2b, and 4b. Molecular subtyping techniques have made it easier to discriminate among strains of *Listeria* and thus to link environmental or food isolates with clinical infections.

PATHOGENESIS

L. monocytogenes is an intracellular pathogen -- a characteristic consistent with its predilection for causing illness in persons with deficient cell-mediated immunity. The organism can be found as part of the gastrointestinal flora in healthy individuals. Lack of gastric acidity and abnormal gastrointestinal functioning may increase the risk of invasive disease following exposure to the organism in the gastrointestinal tract. The increased risk of *L. monocytogenes* infection in pregnant women may be due to both systemic and local immunologic changes associated with pregnancy. For example, local immunosuppression at the maternal-fetal interface of the placenta may facilitate intrauterine infection following transient maternal bacteremia.

The molecular pathogenesis of *L. monocytogenes* has recently been elucidated. The cell-surface protein internalin interacts with specific receptors to induce phagocytosis. Both listeriolysin O and phospholipases permit the organism to escape from the phagosome into the cytosol while avoiding intracellular killing. Through the surface protein Act A, *L. monocytogenes* uses actin-based motility to move to the cell membrane. Efficient cell-to-cell spread is accomplished by both actin filament formation and phospholipase production. Genetic determinants of these proteins have been characterized. Because the organism is adapted for both intracellular survival and direct cell-to-cell spread, it is not eliminated by antibodies.

EPIDEMIOLOGY

Long recognized as a veterinary pathogen, *L. monocytogenes* causes basilar meningitis

("circling disease") and stillbirth in sheep and cattle. The occurrence of listeriosis among humans has received increasing attention as the role of contaminated foods in the pathogenesis of epidemic listeriosis has been recognized and reports of disease associated with the expanding immunosuppressed population have accumulated.

Invasive listeriosis -- confirmed by culture of blood or cerebrospinal fluid (CSF) -- occurs in approximately 5 individuals per million population annually in the United States, for an estimated 1400 cases per year. Perinatal listeriosis complicates 9 births per 100,000. A 40% decline in incidence since the period from 1986 through 1990 may be attributable to aggressive food regulation and industrial clean-up efforts. Multistate surveillance for sporadic listeriosis suggests that 20% of infections are fatal or result in stillbirth, although higher case-fatality rates have been reported during listeriosis epidemics and were described in early series. Most cases of disease due to *L. monocytogenes* are sporadic; however, investigation of several outbreaks of listeriosis during the 1980s and 1990s demonstrated common-source food-borne transmission as a cause of human illness and showed that the incubation period for disease following consumption of contaminated food can be 2 to 6 weeks. The largest North American outbreak, which took place in Los Angeles in 1985, involved more than 100 cases and 48 deaths or stillbirths. A nationwide outbreak in France in 1992 involved 279 cases and 63 deaths. Foods implicated in outbreaks of listeriosis include contaminated coleslaw, pasteurized milk, soft cheeses, pate, ready-to-eat pork products, and hot dogs, while epidemiologic studies have implicated undercooked chicken, uncooked hot dogs, soft cheeses, and food from store delicatessen counters in sporadic disease. Listerial contamination of foods is relatively common. Among foods contaminated with the organism, those that are purchased ready to eat, are contaminated with serotype 4b, and are contaminated at a relatively high level may be the most likely to cause illness. The long incubation period associated with listeriosis contributes to the difficulty of implicating specific foods as the cause of either common-source outbreaks or sporadic cases.

Although food-borne transmission appears to be the foremost cause of epidemic and sporadic disease, several clusters of late-onset neonatal infection suggest nosocomial transmission of *L. monocytogenes*. Contaminated multiuse materials and equipment have been suggested as causes of some nosocomial clusters. Listeriosis has been reported in veterinarians and other persons in close contact with infected animals.

CLINICAL PRESENTATION

Pregnancy-associated listeriosis may occur during any stage of pregnancy, although most infections are detected during the third trimester, possibly because of failure to obtain specimens for bacterial culture earlier during gestation in instances of abortion and stillbirth. One-half to two-thirds of pregnant women with perinatal listeriosis experience a mild illness characterized by fever, myalgias, malaise, and backache, which sometimes are accompanied by diarrhea, abdominal pain, nausea, and/or vomiting during the bacteremic phase. Blood cultures should be used for diagnosis. Transplacental spread of the organism results in intrauterine infection, which can lead to chorioamnionitis, premature labor, intrauterine fetal demise, or early-onset disease of the newborn. Women with listeriosis diagnosed during pregnancy have a favorable clinical outcome after antibiotic therapy or delivery. Although often included in the differential diagnosis of recurrent spontaneous abortion, infection with *L.*

monocytogenes appears to cause fewer than 2% of stillbirths.

Neonatal listeriosis can be classified under the same categories used for group B streptococcal infection (Chap. 140), with early-onset disease evident during the first week of life and late-onset disease developing thereafter. Infants may be symptomatic at birth; most infants with early-onset disease are symptomatic by the second day of life. Aspiration of infected amniotic fluid contributes to pathogenesis. Early-onset disease may include sepsis, respiratory distress, skin lesions, and the syndrome called *granulomatosis infantisepticum*, which is characterized by disseminated abscesses involving the liver, spleen, adrenal glands, lungs, and other sites. Infants with late-onset neonatal disease are more likely than those with early-onset disease to develop meningitis. While early-onset disease is often associated with obstetric complications such as premature delivery and chorioamnionitis, late-onset disease typically affects infants born at term by uncomplicated deliveries. Infants may acquire *L. monocytogenes* during passage through the birth canal; except in several clusters of late-onset neonatal infections linked to nosocomial transmission, the pathogenesis of late-onset disease is not well understood.

Listeriosis not associated with pregnancy usually affects persons with immunosuppressive conditions, although invasive disease can also affect immunocompetent adults, particularly elderly persons. The most common underlying conditions in nonpregnant adults with listeriosis are chronic glucocorticoid therapy, solid or hematologic malignancies, diabetes mellitus, renal disease, liver disease, and AIDS. Although the prevalence of listeriosis among persons infected with HIV is much higher than that in the general population, listeriosis is a relatively uncommon opportunistic infection in AIDS.

Sepsis Clinical studies have shown that bacteremic infection without an evident focus is the most common clinical manifestation of listeriosis among immunocompromised hosts, while infection of the central nervous system (CNS) ranks second in frequency. Listerial sepsis cannot be distinguished clinically from bacteremia involving other organisms. Patients are usually febrile, often appear extremely ill, and may have prodromal symptoms including myalgia, nausea, vomiting, and diarrhea. Immunocompromised patients with listeriosis are less likely than other adults to present with CNS infection, possibly because they are more likely to have blood cultured during febrile episodes and thus to have transient listerial bacteremia recognized.

CNS Infection The most common presentation ofCNSinfection due to *L. monocytogenes* is meningitis, which can present as either an acute or (less often) a subacute illness. Presenting symptoms include fever, headache, and an altered level of consciousness. Examination ofCSFusually reveals pleocytosis, increased protein concentrations, and normal glucose levels, although other patterns are sometimes found. Gram's stain is often unrevealing. The diagnosis is made when *L. monocytogenes* is identified on culture. Despite its name, *L. monocytogenes* is rarely associated with monocytosis of either CSF or blood. Other syndromes seen in CNS infection include meningoencephalitis; cerebritis; and brainstem, spinal cord, or intracranial abscesses. The unusual syndrome of rhombencephalitis includes asymmetric cranial-nerve palsies, altered consciousness, cerebellar signs, and motor or sensory loss. Symptoms of other nonmeningitic CNS infections include fever, ataxia,

seizures, personality changes, and coma. Nuchal rigidity is rare in nonmeningitic infections. CSF cultures may be sterile; blood cultures are usually diagnostic.

Endocarditis Like most forms of bacterial endocarditis, listerial endocarditis typically occurs in patients with prosthetic or previously damaged valves. The organism has a predilection for the left side of the heart. Endocarditis due to *L. monocytogenes* is often associated with systemic embolization.

Focal Infections Other focal infections that can follow unrecognized bacteremia include endophthalmitis, peritonitis, osteomyelitis, visceral abscess, pleuropulmonary infection, and cholecystitis. Cutaneous lesions may develop without systemic involvement and have been reported in veterinarians and poultry workers.

Recurrences Recurrent infection with *L. monocytogenes* has been reported but is rare. Many recurrences are due to the subtype responsible for the initial infection. The implication is that such recurrences result either from insufficient treatment of a focus of primary infection or from repeated exposure to a persistently contaminated source.

Gastrointestinal Illness Several common-source outbreaks of acute gastroenteritis suggest that *L. monocytogenes* can cause an acute diarrheal syndrome in persons without immunocompromising conditions. The importance of *L. monocytogenes* in sporadic diarrheal illness is unclear. Although the organism is not identified by the culture methods routinely used for stool specimens, studies using selective enrichment media for evaluation of consecutive specimens from patients hospitalized with acute diarrhea have suggested that *L. monocytogenes* is not a major cause of sporadic diarrhea.

DIAGNOSIS

Invasive listeriosis is diagnosed when the organism is cultured from a site that is usually sterile, such as blood,CSF, or amniotic fluid. The organism grows readily within 36 h on routine culture media, but morphologic similarities between *Listeria* and both diphtheroids and streptococci make it necessary to use biochemical tests to identify the species. Serologic assays with whole-cell antigens have not been useful for the diagnosis of listeriosis, both because exposure to the organism (and thus the presence of antibody) may be common and because infected individuals may not produce antibody. Assays for antibody to listeriolysin O have been applied in epidemiologic investigations and, retrospectively, in the diagnosis of culture-negativeCNSinfection. Culture of the organism from nonsterile sites such as the vagina and rectum is not useful for clinical diagnosis, as the organism may be carried at these sites by approximately 5% of healthy individuals.

Differential diagnosis of prematurity, spontaneous abortion, or stillbirth includes infectious diseases such as group B streptococcal infection, congenital syphilis, and toxoplasmosis; pathogens such as group B streptococci and *Escherichia coli* are more common than *L. monocytogenes* as causes of meningitis and sepsis in the newborn period. Listerial infection should always be considered in the differential diagnosis of meningitis in immunosuppressed persons, particularly transplant recipients and others undergoing glucocorticoid treatment, patients with hematologic malignancy, and

HIV-infected patients. Among healthy adults, meningitis is much more likely to be caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*, or viral pathogens than by *L. monocytogenes*.

TREATMENT

The treatment of choice for listeriosis is intravenous administration of either ampicillin or penicillin, often in combination with an aminoglycoside for synergy. Trimethoprim-sulfamethoxazole is bactericidal against *L. monocytogenes* and has been used successfully in the treatment of patients with penicillin allergy. *L. monocytogenes* is susceptible in vitro to penicillin G, ampicillin, erythromycin, trimethoprim-sulfamethoxazole, chloramphenicol, rifampin, tetracyclines, aminoglycosides, and imipenem. However, chloramphenicol and rifampin may antagonize the bactericidal effect of penicillins. Because *L. monocytogenes* is not sensitive to cephalosporins, these agents should not be used for single-agent empirical treatment of neonatal sepsis or of meningitis in newborns or immunocompromised hosts.

Dosages and durations of therapy have not been subjected to controlled trials. For nonpregnant adults with listeriosis, the regimen of choice is either ampicillin (12 g intravenously per day in six divided doses) or penicillin G (15 to 20 million units intravenously per day in six divided doses); for immunosuppressed patients with meningitis, some experts add gentamicin (1.3 mg/kg intravenously every 8 h) for synergy. Penicillin-allergic patients may be treated with trimethoprim-sulfamethoxazole (15/75 mg/kg intravenously per day in three equal portions every 8 h). Meningitis in an immunocompetent patient may require 2 to 3 weeks of antibiotic therapy after defervescence. Meningitis, bacteremia, endocarditis, and nonmeningitic listeriosis in immunosuppressed patients should be treated longer, probably for 4 to 6 weeks. Neonatal listeriosis can be treated with a 2-week course of ampicillin. Infants weighing <2000 g should receive 100 mg/kg per day in two equal doses during the first week of life and 150 mg/kg per day during the second week. Infants weighing³2000 g should receive 150 mg/kg per day in three equal doses during the first week of life and 200 mg/kg per day during the second week. The addition of an aminoglycoside should be considered for neonatal infection (gentamicin, 5 mg/kg per day in two divided doses during the first week of life; 7.5 mg/kg per day in three equal doses during the second week). For listeriosis in pregnant women, a 2-week course of ampicillin (4 to 6 g per day in four equal doses) is recommended. During the last month of pregnancy, infected women with serious penicillin allergies may be treated with erythromycin.

PROGNOSIS

Treatment of maternal bacteremia during pregnancy can prevent neonatal infection. Antibiotic therapy for the newborn can limit sequelae, although the widely disseminated disease characteristic of granulomatosis infantisepticum is frequently fatal regardless of treatment. Early-onset disease carries a higher mortality risk than late-onset infection, and immunocompromised hosts have a worse prognosis than do otherwise healthy adults with listeriosis.

PREVENTION

L. monocytogenes is frequently isolated from food; the Food and Drug Administration, the U.S. Department of Agriculture, and manufacturers are pursuing further measures to reduce *L. monocytogenes* contamination of foods that have been subjected to listericidal processing. Prevention of listeriosis requires dietary counseling of persons at increased risk of disease (Table 142-1). There is no role for the administration of prophylaxis to contacts of patients with listeriosis. Clinicians are encouraged to report cases of listeriosis to local or state health departments. Case reporting and subtyping of clinical isolates can facilitate early recognition of outbreaks and prevention of subsequent cases.

143. TETANUS - *Elias Abrutyn*

DEFINITION

Tetanus is a neurologic disorder, characterized by increased muscle tone and spasms, that is caused by tetanospasmin, a powerful protein toxin elaborated by *Clostridium tetani*. Tetanus occurs in several clinical forms, including generalized, neonatal, and localized disease.

ETIOLOGIC AGENT

C. tetani is an anaerobic, motile gram-positive rod that forms an oval, colorless, terminal spore and thus assumes a shape resembling a tennis racket or drumstick. The organism is found worldwide in soil, in the inanimate environment, in animal feces, and occasionally in human feces. Spores may survive for years in some environments and are resistant to various disinfectants and to boiling for 20 min. Vegetative cells, however, are easily inactivated and are susceptible to several antibiotics (metronidazole, penicillin, and others).

Tetanospasmin is formed in vegetative cells under plasmid control. It is a single-polypeptide chain. With autolysis, the single-chain toxin is released and cleaved to form a heterodimer consisting of a heavy chain (100 kDa), which mediates binding to nerve-cell receptors and entry into these cells, and a light chain (50 kDa), which acts to block neurotransmitter release. The amino acid structures of the two most powerful toxins known, botulinum toxin and tetanus toxin, are partially homologous.

EPIDEMIOLOGY

Tetanus occurs sporadically and almost always affects nonimmunized persons, partially immunized persons, or fully immunized individuals who fail to maintain adequate immunity with booster doses of vaccine. Although tetanus is entirely preventable by immunization, the burden of disease is large worldwide. The disease is common in areas where soil is cultivated, in rural areas, in warm climates, during summer months, and among males. In countries without a comprehensive immunization program, tetanus occurs predominantly in neonates and other young children; an estimated 490,000 neonates died of tetanus worldwide in 1994 -- a reduction from 550,000 in 1993. In the United States and other nations with successful immunization programs, neonatal tetanus is rare and the disease affects other age groups and groups inadequately covered by immunization (such as nonwhites). The risk for the development of tetanus and for the most severe illness is highest among the elderly. Only 27% of persons aged 70 or older -- as opposed to 88% of 6- to 11-year-olds -- have protective antibody levels. During the years 1995 through 1997, a total of 124 cases were reported to the Centers for Disease Control and Prevention; both the overall incidence (0.15 cases per 100,000 population) and the annual average (41 cases) were the lowest ever reported in the United States. The actual burden of illness, however, was greater, because reporting is incomplete. Although the elderly customarily account for the highest proportion of cases, in 1995 through 1997 individuals ³60 years of age accounted for only 35% of cases, whereas those 20 to 59 years of age accounted for 60% and those under 20 for 5% (with one case of neonatal tetanus). The change is attributed to a decrease in incidence

in both the ³60 and the<20 age groups, along with an increase among persons 20 to 59 years of age, particularly injection drug users.

In the United States, most cases of tetanus follow an acute injury, such as a puncture wound, laceration, or abrasion. Tetanus is acquired indoors or during farming, gardening, and other outdoor activities. The injury may be major but often is trivial, so that medical attention is not sought; in some instances no injury can be identified. The disease may complicate chronic conditions such as skin ulcers, abscesses, and gangrene. Tetanus is also associated with burns, frostbite, middle-ear infection, surgery, abortion, childbirth, and drug abuse, notably "skin popping." In some patients no portal of entry for the organism can be identified.

PATHOGENESIS

Contamination of wounds with spores of *C. tetani* is probably frequent. Germination and toxin production, however, take place only in wounds with low oxidation-reduction potential, such as those with devitalized tissue, foreign bodies, or active infection. *C. tetani* does not itself evoke inflammation, and the portal of entry retains a benign appearance unless infection with other organisms is present.

Toxin released in the wound binds to peripheral motor neuron terminals, enters the axon, and is transported to the nerve-cell body in the brainstem and spinal cord by retrograde intraneuronal transport. The toxin then migrates across the synapse to presynaptic terminals, where it blocks release of the inhibitory neurotransmitters glycine andg-aminobutyric acid (GABA). The blocking of neurotransmitter release by tetanospasmin, a zinc metalloprotease, involves the cleavage of protein(s) critical to proper function of the synaptic vesicle release apparatus. With diminished inhibition, the resting firing rate of thea motor neuron increases, producing rigidity. With lessened activity of reflexes that limit polysynaptic spread of impulses (a glycinergic activity), agonists and antagonists may be recruited rather than inhibited, with the consequent production of spasms. Loss of inhibition may also affect preganglionic sympathetic neurons in the lateral gray matter of the spinal cord and produce sympathetic hyperactivity and high circulating catecholamine levels. Tetanospasmin, like botulinum toxin, may block neurotransmitter release at the neuromuscular junction and produce weakness or paralysis; recovery requires sprouting of new nerve terminals.

In local tetanus, only the nerves supplying the affected muscles are involved. Generalized tetanus occurs when toxin released in the wound enters the lymphatics and bloodstream and is spread widely to distant nerve terminals; the blood-brain barrier blocks direct entry into the central nervous system. If it is assumed that intraneuronal transport times are equal for all nerves, short nerves are affected before long nerves: this fact explains the sequential involvement of nerves of the head, trunk, and extremities in generalized tetanus.

CLINICAL MANIFESTATIONS

Generalized tetanus, the most common form of the disease, is characterized by increased muscle tone and generalized spasms. The median time of onset after injury is 7 days; 15% of cases occur within 3 days and 10% after 14 days.

Typically, the patient first notices increased tone in the masseter muscles (trismus, or lockjaw). Dysphagia or stiffness or pain in the neck, shoulder, and back muscles appears concurrently or soon thereafter. The subsequent involvement of other muscles produces a rigid abdomen and stiff proximal limb muscles; the hands and feet are relatively spared. Sustained contraction of the facial muscles results in a grimace or sneer (risus sardonicus), and contraction of the back muscles produces an arched back (opisthotonos). Some patients develop paroxysmal, violent, painful, generalized muscle spasms that may cause cyanosis and threaten ventilation. These spasms occur repetitively and may be spontaneous or provoked by even the slightest stimulation. A constant threat during generalized spasms is reduced ventilation or apnea or laryngospasm. The severity of illness may be mild (muscle rigidity and few or no spasms), moderate (trismus, dysphagia, rigidity, and spasms), or severe (frequent explosive paroxysms). The patient may be febrile, although many have no fever; mentation is unimpaired. Deep tendon reflexes may be increased. Dysphagia or ileus may preclude oral feeding.

Autonomic dysfunction commonly complicates severe cases and is characterized by labile or sustained hypertension, tachycardia, dysrhythmia, hyperpyrexia, profuse sweating, peripheral vasoconstriction, and increased plasma and urinary catecholamine levels. Periods of bradycardia and hypotension may also be documented. Sudden cardiac arrest sometimes occurs, but its basis is unknown. Other complications include aspiration pneumonia, fractures, muscle rupture, deep vein thrombophlebitis, pulmonary emboli, decubitus ulcer, and rhabdomyolysis.

Neonatal tetanus usually occurs as the generalized form and is usually fatal if left untreated. It develops in children born to inadequately immunized mothers, frequently after unsterile treatment of the umbilical cord stump. Its onset generally comes during the first 2 weeks of life. Poor feeding, rigidity, and spasms are typical features of neonatal tetanus.

Local tetanus is an uncommon form in which manifestations are restricted to muscles near the wound. The prognosis is excellent.

Cephalic tetanus, a rare form of local tetanus, follows head injury or ear infection. Trismus and dysfunction of one or more cranial nerves, often the seventh nerve, are found. The incubation period is a few days and the mortality is high.

DIAGNOSIS

The diagnosis of tetanus is based entirely on clinical findings. Tetanus is unlikely if a reliable history indicates the completion of a primary vaccination series and the receipt of appropriate booster doses. Wounds should be cultured in suspected cases. However, *C. tetani* can be isolated from wounds of patients without tetanus and frequently cannot be recovered from wounds of those with tetanus. The leukocyte count may be elevated. Cerebrospinal fluid examination yields normal results. Electromyograms may show continuous discharge of motor units and shortening or absence of the silent interval normally seen after an action potential. Nonspecific changes may be evident on the electrocardiogram. Muscle enzyme levels may be raised. Serum antitoxin levels of^{3}0.01

U/mL are considered protective and make tetanus unlikely, although cases developing despite protective antitoxin levels have been reported.

The differential diagnosis includes local conditions also producing trismus, such as alveolar abscess, strychnine poisoning, dystonic drug reactions (e.g., to phenothiazines and metoclopramide), and hypocalcemic tetany. Other conditions sometimes confused with tetanus include meningitis/encephalitis, rabies, and an acute intraabdominal process (because of the rigid abdomen). Markedly increased tone in central muscles (face, neck, chest, back, and abdomen) with superimposed generalized spasms and relative sparing of the hands and feet strongly suggests tetanus.

TREATMENT

General Measures The goals of therapy are to eliminate the source of toxin, neutralize unbound toxin, and prevent muscle spasms, monitoring the patient's condition and providing support -- especially respiratory support -- until recovery. Patients should be admitted to a quiet room in an intensive care unit, where observation and cardiopulmonary monitoring can be maintained continuously but stimulation can be minimized. Protection of the airway is vital. Wounds should be explored, carefully cleansed, and thoroughly debrided.

Antibiotic Therapy Although of unproven value, antibiotic therapy is administered to eradicate vegetative cells -- the source of toxin. The use of penicillin (10 to 12 million units intravenously, given daily for 10 days) has been recommended, but metronidazole (500 mg every 6 h or 1 g every 12 h) is preferred by some experts on the basis of this drug's excellent antimicrobial activity, a survival rate higher than that obtained with penicillin in one nonrandomized trial, and the absence of theGABAantagonistic activity seen with penicillin. Clindamycin and erythromycin are also alternatives for the treatment of penicillin-allergic patients. Additional specific antimicrobial therapy should be given for active infection with other organisms.

Antitoxin Given to neutralize circulating toxin and unbound toxin in the wound, antitoxin effectively lowers mortality; toxin already bound to neural tissue is unaffected. Human tetanus immune globulin (TIG) is the preparation of choice and should be given promptly. The dose is 3000 to 6000 units intramuscularly, usually in divided doses because the volume is large. The optimal dose is not known, however, and results from one study indicated that a 500-unit dose was as effective as higher doses. Pooled intravenous immunoglobulin may be an alternative to TIG, but the specific antitoxin concentration in this formulation is not standardized. It may be best to administer antitoxin before manipulating the wound; the value of injecting a dose proximal to the wound or infiltrating the wound is unclear. Additional doses are unnecessary because the half-life of antitoxin is long. Antibody does not penetrate the blood-brain barrier. Intrathecal administration should be considered experimental. Equine tetanus antitoxin (TAT) is not available in the United States but is used elsewhere. It is cheaper than human antitoxin, but its half-life is shorter and its administration commonly elicits hypersensitivity and serum sickness.

Control of Muscle Spasms Many agents, alone and in combination, have been used to treat the muscle spasms of tetanus, which are painful and can threaten ventilation by

causing laryngospasm or sustained contraction of ventilatory muscles. The ideal therapeutic regimen would abolish spasmodic activity without causing oversedation and hypoventilation. Diazepam, a benzodiazepine andGABAagonist, is in wide use. The dose is titrated, and large doses (³250 mg/d) may be required. Lorazepam, with a longer duration of action, and midazolam, with a short half-life, are other options. Barbiturates and chlorpromazine are considered second-line agents. Therapeutic paralysis with a nondepolarizing neuromuscular blocking agent and mechanical ventilation may be required for the treatment of spasms unresponsive to medication or spasms that threaten ventilation. However, prolonged paralysis after the discontinuation of therapy with such agents has been described, and both the need for continued paralysis and the occurrence of complications should be assessed daily. Alternative agents include propofol, which is expensive, and dantrolene and baclofen, which are being investigated in the hope of shortening the period of therapeutic paralysis.

Respiratory Care Intubation or tracheostomy, with or without mechanical ventilation, may be required for hypoventilation due to oversedation or laryngospasm or for the avoidance of aspiration by patients with trismus, disordered swallowing, or dysphagia. The need for these procedures should be anticipated, and they should be undertaken electively and early.

Autonomic Dysfunction The optimal therapy for sympathetic overactivity has not been defined. Agents that have been considered include labetalol (ana- and b-adrenergic blocking agent that is recommended by some experts but that reportedly has caused sudden death), esmolol administered by continuous infusion (a beta blocker whose short half-life may be advantageous in the event of severe hypertension from unopposeda-adrenergic activity), clonidine (a central-acting antiadrenergic drug), and morphine sulfate. Parenteral magnesium sulfate and continuous spinal or epidural anesthesia have been used but may be more difficult to administer and monitor. The relative efficacy of these modalities has yet to be determined. Hypotension or bradycardia may require volume expansion, use of vasopressors or chronotropic agents, or pacemaker insertion.

Vaccine Patients recovering from tetanus should be actively immunized (see below) because immunity is not induced by the small amount of toxin that produces disease.

Additional Measures Additional therapeutic measures include hydration to control insensible and other fluid losses, which may be significant; the meeting of the patient's increased nutritional requirements by enteral or parenteral means; physiotherapy to prevent contractures; and administration of heparin or another anticoagulant to prevent pulmonary emboli. Bowel, bladder, and renal function must be monitored. Gastrointestinal bleeding and decubitus ulcers must be prevented, and intercurrent infection should be treated.

PREVENTION

Active Immunization All partially immunized and unimmunized adults should receive vaccine, as should those recovering from tetanus. The primary series for adults consists of three doses: the first and second doses are given 4 to 8 weeks apart, and the third dose is given 6 to 12 months after the second. A booster dose is required every 10

years and may be given at mid-decade ages -- 35, 45, and so on. Combined tetanus and diphtheria toxoid (Td) adsorbed (for adult use), rather than single-antigen tetanus toxoid, is preferred for persons >7 years of age.

Wound Management Proper wound management requires consideration of the need for (1) passive immunization withTIG and (2) active immunization with vaccine, preferably Td in persons over age 7. For clean minor wounds, Td is administered to persons who (1) have unknown tetanus immunization histories; (2) have received fewer than three doses of adsorbed tetanus toxoid; (3) have received three or more doses of adsorbed vaccine, with the last dose given >10 years previously; and (4) have received three doses of *fluid* (nonadsorbed) vaccine. The recommendations for contaminated or severe wounds are identical, except that vaccine should be given to those who have received three or more doses of adsorbed tetanus toxoid if >5 years have elapsed since the last dose. Passive immunization with TIG is not recommended for clean minor wounds but is given for all other wounds if the patient's vaccination history indicates unknown or partial immunization. The dose of TIG for passive immunization of persons with wounds of average severity is 250 units intramuscularly, which produces a protective antibody level in the serum for at least 4 to 6 weeks; the appropriate dose ofTAT is 3000 to 6000 units. Vaccine and tetanus antitoxin should be administered at separate sites in separate syringes.

Neonatal Tetanus Measures aimed at preventing neonatal tetanus include maternal vaccination, even during pregnancy; efforts to increase the proportion of births that take place in the hospital; and the provision of training for nonmedical birth attendants.

PROGNOSIS

The application of methods to monitor and support oxygenation has markedly improved the prognosis in tetanus; mortality rates as low as 10% have been reported from units accustomed to handling such cases. In the United States during the period 1995 through 1997, the case-fatality rate was 11%; 11 deaths from tetanus were reported in 1990, 11 in 1991, and 9 in 1992. The outcome is poor in neonates and the elderly and in patients with a short incubation period, a short interval from the onset of symptoms to admission, or a short period from onset of symptoms to the first spasm (period of onset). Outcome is also related to the extent of prior vaccination.

The course of tetanus extends over 4 to 6 weeks, and patients may require ventilatory support for 3 weeks during this period. Increased tone and minor spasms can last for months, but recovery is usually complete.

144. BOTULISM - *Elias Abrutyn*

DEFINITION

Botulism is a paralytic disease that begins with cranial nerve involvement and progresses caudally to involve the extremities. It is caused by potent protein neurotoxins elaborated by *Clostridium botulinum*. The toxins' high potency has led to consideration of their use in bioterrorism or biological warfare. Cases may be classified as (1) *food-borne botulism*, from ingestion of preformed toxin in food contaminated with *C. botulinum*; (2) *wound botulism*, from toxin produced in wounds contaminated with the organism; (3) *infant botulism*, from ingestion of spores and production of toxin in the intestine of infants; or (4) *adult infectious botulism*, a group that includes some cases in older children and adults in which disease is produced by a mechanism similar to that described for infant botulism.

ETIOLOGIC AGENT

C. botulinum, a species encompassing a heterogeneous group of anaerobic gram-positive organisms that form subterminal spores, is found in soil and marine environments throughout the world and elaborates the most potent bacterial toxin known. Organisms of types A through G have been distinguished by the antigenic specificities of their toxins; a classification system based on physiologic characteristics has also been described. Rare strains of other clostridial species -- *C. butyricum* and *C. baratii* -- have also been found to produce toxin. *C. botulinum* strains with proteolytic activity can digest food and produce a spoiled appearance; nonproteolytic types leave the appearance of food unchanged.

Of the eight distinct toxin types described (A, B, C_1, C_2, D, E, F, and G), all except C_2 are neurotoxins; C_2 is a cytotoxin of unknown clinical significance. Botulinum neurotoxin, whether ingested or produced in the intestine or a wound, enters the vascular system and is transported to peripheral cholinergic nerve terminals, including neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. The central nervous system is not involved. Active neurotoxin (150 kDa) is composed of a heavy chain (a 100-kDa fragment responsible for neurospecific binding and translocation into the nerve cell) and a light chain (a 50-kDa fragment responsible for intracellular catalytic activity). The steps involved in neurotoxin activity include (1) specific binding to presynaptic nerve cells at the myoneural junction, (2) internalization of the toxin inside the nerve cell in endocytic vesicles, (3) translocation of the toxin into the cytosol, and (4) proteolysis by toxin (a zinc endopeptidase) of components of the neuroexocytosis apparatus curtailing release of the neurotransmitter acetylcholine. Cure follows sprouting of new nerve terminals.

Toxin is heat-labile, but spores are highly heat-resistant; both can be inactivated under appropriate conditions (see "Prevention," below). In the gastrointestinal tract, toxin is complexed with nontoxin proteins and resists degradation.

Toxin types A, B, E, and (in rare instances) F cause human disease; type G (now called *C. argentinense*) has been associated with sudden death, but not with neuroparalytic illness, in a few patients in Switzerland; and types C and D cause animal disease.

EPIDEMIOLOGY

Human botulism occurs worldwide. In the United States, the geographic distribution of cases by toxin type parallels the distribution of organism types found in the environment. Type A predominates west of the Rocky Mountains; type B is generally distributed but is more common in the East; and type E is found in the Pacific Northwest, Alaska, and the Great Lakes area. In the United States, food-borne botulism has been associated primarily with home-canned food, particularly vegetables, fruit, and condiments, and less commonly with meat and fish. Type E outbreaks are frequently associated with fish products. Commercial products occasionally cause outbreaks, but some of these outbreaks have resulted from improper handling after purchase. Outbreaks in restaurants, schools, and private homes have been traced to uncommon sources (commercial potpies, beef stew, turkey loaf, sauteed onions, baked potatoes, and chopped garlic in oil). Food-borne botulism can occur when (1) a food to be preserved is contaminated with spores, (2) preservation does not inactivate the spores but kills other putrefactive bacteria that might inhibit the growth of *C. botulinum* and provides anaerobic conditions at a pH and temperature that allow germination and toxin production, and (3) food is not heated to a temperature that destroys toxin before being eaten.

CLINICAL MANIFESTATIONS

Food-Borne Botulism Following ingestion of food containing toxin, illness varies from a mild condition for which no medical advice is sought to very severe disease that can result in death within 24 h. The incubation period is usually 18 to 36 h but, depending on toxin dose, can extend from a few hours to several days. Symmetric descending paralysis is characteristic and can lead to respiratory failure and death. Cranial nerve involvement, which almost always marks the onset of symptoms, usually produces diplopia, dysarthria, and/or dysphagia. Weakness progresses, often rapidly, from the head to involve the neck, arms, thorax, and legs; the weakness is occasionally asymmetric. Nausea, vomiting, and abdominal pain may precede or follow the onset of paralysis. Dizziness, blurred vision, dry mouth, and very dry, occasionally sore throat are common. Patients are generally alert and oriented, but they may be drowsy, agitated, and anxious. Typically, they have no fever. Ptosis is frequent; the pupillary reflexes may be depressed, and fixed or dilated pupils are noted in half of patients. The gag reflex may be suppressed, and deep tendon reflexes may be normal or decreased. Paralytic ileus, severe constipation, and urinary retention are common.

Wound Botulism When wounds are contaminated with *C. botulinum* spores, the spores may germinate into vegetative organisms that produce toxin. This rare condition resembles food-borne illness except that the incubation period is longer, averaging about 10 days, and gastrointestinal symptoms are lacking. Wound botulism has been documented after traumatic injury involving contamination with soil; in injection drug users, for whom black-tar heroin use has been identified as a risk factor; and after cesarean delivery. The illness has occurred even after antibiotics have been given to prevent wound infection. When present, fever is probably attributable to concurrent infection with other bacteria. The wound may appear benign.

Infant Botulism In infant botulism, the most common form of the disease, toxin is produced in and absorbed from the intestine after the germination of ingested spores. The severity ranges from mild illness with failure to thrive to fulminant severe paralysis with respiratory failure and may be one cause of sudden infant death. The identification of contaminated honey as one source of spores has led to the recommendation that honey not be fed to children<12 months of age. Most cases cannot be attributed to a particular food source. The factors permitting intestinal colonization with *C. botulinum* are not fully defined, but cases usually involve infants<6 months of age; susceptibility may decrease as the normal intestinal flora develops.

Adult Infectious Botulism Rarely, botulism in adults is produced by a mechanism similar to that operative in infant botulism: intestinal colonization and toxin production. The patient may have a history of gastrointestinal disease, surgery, or recent antibiotic therapy. Toxin and organisms may be identified in the stool.

DIAGNOSIS

A diagnosis of botulism must be considered in afebrile, mentally intact patients who have symmetric descending paralysis without sensory findings. The diagnosis must be suspected on clinical grounds in the context of an appropriate history. Conditions often confused with botulism include myasthenia gravis, which may be ruled out by electromyography and antibody studies, and Guillain-Barre syndrome, which is characterized by ascending paralysis, sensory abnormalities, and elevation of the protein concentration in cerebrospinal fluid. The Fisher variant of Guillain-Barre -- a descending paralysis -- can indeed be difficult to differentiate from botulism. Other conditions that may resemble botulism include Lambert-Eaton syndrome, poliomyelitis, tick paralysis, diphtheria, and intoxications from mushrooms, medications, or chemicals. Hypermagnesemia should be considered.

The demonstration of toxin in serum by bioassay in mice is definitive, but this test may be negative, particularly in wound and infant botulism. It is performed only by specific laboratories, which can be identified through regional public health authorities. Other assays are being developed and remain experimental. The demonstration of the organism or its toxin in vomitus, gastric fluid, or stool is strongly suggestive of the diagnosis, because intestinal carriage is rare. Isolation of the organism from food without toxin is insufficient grounds for the diagnosis. Wound cultures yielding the organism are suggestive of botulism. The edrophonium chloride (Tensilon) test for myasthenia gravis may be falsely positive in botulism but is usually less dramatically positive than in the former condition. Nerve conduction velocity is normal, but compound muscle action potentials on routine nerve stimulation studies are decreased with a supramaximal stimulus, and facilitation is evident after repetitive stimulation at high frequency. Single-fiber electromyography may be helpful. The white blood cell count and erythrocyte sedimentation rate are normal.

TREATMENT

Patients should be hospitalized and monitored closely, both clinically and by spirometry, pulse oximetry, and measurement of arterial blood gases for incipient respiratory failure. Intubation and mechanical ventilation should be strongly considered when the vital

capacity is <30% of predicted, especially when paralysis is progressing rapidly and hypoxemia with absolute or relative hypercarbia is documented (Chap. 266). Serial measurements of the maximal static inspiratory pressure may be useful in predicting respiratory failure.

In food-borne illness, trivalent (types A, B, and E) equine antitoxin should be administered as soon as possible after specimens are obtained for laboratory analysis. The initiation of treatment should not await laboratory confirmation, which may take days. After testing for hypersensitivity to horse serum, a vial of antitoxin is given; repeated doses are not considered necessary. Anaphylaxis and serum sickness are risks inherent in use of the equine product, and desensitization of allergic patients may be required. If there is no ileus, cathartics and enemas may be given to purge the gut of toxin; emetics or gastric lavage can also be used if the time since ingestion is brief (only a few hours). Use of antibiotics to eliminate an intestinal source for possible continued toxin production and of guanidine hydrochloride and other drugs to reverse paralysis is of unproven value. In the United States, antitoxin as well as help in clinical management and laboratory confirmation are available at *any* time from state health departments or from the Centers for Disease Control and Prevention [at (404)639-2206; emergency number: (404)639-2888].

Treatment of infant botulism requires supportive care. Neither equine antitoxin nor antibiotics have been shown to be beneficial, and the value of human botulism immune globulin, an experimental preparation, is still being evaluated. In wound botulism, equine antitoxin is administered. The wound should be thoroughly explored and debrided, and an antibiotic such as penicillin should be given to eradicate *C. botulinum* from the site, even though the benefit of this therapy is unproven. Results of wound cultures should guide the use of other antibiotics.

Botulinum toxin is being used as therapy for strabismus, blepharospasm, and other dystonias and appears safe and effective. Generalized botulism-like weakness complicating therapy has been reported.

PROGNOSIS

Type A disease is generally more severe than type B, and mortality from botulism is higher among patients above age 60 than among younger patients. With improved respiratory and intensive care, the case-fatality rate in food-borne illness has been reduced to ~7.5% and is low in infant botulism as well. Artificial respiratory support may be required for months in severe cases. Some patients experience residual weakness and autonomic dysfunction for as long as a year after disease onset.

PREVENTION

A pentavalent vaccine (A-E) is available for use in highly exposed individuals. Spores can be inactivated by exposure to a temperature of 116° to 121°C (e.g., in steam sterilizers or pressure cookers). Toxin can be inactivated by exposure to a temperature of 100°C for 10 min. Newly identified cases should be reported immediately to public health authorities.

145. GAS GANGRENE, ANTIBIOTIC-ASSOCIATED COLITIS, AND OTHER CLOSTRIDIAL INFECTIONS - *Dennis L. Kasper*, *Dori F. Zaleznik*

DEFINITION

Bacteria of the genus *Clostridium* are gram-positive, spore-forming, obligate anaerobes that are ubiquitous in nature. There are more than 60 recognized species of clostridia, many of which are generally considered saprophytic. Some of these species are pathogenic for humans and animals, particularly under conditions of lowered oxidation-reduction potential. Infections associated with these organisms range from localized wound contamination to overwhelming systemic disease. The four major disease categories for which clostridia are responsible are intestinal disorders, deep tissue suppurative infections, skin and soft tissue infections, and bacteremia (Table 145-1). Toxins play a major role in some of these syndromes.

ETIOLOGY

In humans, clostridia normally reside in the gastrointestinal tract and in the female genital tract, although they occasionally are isolated from the skin or the mouth. Of the known species of the genus *Clostridium*, at least 30 have been isolated from human infections. Like several other pathogenic anaerobic bacterial species, clostridia are quite aerotolerant, but they do not grow on artificial media in the presence of oxygen. Clostridia characteristically produce abundant gas in artificial media and form subterminal endospores. *C. perfringens*, one of the most important species, is encapsulated and nonmotile and rarely sporulates in artificial media; the spores can usually be destroyed by boiling. *C. tetani* and *C. botulinum* are discussed in detail in Chaps. 143 and144, respectively.

Clostridia are present in the normal colonic flora at concentrations of 10^9 to 10^{10} per gram. Of the 30 or more species that normally colonize humans, *C. ramosum* is the most common and is followed in frequency by *C. perfringens*. These organisms are universally present in soil at concentrations of up to 10^4 per gram. Although clostridia are gram-positive organisms, many species may appear to be gram-negative in clinical specimens or stationary-phase cultures. Therefore, the results of Gram's staining of cultures or clinical material should be interpreted with great care.

C. perfringens is the most common of the clostridial species isolated from tissue infections and bacteremias; next in frequency are *C. novyi* and *C. septicum*. In the category of enteric infections, *C. difficile* is an important cause of antibiotic-associated colitis, and *C. perfringens* is associated with food poisoning (type A) and enteritis necroticans (type C).

PATHOGENESIS

Despite the isolation of clostridial species from many serious traumatic wounds, the prevalence of severe infections due to these organisms is low. Two factors that appear to be essential to the development of severe disease are tissue necrosis and a low oxidation-reduction potential. *C. perfringens* requires about 14 amino acids and at least 6 additional growth factors for optimal growth. These nutrients are not found in

appreciable concentrations in normal body fluids but are present in necrotic tissue. When *C. perfringens* grows in necrotic tissue, a zone of tissue damage due to the toxins elaborated by the organism allows progressive growth. In contrast, when only a few bacteria leak into the bloodstream from a small defect in the intestinal wall, the organisms do not have the opportunity to multiply rapidly because blood as a medium for growth is relatively deficient in certain amino acids and growth factors. Therefore, in a patient without tissue necrosis, bacteremia is usually benign.

C. perfringens possesses at least 17 possible virulence factors, including 12 active tissue toxins and enterotoxins. This species has been divided into five types (A through E) on the basis of four major lethal toxins: a,b, e, andi. The a toxin is a phospholipase C (lecithinase) that splits lecithin into phosphorylcholine and diglyceride. This a toxin has been associated with gas gangrene and is known to be hemolytic, to destroy platelets and polymorphonuclear leukocytes (PMNs), and to cause widespread capillary damage. When injected intravenously, it causes massive intravascular hemolysis and damages liver mitochondria. The a toxin may be important in the initiation of muscle infections that may progress to gas gangrene. Experimentally, the higher the concentration ofa toxin in the culture fluid, the smaller the dose of *C. perfringens* required to produce infection. The protective effect of antiserum is directly proportional to its content of aantitoxin. Studies suggest that q toxin may also play an important role in pathogenesis by promoting vascular leukostasis, endothelial cell injury, and regional tissue hypoxia. The resulting perfusion defects extend the anaerobic environment and contribute to rapidly advancing tissue destruction. A characteristic pathologic finding in gas gangrene is the near absence of PMNs despite extensive tissue destruction. Experimental data indicate that both a and q toxins are essential in the leukocyte aggregation that occurs at the margins of tissue injury instead of the expected infiltration of these cells into the area of damage. Genetically altered strains induce less leukocyte aggregation whena toxin is absent and none whenq toxin is missing. The other major toxins,b, e, andi, are known to increase capillary permeability.

C. difficile produces two major toxins, designated A and B. Both toxins appear to act by the same mechanism, but toxin B is 1000 times more potent. These toxins exert their effect by binding to small guanosine triphosphate-binding proteins in the Rho family within target cells. The toxins are uridine diphosphoglucose hydrolases and glucosyltransferases that glycosylate the guanosine triphosphatases, inactivating these proteins and resulting in disruption of actin. Once the actin filaments are destroyed, the cell is unable to function. Toxin B has 100-fold greater enzymatic activity than toxin A.

Diarrheal disease due to *C. difficile* is toxin-mediated. Earlier teaching about the pathogenesis of this disease centered on the overgrowth of *C. difficile* when antibiotics suppress the normal bowel flora. Actually, the mechanism is probably more complex, since many of the antibiotics that cause this disease are active against *C. difficile* as well as other members of the bowel flora and since many patients who become colonized with *C. difficile* do not develop diarrhea. Critical features in the pathogenesis of this disease include mechanisms of toxin production and the interaction of *C. difficile* with other components of the bowel flora. Some antibiotics may actually trigger toxin production by the organism. In turn, other constituents of the bowel flora may suppress or inhibit toxin production. *C. sordellii*, for example, neutralizes cytotoxin B in vitro. In addition, when antibiotics eliminate more sensitive members of the bowel flora, more

resistant organisms may produce enzymes such as b-lactamases that can inactivate antibiotics and thereby facilitate the growth of *C. difficile*.

CLINICAL MANIFESTATIONS

Intestinal Disorders

Food Poisoning C. perfringens, primarily type A, is the second or third most common cause of food poisoning in the United States (Chap. 131). The responsible toxin is thought to be a cytotoxin produced by more than 75% of strains isolated from cases of foodborne disease. The cytotoxin binds to a receptor on the small-bowel brush border and induces a calcium ion-dependent alteration in permeability. The associated loss of ions alters intracellular metabolism, resulting in cell death. Outbreaks generally have resulted from problems in the cooling and storage of food cooked in bulk. The food sources primarily involved are meat, meat products, and poultry. Generally, the implicated meats have been cooked, allowed to cool, and then recooked the following day, often in a stew or hash. Strains of *C. perfringens* that contaminate meat manage to survive initial cooking. During reheating, the organisms sporulate and germinate. The disease is associated with an attack rate that is often as high as 70%. Symptoms of food poisoning from type A strains develop 8 to 24 h after ingestion of foods heavily contaminated with the organism. The primary symptoms include epigastric pain, nausea, and watery diarrhea usually lasting 12 to 24 h. Fever and vomiting are uncommon. Molecular methods including ribotyping and pulsed-field gel electrophoresis have been used to detect fecal cytotoxin in outbreaks of food poisoning caused by *C. perfringens*.

C. perfringens has also been implicated in a more severe form of diarrhea than that of classic food poisoning. This more severe disease tends to occur in the elderly and has been associated with antibiotic use in hospitalized populations. In this form of disease, diarrhea is generally more profuse, of longer duration, and accompanied by abdominal pain. Blood and mucus have been detected in the feces of the affected patients. In one hospital-based study of a cluster of cases, widespread environmental contamination with *C. perfringens* spores was documented.

Enteritis necroticans Necrotizing enteritis (enteritis necroticans, or *pigbel*) is caused byb toxin produced by type C strains of *C. perfringens* following ingestion of a high-protein meal in conjunction with trypsin inhibitors (e.g., in sweet potatoes) by a susceptible host who has limited intestinal proteolytic activity. This disease has been reported among children and adults in New Guinea. A similar disease, *darmbrand*, was epidemic in Germany after World War II. Clinical features of pigbel include acute abdominal pain, bloody diarrhea, vomiting, shock, and peritonitis; 40% of patients die. Pathologic studies reveal an acute ulcerative process of the bowel restricted to the small intestine. The mucosa is lifted off the submucosa, with the formation of large denuded areas. Pseudomembranes composed of sloughed epithelium are common, and gas may dissect into the submucosa. The source of the organisms may be the patient's own intestinal flora; cultures of ingested pork have failed to yield the organism. Antibodies to the btoxin of *C. perfringens* have been of considerable benefit in changing the course of established disease. In a large-scale trial, children immunized with *C. perfringens* b toxoid were protected.

Neutropenic enterocolitis (typhlitis) See Chaps. 85 and167.

Antibiotic-associated colitis Strains of *C. difficile* that produce toxins detectable in the stool are the only identified cause of colitis induced by antibiotic use. The diagnosis of this type of colitis requires that there be no other identifiable cause of diarrhea and that the onset of symptoms occur either during antimicrobial administration or within 4 weeks after treatment with the implicated agent has been discontinued. Essentially any antibiotic can cause this syndrome; even metronidazole and vancomycin, which are used to treat the disease, have been implicated as etiologic agents in some cases. On a per-use basis, clindamycin, which was the first antibiotic described to cause this entity, is the most commonly implicated antibiotic. However, since other antibiotics are prescribed more often than clindamycin in the United States, cephalosporins are currently the antibiotics that most commonly cause *C. difficile* enterocolitis, and penicillins rank next in frequency. Diarrhea due to *C. difficile* has been reported in patients with some forms of malignancy or renal transplantation who have received tacrolimus without concomitant or previous antibiotic administration.

Antimicrobial-associated diarrhea can be divided into four categories based on the appearance of the colon: (1) normal colonic mucosa; (2) mild erythema with some edema; (3) granular, friable, or hemorrhagic mucosa; and (4) pseudomembrane formation. Most patients with antibiotic-associated diarrhea have a normal, minimally erythematous colonic mucosa with some edema. Occasionally, colitis is more severe and is characterized by a granular, friable, or hemorrhagic mucosa. Examination of stool from the affected patients may reveal large numbers of red blood cells and some leukocytes. Biopsy shows subepithelial edema with round cell infiltration of the lamina propria and focal extravasation of erythrocytes. *C. difficile* cytotoxin B has been found in 15 to 75% of stools from patients in the first three categories, which suggests that other factors are involved in the pathogenesis of antibiotic-associated diarrhea.

The most characteristic form of antibiotic-associated colitis caused by *C. difficile* is pseudomembranous colitis (PMC) (Fig. 145-CD1). More than 95% of patients with documented PMC have positive stool toxin assays. Close inspection of pseudomembranes reveals exudative, punctate, raised plaques with skip areas or edematous hyperemic mucosa. These plaques can enlarge and coalesce over large segments of intestine in the later stages of disease. The clinical spectrum of antibiotic-associated PMC is diverse. Diarrhea is the key feature; stools are usually watery, voluminous, and without gross blood or mucus. Most patients have abdominal cramps and tenderness, fever, and leukocytosis. However, the symptoms vary considerably. At one end of the spectrum are many patients with annoying diarrhea but no systemic signs or symptoms, while at the other end are those with severe systemic toxicity, fever (40° to 40.6°C, or 104° to 105°F), and peripheral white blood cell counts of up to 50,000/uL with a marked left shift. Fecal examination frequently reveals leukocytes. Without specific therapy, the course is highly variable. Some patients, particularly those with clinically mild disease, experience prompt resolution of symptoms with discontinuation of drug treatment, while others have protracted diarrhea with large stool volumes for up to 8 weeks, with resultant hypoalbuminemia and electrolyte imbalance. Severely ill patients with toxic megacolon and colonic perforation have been reported. Among patients who are severely ill mortality rates may be as high as 30%,

while in most of those with minimal symptoms disease may resolve with the discontinuation of antibiotic treatment alone. In the majority of patients, symptoms begin 4 to 10 days after antibiotic therapy is initiated. However, ~25% of patients do not develop symptoms until use of the implicated antimicrobial has been discontinued, in some instances as long as 4 weeks afterward. Some cases have been reported within hours after initiation of antibiotic therapy or after a single dose of antibiotic administered for surgical prophylaxis.

Suppurative Deep Tissue Infections Clostridia are frequently recovered from various suppurative conditions in conjunction with other anaerobic and aerobic bacteria but can also be the only organisms isolated. These suppurative conditions, which exist with severe local inflammation but usually without the characteristic systemic signs induced by clostridial toxins, include intraabdominal sepsis, empyema, pelvic abscess, subcutaneous abscess, frostbite with gas gangrene, infection of a stump in an amputee, brain abscess, prostatic abscess, perianal abscess, conjunctivitis, infection of a renal cell carcinoma, and infection of an aortic graft.

Clostridia are isolated from approximately two-thirds of patients with intraabdominal infections resulting from intestinal perforation. *C. ramosum*, *C. perfringens*, and *C. bifermentans* are the most commonly isolated species. The presence of clostridial species does not affect the clinical presentation or outcome of these infections (Chap. 167).

An association has been made between malignancy and the isolation of *C. septicum* in the absence of grossly contaminated deep traumatic wounds. A major site for such a malignancy is the gastrointestinal tract, particularly the colon. An association with leukemia or with other solid tumors has also been noted, and one case of fatal myonecrosis has been reported in a patient with ovarian cancer. Some of these patients present with *C. septicum* bacteremia; these cases have a fulminant clinical course (discussed below). Others develop localized suppurative infection in the abdomen or the abdominal wall without bacteremia. Presumably, this infection arises from a silent perforation that leads to intraabdominal abscess formation.

Clostridia have been isolated from suppurative infections of the female genital tract, particularly tuboovarian and pelvic abscesses. The major species involved has been *C. perfringens*. Most of these are mild suppurative infections without evidence of uterine gangrene. *C. perfringens* has been isolated from as many as 20% of diseased gallbladders at surgery. One clinical syndrome, emphysematous cholecystitis, is caused by clostridial species at least 50% of the time. In this syndrome, gas forms in the biliary radicles and the wall of the gallbladder. It is seen most often in diabetic patients. Although the mortality rate in this entity is higher than in more common forms of cholecystitis, there is no evidence of myonecrosis.

Clostridia are among the many organisms found in empyema fluid or isolated by transtracheal aspiration from patients with lung abscesses. There is no unique clinical clue to the presence of clostridia (as opposed to other organisms) in these infections. *C. perfringens* has been reported as a cause of empyema arising from aspiration pneumonia, pulmonary emboli, and infarction. However, the majority of cases of clostridial empyema are secondary to trauma.

Skin and Soft Tissue Infections Various categories of traumatic wound infections due to clostridia have been described: simple contamination, anaerobic cellulitis, fasciitis with or without systemic manifestations, and anaerobic myonecrosis.

Simple contamination Clostridia are cultured most often from wounds in the absence of clinical signs of sepsis. As many as 30% of battle wounds are contaminated by clostridia without signs of suppuration, and 16% of penetrating abdominal wounds yield clostridia on culture despite treatment with cephalothin and kanamycin. In cases of trauma, clostridia are isolated with equal frequency from suppurative and well-healing wounds. Thus the diagnosis of clostridial infection should be based on clinical rather than bacteriologic criteria.

Localized infection of the skin and soft tissue without systemic signs This condition, originally referred to as *anaerobic cellulitis*, is a localized infection involving the skin and soft tissue and is due to clostridia alone or with other bacteria. There are no systemic signs of toxicity, although the infection may invade locally, producing necrosis. These infections tend to be relatively indolent, spreading slowly to contiguous areas. Localized infections are relatively free of pain and edema. Perhaps because of the lack of edema, gas that is limited to the wound and the immediately surrounding tissue may be more evident than in gas gangrene. In these localized infections, gas is never found intramuscularly. Cellulitis, perirectal abscesses, and diabetic foot ulcers are typical infections from which clostridial species can be isolated. If inadequately treated, these localized infections advance by extension through subcutaneous tissue and fascial planes into muscle and may produce severe systemic disease with signs of toxemia.

A localized form of suppurative myositis has been described in heroin addicts. These patients develop local pain and tenderness in discrete areas (particularly the thigh and forearm), with the subsequent appearance of fluctuance and crepitance that require surgical drainage. The unusual aspect of these infections is that they remain localized without systemic signs of toxicity. Moreover, the affected local areas are not necessarily sites of trauma or heroin injection. Pathologic examination reveals subcutaneous abscesses, purulent myositis, and fasciitis from which clostridia are recovered in pure culture; on occasion, mixed infections involving aerobes and anaerobes are found. Wound botulism has been reported in association with the injection of black tar heroin.

Spreading cellulitis and fasciitis with systemic toxicity This condition involves diffuse spreading cellulitis and fasciitis, without myonecrosis and with only mild inflammation in muscle. Patients present with the abrupt onset of a syndrome that progresses rapidly (within hours) through the fascial planes. In cases with suppuration and gas in soft tissues as well as overwhelming toxemia, the infection is rapidly fatal. On physical examination there is subcutaneous crepitation but little localized pain. Surgery is of no proven value because there are no discretely involved tissues amenable to resection, as may be the case in myonecrosis. However, in rapidly advancing fasciitis, incision of the affected area is still the cornerstone of therapy. The initial local lesion may be quite innocuous and arises from an area involved by tumor or other infection and not by injury. The systemic toxic effects include hemolysis and injury of capillary membranes. Usually, this infection is uniformly fatal within 48 h, despite intensive therapy involving antitoxin and exchange transfusion. This syndrome is seen most commonly in patients

with carcinoma, especially of the sigmoid or the cecum. Presumably, the tumor invades the fascia, and colonic contents leak into the abdominal wall. Patients present with extreme toxicity and occasionally with total-body crepitation. The syndrome differs from necrotizing fasciitis caused by other organisms in three respects: (1) rapid mortality, (2) rapid tissue invasion, and (3) the systemic effects of the toxin, typified by massive hemolysis.

Clostridial myonecrosis (gas gangrene) (Fig. 145-CD2) Clostridial myonecrosis occurs when bacteria invade healthy muscle from adjacent traumatized muscle or soft tissue. The infection originates in a wound contaminated with clostridia. Although >30% of deep wounds are infected with clostridia, the incidence of clostridial myonecrosis is quite low. These infections occur in both military and civilian settings. An essential factor in the genesis of gas gangrene appears to be trauma, particularly involving deep muscle laceration. The entity of clostridial myonecrosis is relatively uncommon after simple, through-and-through bullet wounds without shattering of bone and is relatively common following shrapnel fragmentation wounds, particularly when deep muscle is involved. In civilian cases, gas gangrene can follow trauma, surgery, or intramuscular injection. The trauma need not be severe; however, the wound must be deep, necrotic, and without communication to the surface.

The incubation period of gas gangrene is usually short: almost always <3 days and frequently <24 h. Some 80% of cases are caused by *C. perfringens*, while *C. novyi*, *C. septicum*, and *C. histolyticum* cause most of the other cases. Typically, gas gangrene begins with the sudden onset of pain in the region of the wound, which helps to differentiate it from spreading cellulitis. Once established, the pain increases steadily in severity but remains localized to the infected area and spreads only if the infection spreads. Soon after pain develops, local swelling and edema -- accompanied by a thin, often hemorrhagic exudate -- appear. Patients frequently develop marked tachycardia, but elevation in temperature may be only minimal. Gas is usually not obvious at this early stage and may be completely absent. Frothiness of the wound exudate may be noted. The skin is tense, white, often marbled with blue, and cooler than normal. The symptoms progress rapidly; swelling, edema, and toxemia increase, and a profuse serous discharge, which may have a peculiar sweetish smell, appears. Gram's staining of the wound exudate shows many gram-positive rods with relatively few inflammatory cells.

At surgery, muscle may appear pale because of the intensity of edema, but it does not contract when probed with a scalpel. When dissected, the muscle is beefy red and nonviable and can progress to become black, friable, and gangrenous. It is important to establish a diagnosis early, preferably by frozen-section biopsy of muscle.

Despite hypotension, renal failure, and (often) body crepitation, patients with myonecrosis frequently have a heightened awareness of their surroundings until just before death, when they lapse into toxic delirium and coma. In untreated cases, as the local wounds progress, the skin becomes bronzed; bullae appear, become filled with dark red fluid, and are accompanied by dark patches of cutaneous gangrene. Gas appears in later phases (Fig. 145-1) but may not be as obvious as in anaerobic cellulitis. Jaundice is rare in wound gas gangrene (in contrast to uterine infections) and, when it does appear, is almost invariably associated with hemoglobinuria, hemoglobinemia, and

septicemia. Cases of clostridial myonecrosis without a history of trauma have been reported. These patients have bullous lesions and crepitation of the skin; they present with a rapidly worsening course that includes myonecrosis, especially of the extremities.

Bacteremia and Clostridial Sepsis The relatively common entity of transient clostridial bacteremia can arise in any hospitalized patient but is most common with a predisposing focus in the gastrointestinal tract, biliary tract, or uterus. Fever frequently resolves within 24 to 48 h without therapy. Despite the finding of clostridial bacteremia following septic abortions and the frequent isolation of clostridia from the lochia, most of the patients involved do not have evidence of sepsis. In one series of 60 patients with clostridial bacteremia, half had an infected site that could be associated with the bacteremia, while the other half had a totally unrelated illness, such as tuberculous pneumonia, meningitis, or benign gastroenteritis. By the time blood culture reports are returned, patients frequently are completely well and sometimes have been discharged. Therefore, when a blood culture is positive for clostridia, the patient must be assessed clinically rather than simply treated on the basis of the culture result.

Clostridial sepsis is an uncommon but almost invariably fatal illness following clostridial infection -- primarily that of the uterus, colon, or biliary tract. This entity must be differentiated from transient clostridial bacteremia, which is much more common. *C. perfringens* causes the majority of cases of sepsis as well as the majority of cases of transient bacteremia. *C. septicum*, *C. sordellii*, and *C. novyi* account for most of the remainder of cases. Clostridia account for 1 to 2.5% of all positive blood cultures in major hospital centers.

The majority of cases of clostridial sepsis originate from the female genital tract and follow septic abortion. Introduction of a foreign body is a common antecedent event. In the uterus, residual necrotic fetal and placental tissues and traumatized endometrium may allow the growth of clostridia. Only a small fraction of cases of septic abortion (1%) are followed by serious sepsis. In these patients, sepsis, fever, and chills begin from 1 to 3 days after the attempted abortion. The initial signs are malaise, headache, severe myalgias, abdominal pain, nausea, vomiting, and occasionally diarrhea. Frequently, a bloody or brown vaginal discharge is noted. Patients may rapidly develop oliguria, hypotension, jaundice, and hemoglobinuria. The hemolysis, which is secondary to *C. perfringens* a toxin, causes a characteristic bronzing of the skin. As in myonecrosis, the mental status of severely ill patients is characterized by increased alertness and apprehension. Local examination of the pelvis reveals foul cervical discharge, occasionally with gas. Frequently, laceration marks around the cervix or perforation of the cervical segment is evident. If the infection involves the myometrium or has spread to the adnexa, extreme tenderness, guarding, and an adnexal mass may be found.

Laboratory studies in patients with sepsis reveal an elevated white blood cell count and may show pink, hemoglobin-tinged plasma. Anemia is proportional to the degree of hemolysis, and the hematocrit may be extremely low. Platelet counts may be reduced, and there is often evidence of disseminated intravascular coagulation. Oliguria or anuria, increasingly refractory hypotension, and hemorrhage and bruising may develop.

Clostridia may enter the bloodstream from the gastrointestinal or biliary tract. This occurrence is associated with ulcerative lesions or obstruction of the small or large

intestine, necrotic or infiltrating malignancy, bowel surgery, or various abdominal catastrophes. The patient may present with an acute febrile illness, with chills and fever but no other signs of localized infection. Intravascular hemolysis occurs in as many as half of such cases. Biliary or gastrointestinal symptoms, if present, may be the only clue to the etiology. Positive blood cultures provide the definitive clue to the diagnosis.

Patients with malignant disease can also develop rapidly fatal clostridial sepsis, particularly from a gastrointestinal focus. The most common species in this setting is *C. septicum*. Characteristic signs and symptoms include fever, tachycardia, hypotension, abdominal pain or tenderness, nausea, vomiting, and (preterminally) coma. The tachycardia may be out of proportion to the fever. Only ~20 to 30% of patients develop hemolysis. A striking feature of this syndrome is the rapidity of death, which frequently occurs in <12 h.

DIAGNOSIS

The diagnosis of clostridial disease, in association with positive cultures, must be based primarily on clinical findings. Because of the presence of clostridia in many wounds, their mere isolation from any site, including the blood, does not necessarily indicate severe disease. Smears of wound exudates, uterine scrapings, or cervical discharge may show abundant large gram-positive rods as well as other organisms. Cultures should be placed in selective media and incubated anaerobically for identification of clostridia. The diagnosis of clostridial myonecrosis can be established by frozen-section biopsy of muscle.

The urine of patients with severe clostridial sepsis may contain protein and casts, and some patients may develop severe uremia. Profound alterations of circulating erythrocytes are seen in severely toxemic patients. Patients have hemolytic anemia, which develops extremely rapidly, along with hemoglobinemia, hemoglobinuria, and elevated levels of serum bilirubin. Spherocytosis, increased osmotic and mechanical red blood cell fragility, erythrophagocytosis, and methemoglobinemia have been described. Disseminated intravascular coagulation may develop in patients with severe infection. In patients with severe sepsis, Wright's or Gram's staining of a smear of peripheral blood or buffy coat may demonstrate clostridia.

X-ray examination sometimes provides an important clue to the diagnosis by revealing gas in muscles, subcutaneous tissue, or the uterus. However, the finding of gas is not pathognomonic for clostridial infection. Other anaerobic bacteria, frequently mixed with aerobic organisms, may produce gas.

The diagnosis of *C. difficile*-associated colitis is most often made by an enzyme-linked immunosorbent assay (ELISA) for toxin A. Compared with the "gold standard" tissue culture assay used primarily for the detection of toxin B, the ELISA exhibits comparable specificity and only slightly lower sensitivity (70 to 90%). The cytotoxicity assay requires a tissue culture facility, skilled laboratory technicians, and time (usually 48 h), since neutralization of the cytopathic effect with *C. sordellii* or *C. difficile* antitoxin is required before the test can be labeled positive. ELISA is more rapid and easier to perform. However, in difficult situations where the clinical diagnosis remains a possibility and ELISA results are negative, consideration should be given to requesting the cytotoxicity

assay since it may detect 5 to 10% more cases. Repeat stool testing with the same assay generally does not increase the diagnostic yield for this entity. Endoscopy, although useful in establishing the presence ofPMC, does not establish the etiology and should be reserved for cases with more serious disease manifestations, in which it can be used to exclude alternative diagnoses. Isolation of *C. difficile* from stool cultures is difficult. This approach should be reserved for epidemiologic studies of outbreaks since asymptomatic persons may harbor the pathogen, but production of toxin is the hallmark of disease.

TREATMENT

Traumatic wounds should be thoroughly cleansed and debrided. Traditionally, the antibiotic treatment of choice for severe clostridial infection has been penicillin G (20 million units a day in adults). Penicillin G treatment of gas gangrene has become more controversial because of increasing resistance to this drug and data obtained from animal models of infection. In a mouse model of gas gangrene, antibiotics inhibiting toxin synthesis appeared to be preferable to cell wall-active drugs; clindamycin treatment enhanced survival more than therapy with penicillin; and the combination of clindamycin and penicillin was superior to penicillin alone. For severe clostridial sepsis, clindamycin may be used at a dose of 600 mg every 6 h in combination with high-dose penicillin (3 to 4 million units every 4 h). Although no clinical trials validate this choice, it is gaining acceptance in the infectious disease community.

In cases of penicillin sensitivity or allergy, other antibiotics should be considered, but all should be tested for in vitro activity because of the occasional isolation of resistant strains. Clostridia are frequently, but not universally, susceptible in vitro to cefoxitin, carbenicillin, chloramphenicol, clindamycin, metronidazole, doxycycline, imipenem, minocycline, tetracycline, third-generation cephalosporins, and vancomycin. For severe clostridial infections, sensitivity testing should be done before an antimicrobial with unpredictable activity is used. Simple contamination of a wound with clostridia should not be treated with antibiotics. Localized skin and soft tissue infection can be managed by debridement rather than with systemic antibiotics. Drugs are required when the process extends into adjacent tissue or when fever and systemic signs of sepsis are present. Surgery is a mainstay of therapy for clostridial myonecrosis or gas gangrene. Amputation may be required for rapidly spreading infection involving a limb. Hysterectomy is required for uterine myonecrosis. Abdominal wall myonecrosis usually continues despite initial aggressive surgery and antibiotic therapy and requires repeated surgical debridement of all involved muscle.

Suppurative infections should be treated with antibiotics. Frequently, broad-spectrum antibiotics must be used because of the mixed flora involved in these infections. Aminoglycosides can be used for the aerobic gram-negative bacteria involved in mixed infections.

The use of a polyvalent gas gangrene antitoxin is still recommended by some authorities. At present, no such antitoxin is produced in the United States, and most centers have discontinued its use in the management of patients with suspected gas gangrene or clostridial postabortion sepsis because of questionable efficacy and the substantial risk of hypersensitivity to horse serum, from which the antitoxin is derived.

The use of hyperbaric oxygen in the treatment of gas gangrene is also controversial. Studies in humans are not well designed to answer questions on efficacy, but several knowledgeable authors believe that hyperbaric oxygen therapy has contributed to dramatic clinical improvement. Such therapy may, however, be associated with untoward effects due to oxygen toxicity and high atmospheric pressure. Some centers without hyperbaric chambers have reported acceptable mortality rates; thus expert surgical and medical management and control of complications are probably the most important factors in the treatment of gas gangrene. Fasciotomy should not be delayed for hyperbaric oxygen therapy.

The treatment of *C. difficile*-associated colitis requires discontinuation of therapy with the offending antimicrobial agent. In some patients, symptoms will resolve over a period of 2 weeks if the infection is left untreated. However, specific therapy shortens the duration of symptoms.

Diarrhea due to *C. difficile* should be treated with metronidazole (500 mg orally tid for 10 to 14 days). A randomized trial comparing metronidazole (250 mg qid) with oral vancomycin showed equal efficacy and relapse rates of ~9% for both regimens. Since both treatment regimens are effective, metronidazole is preferred because it is far less costly and has not been linked to the development of vancomycin-resistant enterococci. When a patient relapses, antibiotic resistance should not be inferred since it is rare; a repeat course of metronidazole is appropriate. When a patient with *C. difficile*-associated diarrhea requires continued antibiotic treatment for a serious infection such as infective endocarditis, it is often reasonable to continue therapy against *C. difficile* for the duration of the offending antibiotic treatment course and for a full 10 to 14 days following its completion. When vancomycin is used for the treatment of *C. difficile*-associated diarrhea, the starting dose should be 125 mg orally qid, although doses as high as 500 mg qid can be used if needed. When a patient requires parenteral therapy for antibiotic-associated diarrhea, intravenous metronidazole can be administered. Vancomycin is effective only if used orally; the drug is poorly absorbed after oral administration. If patients continue to have diarrhea and have signs of systemic toxicity (e.g., fever and/or leukocytosis) after 48 h of treatment with metronidazole, it is reasonable to switch to vancomycin. For especially severe disease, some experts advocate treatment with both oral vancomycin and metronidazole, although there are no trials to support this regimen.

A number of patients who respond to initial therapy present with a relapse of symptoms and a repeat positive toxin assay. Relapses following therapy are much more frequent than failures to respond to initial therapy. Most relapses occur 3 to 10 days after discontinuation of treatment. Most relapsing patients respond to a second course of antibiotics, but some go on to suffer multiple relapses. A number of options are available in this situation. Some authors report success with tapering regimens of vancomycin given daily or every other day for 1 to 2 months to avoid relapse. The resin cholestyramine binds the cytotoxin of *C. difficile* and has been used with some success to treat severe cases. Since cholestyramine also binds vancomycin, the two agents should not be used in combination. Repopulation of the normal colonic flora has also been tried in relapsing disease. Ingestion of capsules of the yeast *Saccharomyces boulardii* showed some promise in one trial; oral lactobacilli have also been used in

uncontrolled studies. The administration of intravenous immunoglobulin has been tried with success in a few children and adults with relapsing infection, although this approach is not yet considered to be recommended therapy.

SECTION 6 -DISEASES CAUSED BY GRAM-NEGATIVE BACTERIA

146. MENINGOCOCCAL INFECTIONS - *Robert S. Munford*

DEFINITION

Neisseria meningitidis is the etiologic agent of two life-threatening diseases: meningococcal meningitis and fulminant meningococcemia. Meningococci also cause pneumonia, septic arthritis, pericarditis, urethritis, and conjunctivitis. Most cases are potentially preventable by vaccination.

ETIOLOGIC AGENT

N. meningitidis bacteria are gram-negative aerobic diplococci. Unlike the other neisseriae, they have a polysaccharide capsule. They are transmitted among humans, their only known habitat, via respiratory secretions. Colonization of the nasopharynx or pharynx is much more common than invasive disease.

EPIDEMIOLOGY

Meningococcal disease occurs worldwide as isolated (sporadic) cases, institution- or community-based outbreaks, and large epidemics.

Meningococci are classified into serogroups based on the antigenicity of their capsular polysaccharides. Antigenicity reflects structural differences in these polysaccharides. Five serogroups (A, B, C, Y, and W-135) are responsible for>90% of cases of meningococcal disease worldwide. Serogroup A strains, which caused most of the large epidemics of meningococcal disease during the first half of the twentieth century, are now associated with recurring epidemics in sub-Saharan Africa and other locales in the developing world. Serogroups B, C, and Y cause most cases of sporadic and epidemic meningococcal disease in industrialized countries. In the United States and Canada during the 1990s, serogroup B was the most common cause of sporadic disease, while serogroup C was a more frequent cause of outbreaks. Serogroup Y has recently been isolated from almost one-third of cases of meningococcal disease in the United States. In general, patients with serogroup Y disease are older and more likely to have a chronic underlying illness than are patients with disease caused by other serogroups. Serogroups Y and W-135 are isolated more often than the other serogroups from patients with pneumonia.

One limitation of the serogroup classification is that the genes for capsule biosynthesis can be transferred from one strain to another, with consequent changes in the capsule structure of the recipient strain and therefore in its serogroup. Other methods for tracking meningococcal strains have thus become increasingly useful. Meningococcal serotypes and subtypes are defined by antigenic differences in specific outer-membrane proteins (OMPs), whereas multilocus enzyme electrophoresis classifies bacteria into electrophoretic types (ETs). Other techniques for establishing strain identity or nonidentity are pulsed-field gel electrophoresis and amplification of bacterial genomic sequences by polymerase chain reaction. The virulent III-1 clonal complex of serogroup A was first recognized in Nepal in 1983 to 1984; it spread to Mecca, then to

sub-Saharan Africa, and subsequently to temperate Africa. Increased virulence and epidemic potential have also been ascribed to the serogroup B ET-5 complex, which was first identified in Norway in the 1970s and later caused outbreaks in Europe, Cuba, and South and North America (most recently, in the Pacific Northwest). Serogroup C ET-24 (the ET-37 complex) has caused sporadic cases and outbreaks in Canada and the United States and in some analyses has been associated with high mortality and morbidity.

Meningococcal colonization of the nasopharynx (asymptomatic carriage) can persist for months. In nonepidemic periods, ~10% of healthy individuals are colonized. Factors that predispose individuals to colonization with *N. meningitidis* include residence in the same household with a person who has meningococcal disease or is a carrier, household or institutional crowding, active or passive exposure to tobacco smoke, and a recent history of a viral upper respiratory infection. These factors have also been associated with an increased risk of meningococcal disease.

In countries with temperate climates, the attack rate for sporadic meningococcal disease is ~1 case per 100,000 persons per year. Peak disease incidence coincides with the winter peak of respiratory viral illnesses. Disease attack rates are highest among infants 3 to 9 months of age (10 to 15 cases per 100,000 infants per year). Children also have higher attack rates than adults, and there is a second peak of incidence among teenagers, in whom outbreaks have often been tied to residence in barracks, dormitories, or other crowded conditions. Although the age-specific incidence is much lower among adults (<1 case per 100,000 persons per year), approximately one-third of all cases of sporadic meningococcal disease occur in individuals ³18 years of age. During epidemics, disease incidence increases disproportionately among teenagers and young adults and during the summer and autumn.

Meningococcal disease occurs more commonly in the household contacts of primary cases. The secondary attack rate is 400 to 1000 per 100,000 household members. School-based clusters of cases have also been described; the attack rate among school contacts of cases has been estimated at 2 to 4 cases per 100,000 exposed individuals. In outbreaks on college campuses, attack rates have been highest among students living in dormitories. Most secondary cases occur within 2 weeks of the primary case, although some may develop as long as several months later. Secondary cases account for <2% of all cases reported each year in the United States.

In an outbreak, the case isolates of *N. meningitidis* are identical when they are assessed by molecular typing methods. Recent outbreaks of meningococcal disease have occurred among persons whose common exposure took place in military barracks, schools, a university campus tavern, a jail, a school bus, a disco bar, a sports club, and a hotel.

PATHOGENESIS

Meningococci that colonize the upper respiratory tract are internalized by nonciliated mucosal cells and may traverse them to enter the submucosa, from which they can make their way into the bloodstream. While meningococcal colonization occurs often in healthy humans, bloodstream infection is an infrequent event that is not essential for the

organisms' survival and spread; as is often the case, the production of human disease has no obvious evolutionary advantage for either pathogen or host. Although some strains of *N. meningitidis* are thought to cause more severe disease in humans than do other strains, the basis for this difference is not understood. Meningococci may undergo important phenotypic changes when they adapt to growth in vivo; presumed virulence traits include the antiphagocytic capsular polysaccharide, an ability to sialylate the cell wall lipooligosaccharide (LOS) so that it mimics host cell carbohydrate moieties, the secretion of IgA protease, and mechanisms for iron acquisition. TheET-5 strain of serogroup B *N. meningitidis* has been associated with high case-fatality rates in some populations but not in others, however, suggesting that host factors also contribute importantly to disease pathogenesis.

A meningococcus that enters the blood from the nasopharynx and survives host defenses generally has one of two fates. If multiplication occurs slowly, the bacteria eventually seed local sites, such as the meninges, joints, or pericardium. More rapid multiplication in the blood is associated with disseminated intravascular coagulation (DIC) and shock, which usually cause symptoms before local sites become infected. There is thus a remarkable compartmentalization of bacterial growth and host inflammation in either the blood or a local site, usually the meninges.

Fulminant Meningococcemia (Purpura Fulminans) Fulminant meningococcemia is perhaps the most rapidly lethal form of septic shock experienced by humans. It differs from most other forms of septic shock by the prominence of hemorrhagic skin lesions (petechiae, purpura) and the consistent development ofDIC.

The dominant proinflammatory molecule in the meningococcal cell wall is the endotoxin orLOS, and the outer membrane that contains it is poorly tethered to the underlying peptidoglycan. This structural peculiarity seems to account for the fact that meningococci shed LOS-containing membrane blebs as they grow. The bacteria can multiply to very high concentrations in the blood. The concentrations of endotoxin detected in the blood of patients with fulminant meningococcemia are 10- to 1000-fold greater than those found in the blood of patients with bacteremia due to other gram-negative bacteria. The bacteria and endotoxin-containing blebs stimulate monocytes, neutrophils, and endothelial cells, which then release cytokines and other mediators that can activate many distant targets, including other leukocytes and endothelial cells. In addition, meningococci can invade the vascular endothelium. When activated, the endothelium produces molecules that can be procoagulant as well as adhesive for leukocytes.

Patients with fulminant meningococcemia usually have extremely high blood levels of both proinflammatory mediators -- i.e., tumor necrosis factor (TNF)a, interleukin (IL) 1, interferong, and IL-8 -- and anti-inflammatory mediators -- i.e., IL-1 receptor antagonist (IL-1Ra), soluble IL-1 receptors, soluble TNF receptors, and IL-10. The plasma of patients with meningococcal shock can decrease the responses of normal leukocytes to stimuli such asLOS; the implication is that anti-inflammatory mediators predominate in the blood.

Procoagulant, antifibrinolytic forces are predominant in the blood of patients with fulminant meningococcemia (Fig. 146-1). Monocytes express large amounts of tissue

factor. Fibrinopeptide A and thrombin-antithrombin levels are high, reflecting active clotting, while antithrombin and fibrinogen levels are low. Although the tissue factor-regulated ("extrinsic") arm of coagulation predominates, the contact system (factors XII and XI, prekallikrein, high-molecular-weight kininogen) is also activated. Striking deficiencies of antithrombin and proteins C and S can occur; studies have found a strong negative correlation between protein C activity and both the size of purpuric skin lesions and mortality. Plasminogen levels are decreased, while plasmin-antiplasmin complexes and plasminogen activator inhibitor 1 (PAI-1) levels in the blood are very high. PAI-1 levels have been correlated with mortality risk, as has a function-related polymorphism in the promoter of the PAI-1 gene.

Fibrin deposition is therefore favored both by the *procoagulant* tendency, promoted through activation of tissue factor and deficiencies of proteins C and S and antithrombin, and by an *antifibrinolytic* tendency, favored by excessivePAI-1. Both platelets and leukocytes doubtless contribute to the formation of microthrombi and to the vascular injury that ensues. Thrombosis of larger vessels leads to peripheral necrosis and gangrene that may require limb or digit amputation.

None of the candidate mediators of septic shock has proven primacy (Chaps. 38 and124). Numerous studies have suggested that shock andDIC are not intimately linked and that the contact arm of clotting, which is of secondary importance in the pathogenesis of DIC, plays at least a contributory role in the pathogenesis of shock. The independence of DIC and shock suggests that therapies that prevent or reverse DIC may not be helpful for patients with septic shock.

Meningitis *N. meningitidis* has a striking tropism for the meninges. Infection of the central nervous system begins in the choroid plexus or in the ependyma that lines the cerebral ventricles. Meningococci adhere to cerebral capillary endothelial cells and then enter the subarachnoid space. A vigorous local inflammatory response ensues, probably triggered by endotoxin-containing meningococcal membranes. Both bacterial growth and the inflammatory response occur within the cerebrospinal fluid (CSF), where levels of endotoxin,IL-6,TNF-a, IL-1b, IL-1Ra, and IL-10 exceed the concentrations found in plasma by 100- to 1000-fold. The inflammatory response is largely confined to the subarachnoid space and contiguous structures.

Patients who develop meningitis may be individuals in whom meningococci do not grow rapidly in the blood; they may have a more vigorous initial inflammatory response to invading meningococci, may have antibodies or phagocytes that slow meningococcal growth, or may lack the (unknown) factors that allow *N. meningitidis* to multiply rapidly in vivo. The prognosis of patients with meningococcal meningitis is substantially better than that of patients with fulminant meningococcemia (Table 146-1).

HOST DEFENSE MECHANISMS

Preventing meningococcal growth in blood requires bactericidal and opsonic antibodies, complement, and phagocytes (Fig. 146-2). The major bactericidal antibodies are IgM and IgG, which bind to the capsular polysaccharide. Immunity to meningococci is therefore serogroup specific. Antibodies to other surface (subcapsular) antigens may confer cross-serogroup protection. Infants are protected from meningococcal disease

during the first months of life by passively transferred maternal IgG antibodies. As maternal antibody levels wane, the attack rate increases, peaking from 3 to 9 months of age. Disease incidence declines as protective antibodies are induced by colonization with nonpathogenic bacteria that have cross-reactive antigens. In addition to *N. lactamica*, which frequently colonizes young children, some enteric bacteria have antigens that cross-react with those of meningococci. One theory relates the occurrence of meningococcal disease to the presence of high levels of IgA antibodies to meningococci, since these antibodies can block the bactericidal activity of IgM.

Complement is required for bactericidal activity and for efficient opsonophagocytosis. Individuals deficient in any of the late complement components (C5 to C9) cannot assemble the membrane attack complex needed to kill *Neisseria*. These persons typically develop less severe meningococcal disease than complement-sufficient individuals, do so at an older age, and tend to have disease due to uncommon serogroups (W-135, X, Y, Z, and 29E). Although only one-half of individuals with known late-complement-component deficiency ever experience meningococcal disease, some affected persons have several episodes. Deficiency of each of the terminal complement components is inherited in an autosomal recessive fashion. Properdin deficiency, in contrast, is X-linked; some affected males develop overwhelming meningococcal disease, an observation indicating that the alternative complement pathway is also needed for antimeningococcal host defense. The age of disease onset in properdin-deficient individuals is typically in the teens or twenties.

Activation of the classic pathway of complement by antigen-antibody complexes or of the alternative pathway byLOS or capsular polysaccharide is important for producing and maintaining C3b (Fig. 146-2). Without C3b, neither bactericidal lysis nor phagocytosis can proceed effectively. When C3b is generated, meningococcal growth is probably checked by the membrane attack complex, which produces bacterial lysis, and by robust phagocytosis. Most IgG antibodies to the meningococcal polysaccharide are of the IgG_2isotype; a phagocytic cell defect (the FcgRIIA R131 allele) that impairs the phagocytosis of IgG_2-coated particles has been associated with more severe meningococcal disease. This allele has also been associated with a more severe clinical course in patients with late-complement-component deficiency; thus effective phagocytosis may contribute to the relatively mild meningococcal disease usually observed in these individuals.

Indirect evidence indicates that persons who mount a vigorous inflammatory response to meningococcalLOS may experience less severe disease than those whose initial response is anti-inflammatory. This observation suggests that the inflammatory response may be critical for restraining meningococcal growth. Attempts to identify disease- or severity-associated polymorphisms in cytokine genes have had inconclusive results, however.

CLINICAL MANIFESTATIONS

Upper Respiratory Tract Infections Although many patients who develop meningococcal meningitis or meningococcemia report having had throat soreness or other upper respiratory symptoms during the preceding week, it is uncertain whether these symptoms are due to infection with meningococci. Meningococcal pharyngitis is

rarely diagnosed. Adult patients with *N. meningitidis* bacteremia more often have clinically apparent disease of the respiratory tract (pneumonia, sinusitis, tracheobronchitis, conjunctivitis) than do younger patients.

Meningococcemia Most patients with meningococcal disease have both meningococcemia *and* meningitis. These conditions have a wide clinical spectrum, with many overlapping features (Table 146-1).

Approximately 10 to 30% of patients with meningococcal disease have meningococcemia without clinically apparent meningitis. Although meningococcemia is occasionally transient and asymptomatic, in most individuals it is associated with fever, chills, nausea, vomiting, and myalgias. Prostration is common. The most distinctive feature is rash (Fig. 146-CD1). Erythematous macules rapidly become petechial and, in severe cases, purpuric. Although the lesions are typically found on the trunk and lower extremities, they may also occur on the face, arms, and mucous membranes. The petechiae may coalesce into hemorrhagic bullae or may undergo necrosis and ulcerate. Patients with severe coagulopathy may develop ischemic extremities or digits, often with a sharp line of demarcation between normal and ischemic tissue.

In many patients with fulminant meningococcemia, theCSF is normal and the CSF culture is negative. Indeed, the absence of meningitis in a patient with meningococcemia is a poor prognostic sign; it suggests that the bacteria have multiplied so rapidly in the blood that meningeal seeding has not yet had time to elicit inflammation in the CSF. Most of these patients also lack evidence of an acute-phase response; i.e., the erythrocyte sedimentation rate is normal, and the C-reactive protein concentration in blood is low.

The Waterhouse-Friderichsen syndrome is a dramatic example ofDIC-induced microthrombosis, hemorrhage, and tissue injury. Although overt adrenal failure is infrequently documented in patients with fulminant meningococcemia, patients may have partial adrenal insufficiency and be unable to mount the normal hypercortisolemic response to severe stress or cosyntropin stimulation. Almost all patients who die from fulminant meningococcemia have adrenal hemorrhages at autopsy.

Chronic meningococcemia is a rare syndrome of episodic fever, rash, and arthralgias that can last for weeks to months. The rash may be maculopapular; it is occasionally petechial. Splenomegaly may develop. If untreated or if treated with glucocorticoids, chronic meningococcemia may evolve into meningitis, fulminant meningococcemia, or (rarely) endocarditis.

Meningitis (See also Chap. 372) Patients with meningococcal meningitis have usually been sick for ³24 h before they seek medical attention. Common presenting symptoms include nausea and vomiting, headache, neck stiffness, lethargy, and confusion. The symptoms and signs of meningococcal meningitis cannot be distinguished from those elicited by other meningeal pathogens. Many patients with meningococcal meningitis have concurrent meningococcemia, however, and petechial or purpuric skin lesions may suggest the correct diagnosis.CSFfindings are consistent with those of purulent meningitis: hypoglycorrhachia, an elevated protein concentration, and a neutrophilic leukocytosis. A Gram's stain of CSF is usually positive (see "Diagnosis," below); when

this finding is unaccompanied by CSF leukocytosis, the prognosis for normal recovery is often poor.

Other Manifestations Arthritis occurs in ~10% of patients with meningococcal disease. When arthritis develops during the first few days of the patient's illness, it usually reflects direct meningococcal invasion of the joint. Arthritis that begins later in the course is thought to be due to immune complex deposition. Primary meningococcal pneumonia occurs principally in adults, often in military populations, and is most often due to serogroup Y. While meningococcal pericarditis is occasionally seen, endocarditis due to *N. meningitidis* is now exceedingly rare. Primary meningococcal conjunctivitis can be complicated by meningococcemia; systemic therapy is therefore warranted when this condition is diagnosed. Meningococcal urethritis has been reported in individuals who practice oral sex.

Complications Patients with meningococcal meningitis may develop cranial nerve palsies, cortical venous thrombophlebitis, and cerebral edema. In children subdural effusions may occur. Permanent sequelae can include mental retardation, deafness, and hemiparesis. The major long-term morbidity of fulminant meningococcemia is the loss of skin, limbs, or digits that results from ischemic necrosis and infarction.

DIAGNOSIS

Few clinical clues help the physician distinguish the patient with early meningococcal disease from patients with other acute systemic infections. The most useful clinical finding is the petechial or purpuric rash (seePlate IID-44), but it must be differentiated from the petechial lesions seen with gonococcemia (seePlate IID-60), Rocky Mountain spotted fever (seePlate IID-45), hypersensitivity vasculitis (seePlate IIE-71), endemic typhus, and some viruses. In one case series, one-half of the adults with meningococcal bacteremia had neither meningitis nor a rash.

The definitive diagnosis is established by recovering *N. meningitidis*, its antigens, or its DNA from normally sterile body fluids, such as blood,CSF, or synovial fluid, or from skin lesions. Meningococci grow best on Mueller-Hinton or chocolate blood agar at 35°C in an atmosphere that contains 5 to 10% CO_2. Specimens should be plated without delay. *N. meningitidis* bacteria are oxidase-positive, gram-negative diplococci that typically utilize maltose and glucose.

A Gram's stain ofCSFreveals intra- or extracellular organisms in ~85% of patients with meningococcal meningitis. The latex agglutination test for meningococcal polysaccharides is somewhat less sensitive. Reports suggest that polymerase chain reaction amplification of DNA in buffy coat or CSF samples may be more sensitive than either of these tests, and, like the latex agglutination test, this method is not affected by prior antibiotic therapy.

Throat or nasopharyngeal specimens should be cultured on Thayer-Martin medium, which suppresses the competing oral flora. Throat or nasopharyngeal cultures are recommended only for research or epidemiologic purposes, since a positive result merely confirms the carrier state and does not establish the existence of systemic disease.

TREATMENT

A third-generation cephalosporin, such as cefotaxime (2 g intravenously every 8 h) or ceftriaxone (1 g intravenously every 12 h), is preferred for initial therapy, as it may cover other bacteria (such as *Streptococcus pneumoniae* and *Haemophilus influenzae*) that can cause the same syndromes (Chap. 372). Penicillin G (4 million units intravenously every 4 h) remains an acceptable alternative in most countries; high-level penicillin resistance has been reported from Spain. In the patient who is allergic to b-lactam drugs, chloramphenicol (75 to 100 mg/kg every 6 h) is a suitable alternative; chloramphenicol-resistant meningococci have been reported from Vietnam and France, however. Although some cases of mild disease may be cured with only 2 days of treatment, most patients with meningococcal meningitis should be given antimicrobial therapy for at least 5 days. While glucocorticoid therapy for meningitis in adults is controversial, many experts administer dexamethasone, beginning if possible before antibiotic therapy is initiated (Chap. 372).

Patients with fulminant meningococcemia often experience diffuse leakage of fluid into extravascular spaces, shock, and multiple-organ dysfunction (Chaps. 38 and124). Myocardial depression may be prominent. Supportive therapy has never been studied in randomized, placebo-controlled trials. Standard measures include vigorous fluid resuscitation (often requiring several liters over the first 24 h), elective ventilation, and pressors (epinephrine or dopamine). Some authorities recommend early hemodialysis or hemofiltration. Fresh frozen plasma is often given to patients who are bleeding extensively or who have severely deranged clotting parameters. Many European experts prefer to administer antithrombin to such patients. Patients with fulminant meningococcemia in whom shock persists despite vigorous fluid resuscitation should receive supplemental glucocorticoid treatment (hydrocortisone, 1 mg/kg every 6 h) pending tests of adrenal reserve. Investigational drugs for fulminant meningococcemia include bactericidal permeability-increasing (BPI) protein -- a bactericidal neutrophil protein that binds and neutralizes meningococcalLOS -- as well as several anticoagulants (activated protein C, antithrombin, and tissue factor pathway inhibitor). In a recent clinical trial, recombinant BPI protein reduced long-term complications in children with fulminant meningococcemia without definitely reducing mortality.

PROGNOSIS

When patients are first evaluated, the clinical features most strongly associated with a fatal outcome are shock, a purpuric or ecchymotic rash, a low or normal blood leukocyte count, an age ³60 years, and coma. The absence of meningitis, the presence of thrombocytopenia, low blood concentrations of antithrombin or proteins S and C, high blood levels ofPAI-1, and a low erythrocyte sedimentation rate (or C-reactive protein level) have also been associated with increased mortality from meningococcal disease. In contrast, having received antibiotics prior to hospital admission has been associated with lower mortality in some studies.

PREVENTION

Meningococcal Polysaccharide Vaccines A single injection of quadrivalent

meningococcal polysaccharide vaccine (serogroups A, C, W-135, and Y) immunizes ~80 to 95% of immunocompetent adults. Children ³3 months of age can be vaccinated to prevent serogroup A disease, but multiple doses are required; the vaccine is otherwise ineffective in children<2 years old. The duration of vaccine-induced immunity in adults is probably <5 years. There is currently no vaccine for serogroup B; its polysaccharide is a sialic acid homopolymer that is poorly immunogenic in humans. In addition to individuals with late-complement-component or properdin deficiency, persons with sickle cell anemia, asplenia, or splenectomy should receive the quadrivalent vaccine. Vaccination is also recommended for military recruits and for individuals traveling to sub-Saharan Africa during the dry months (June to December) or to other areas with epidemic meningococcal disease. Some authorities recommend vaccination of incoming college freshmen who will live in dormitories. In general, the vaccine should be given only to persons³2 years of age. Investigational polysaccharide-protein conjugate meningococcal vaccines appear promising; a serogroup C conjugate vaccine was licensed for use in the United Kingdom in 1999.

Screening tests for late-complement-component deficiency should be done in family members of patients who have a family history of meningococcal disease, in patients who have a recurrence, in those whose first case occurs at³15 years of age, and in those with cases caused by serogroups other than A, B, or C.

Antimicrobial Chemoprophylaxis The attack rate for meningococcal disease among household contacts of cases is ~500-fold greater than that in the population as a whole. Close contacts of cases should receive chemoprophylaxis with rifampin (adult dosage, 600 mg orally every 12 h for four doses), ciprofloxacin (a single oral dose of 500 mg), or ofloxacin (a single oral dose of 400 mg). A single intramuscular injection of ceftriaxone (250 mg) is also effective. Close contacts include persons who live in the same household, day-care center contacts, and anyone directly exposed to the patient's oral secretions. Casual contacts are not at increased risk. Chemoprophylaxis should be administered as soon as possible after the case is identified.

Isolation Precautions The Centers for Disease Control and Prevention recommend that patients with meningococcal disease who are hospitalized be placed in respiratory isolation for the first 24 h.

Outbreak Control An organization- or community-based outbreak of meningococcal disease is defined as the occurrence of three or more cases within £3 months in persons who have a common affiliation or reside in the same area but who are not close contacts of one another; in addition, the primary disease attack rate must exceed 10 cases per 100,000 persons, and the case strains of *N. meningitidis* must be of the same molecular type. Mass vaccination should be considered when such outbreaks occur, and mass chemoprophylaxis may be used to control school- or other institution-based outbreaks. Consultation with public health authorities is recommended when such campaigns are contemplated.

147. GONOCOCCAL INFECTIONS - *Sanjay Ram*, *Peter A. Rice*

DEFINITION

Gonorrhea is a sexually transmitted infection of epithelium and commonly manifests as cervicitis, urethritis, proctitis, and conjunctivitis. If untreated, infections at these sites can lead to local complications such as endometritis, salpingitis, tuboovarian abscess, bartholinitis, peritonitis, and perihepatitis in the female; periurethritis and epididymitis in the male; and ophthalmia neonatorum in the newborn. Disseminated gonococcemia is an uncommon event whose manifestations include skin lesions, tenosynovitis, arthritis, and (in rare cases) endocarditis or meningitis.

Neisseria gonorrhoeae is a gram-negative, nonmotile, non-spore-forming organism that grows in pairs (diplococci). Each individual organism is shaped like a coffee bean, with adjacent concave sides seen on Gram's stain. Gonococci, like all other *Neisseria* spp., are oxidase positive. They are distinguished from other *Neisseria* by their ability to grow on selective media and to utilize glucose but not maltose, sucrose, or lactose.

EPIDEMIOLOGY

The incidence of gonorrhea has declined significantly in the United States, but there are still ~315,000 newly reported cases each year. Gonorrhea remains a major public health problem worldwide, is a significant cause of morbidity in developing countries, and may play a role in enhancing transmission of HIV.

Gonorrhea predominantly affects young, nonwhite, unmarried, less educated members of urban populations. The number of reported cases probably represents half of the true number of cases -- a discrepancy resulting from underreporting, self-treatment, and nonspecific treatment without a culture-proven diagnosis. The number of reported cases of gonorrhea in the United States rose from ~250,000 in the early 1960s to a high of 1.01 million in 1978. The peak recorded incidence of gonorrhea in modern times was noted in 1975, with 468 cases per 100,000 population in the United States. This peak was attributable to the interaction of several variables, including improved accuracy of diagnosis, changes in patterns of contraceptive use, and changes in sexual behavior. The incidence of the disease has since gradually declined and is currently estimated at 120 cases per 100,000, a figure that is still the highest among industrialized countries. A further decline in the overall incidence of gonorrhea in the United States over the past decade may reflect increased condom use resulting from public health efforts to curtail HIV transmission. Presently, the attack rate in the United States is highest in the 20- to 24-year age group, in which 75% of all cases occur. With adjustment for sexual experience, the risk is highest among sexually active 15- to 19-year-old women. In terms of ethnicity, rates are highest among African-Americans and lowest among persons of Asian or Pacific Island descent.

The highest incidence of gonorrhea occurs in developing countries. The exact incidence of any of the sexually transmitted diseases (STDs) is difficult to ascertain in developing countries because of limited surveillance and variable diagnostic criteria. For example, in Kenya, it was estimated in 1987 that 10% of all live births were adversely affected by STDs, and gonococcal ophthalmia neonatorum reportedly affected 4% of all live-born

infants. The median prevalence of gonorrhea in unselected populations of pregnant women has been estimated at 10% in Africa, 5% in Latin America, and 4% in Asia. Studies in Africa have clearly demonstrated that nonulcerative STDs such as gonorrhea are an independent risk factor for the transmission of HIV (Chap. 309).

Gonorrhea is transmitted from males to females more efficiently than in the opposite direction. The rate of transmission to a woman following a single unprotected sexual encounter with an infected man is on the order of 40 to 60%. Oropharyngeal gonorrhea occurs in ~20% of women who practice fellatio with infected partners. Transmission in either direction by cunnilingus is rare.

There exists in any population a small minority of individuals who have high rates of new partner acquisition. These "core-group members" or "high-frequency transmitters" are vital in sustainingSTDtransmission at the population level. Another instrumental factor in sustaining gonorrhea in the population is the large number of infected individuals who are asymptomatic or have minor symptoms that are ignored. These persons, unlike symptomatic individuals, do not cease sexual activity and therefore continue to transmit the disease. This situation underscores the importance of contact tracing and empirical treatment of sex partners of index cases.

PATHOGENESIS AND IMMUNOLOGY

Outer-Membrane Proteins

Pili Fresh clinical isolates of *N. gonorrhoeae* initially form piliated (fimbriated) colonies distinguishable on translucent agar. Pilus expression is rapidly switched off with unselected subculture because of rearrangements in pilus genes. This change is a basis for phase variation of gonococci. Piliated strains adhere better to cells derived from human mucosal surfaces and are more virulent in organ culture models and human inoculation experiments than nonpiliated variants. In a fallopian tube explant model, pili mediate gonococcal attachment to nonciliated columnar epithelial cells. This event initiates gonococcal phagocytosis and transport through these cells to intercellular spaces near the basement membrane or directly into the subepithelial tissue. Damage to nearby ciliated columnar epithelial cells, which is caused by the release of cytokines, results in loss of cilia and sloughing of ciliated cells and diminishes the integrity of the fallopian tube. Nonpiliated gonococci cause epithelial damage at a much slower rate. CD46 (membrane cofactor protein) is present on urogenital epithelial cells in both men and women and has been determined to be a receptor for PilC; this subunit is located at the tip of the pilus molecule and is critical in mediating adherence. Pili are also essential for genetic competence and transformation of *N. gonorrhoeae*, which permits horizontal transfer of genetic material between different gonococcal lineages in vivo.

Opacity-associated protein Another gonococcal surface protein that is important in adherence to epithelial cells is opacity-associated protein (Opa, formerly called protein II). Opa contributes to intergonococcal adhesion, which is responsible for the opaque nature of gonococcal colonies on translucent agar and the organism's adherence to a variety of eukaryotic cells, including polymorphonuclear leukocytes (PMNs). Certain Opa variants promote invasion of epithelial cells, and this effect has been linked with the ability of Opa to bind vitronectin, glycosaminoglycans, and several members of the

carcinoembryonic antigen family (CD66). Each strain of *N. gonorrhoeae* possesses as many as 11 different *opa* genes, but usually only up to 3 types are expressed at any given time. Isolates from normally sterile sites such as the fallopian tube and synovial fluid usually fail to express Opa, while isolates from mucosal sites usually form opaque colonies. Female commercial sex workers with antibodies to Opa may be less likely to develop pelvic inflammatory disease (PID) than women without such antibodies.

Porin Porin (previously designated protein I) is the most abundant gonococcal surface protein, accounting for >50% of the organism's total outer-membrane protein. Porin molecules exist as trimers that provide anion aqueous channels through the otherwise hydrophobic outer membrane. Porin shows stable interstrain antigenic variation and forms the basis for gonococcal serotyping. Two main serotypes have been identified: Por1A strains are often associated with disseminated gonococcal infection (DGI), while Por1B strains usually cause local genital infections only. DGI strains are generally resistant to the killing action of normal human serum, do not incite a significant local inflammatory response, and therefore may not cause symptoms at genital sites. These characteristics may be related to the ability of Por1A strains to bind to complement-downregulatory molecules, resulting in a diminished inflammatory response. Porin can translocate to the cytoplasmic membrane of host cells -- a process that could initiate gonococcal endocytosis and invasion. In addition, porin is an immunologic target of bactericidal and opsonophagocytic antibodies that may arise in response to immune stimulation resulting from infection or immunization with porin-containing vaccine candidates.

Other outer-membrane proteins Other notable outer-membrane proteins include H.8, a lipoprotein that is present on the surface of all gonococcal strains in high concentration and is an excellent target for antibody-based diagnostic testing, as well as transferrin-binding proteins (Tbp1 and Tbp2) and lactoferrin-binding protein, which are required for scavenging iron from transferrin and lactoferrin in vivo. Transferrin and iron have been shown to increase attachment of iron-deprived *N. gonorrhoeae* to human endometrial cells. Gonococci deficient in transferrin- and lactoferrin-binding proteins cannot establish infection in male volunteers. IgA1 protease is produced by *N. gonorrhoeae* and may protect the organism from the action of mucosal IgA.

Lipooligosaccharide Gonococcal lipooligosaccharide (LOS) consists of a lipid A and a core oligosaccharide that lacks the repeating O-carbohydrate antigenic side chain seen in other gram-negative bacteria (Chap. 120). Gonococcal LOS possesses marked endotoxic activity and contributes to the local cytotoxic effect in the fallopian tube model. LOS core sugars undergo a high degree of antigenic variation under different conditions of growth; this variation reflects genetic regulation and expression of glycotransferase genes that dictate the carbohydrate structure of LOS. These phenotypic changes may affect interactions of *N. gonorrhoeae* with elements of the humoral immune system (antibodies and complement) and may also influence direct binding of organisms to both professional and nonprofessional phagocytes (epithelial cells). For example, gonococci that are sialylated at their LOS sites bind complement factor H and downregulate the alternative pathway of complement. LOS sialylation may also mask bactericidal antibody-binding epitopes on LOS and porin and may decrease opsonophagocytosis and inhibit the oxidative burst inPMNs. While sialylation of LOS confers on the bacteria the ability to attenuate the inflammatory response and evade the innate immune system,

experiments in male volunteers suggest that sialylated gonococci may be less capable of establishing infection than their unsialylated counterparts. This difference could be explained by the observation that the unsialylated terminal lactosamine residue of LOS binds to an asialoglycoprotein receptor on epithelial cells that would otherwise facilitate binding and subsequent gonococcal invasion of these cells.

Host Factors In addition to gonococcal structures that interact with epithelial cells, host factors seem to be important in mediating entry of gonococci into nonphagocytic cells. Activation of phosphatidylcholine-specific phospholipase C and acidic sphingomyelinase by *N. gonorrhoeae*, which results in the release of diacylglycerol and ceramide, is an essential requirement for the entry of *N. gonorrhoeae* into epithelial cells. Ceramide accumulation within cells leads to apoptosis, which may disrupt epithelial integrity and facilitate entry of gonococci into subepithelial tissue. Release of chemotactic factors as a result of complement activation contributes to inflammation, as does the toxic effect of LOSin provoking the release of inflammatory cytokines.

The importance of humoral immunity in host defenses against neisserial infections is best illustrated by the predisposition of persons deficient in terminal complement components (C5 through C9) to recurrent bacteremic gonococcal infections and to recurrent meningococcal meningitis or meningococcemia. Gonococcal porin induces T cell proliferative responses in persons with urogenital gonococcal disease. A significant increase in porin-specific interleukin (IL) 4-producing CD4+ as well as CD8+ lymphocytes is seen in individuals with mucosal gonococcal disease. A portion of these lymphocytes that show a porin-specific T_H2-type response could traffic to mucosal surfaces and play a role in immune protection against the disease. Few data clearly indicate that protective immunity is acquired from a previous gonococcal infection, although bactericidal and opsonophagocytic antibodies to porin andLOS may offer partial protection. On the other hand, women who are infected and acquire high levels of antibody to another outer-membrane protein, Rmp (reduction modifiable protein, formerly called protein III), may be especially likely to become reinfected with *N. gonorrhoeae* because Rmp antibodies block the effect of bactericidal antibodies to porin and LOS. Rmp shows little, if any, interstrain antigenic variation; therefore, Rmp antibodies potentially may block antibody-mediated killing of all gonococci. The mechanism of blocking has not been fully characterized, but Rmp antibodies noncompetitively inhibit binding of porin and LOS antibodies because of the proximity of these structures in the gonococcal outer membrane. Less well understood is how blocking antibody may divert complement binding to the gonococcal surface or otherwise hasten inactivation of complement. In male volunteers who have no history of gonorrhea, the net effect of these events may influence the outcome of experimental challenge with *N. gonorrhoeae*. Because Rmp bears extensive homology to enterobacterial OmpA and meningococcal class 4 proteins, it is possible that these blocking antibodies result from prior exposure to cross-reacting proteins from these species and also play a role in first-time infection with *N. gonorrhoeae*.

CLINICAL MANIFESTATIONS

Gonococcal Infection in Males Acute urethritis is the most common clinical manifestation of gonorrhea in males. The usual incubation period following exposure is 2 to 7 days, although the interval can be longer and some men remain asymptomatic.

Strains of the Por1A serotype, with nutritional requirements for arginine, hypoxanthine, and uracil (i.e., the AHU auxotype), tend to cause a greater proportion of cases of mild and asymptomatic urethritis than Por1B strains. Urethral discharge (Fig. 147-CD1) and dysuria, usually without urinary frequency or urgency, are the major symptoms. The discharge initially is scant and mucoid but becomes profuse and purulent within a day or two. The clinical manifestations of gonococcal urethritis are usually more severe and overt than those of nongonococcal urethritis, including urethritis caused by *Chlamydia trachomatis* (Chap. 179); however, exceptions are common, and it is often impossible to differentiate the causes of urethritis on clinical grounds alone. Most symptomatic males seek treatment and cease to be infectious. The remaining men, who are largely asymptomatic, accumulate in number over time and constitute about two-thirds of all infected men at any point in time. Together with men incubating the organism (who shed the organism but are asymptomatic), they serve as the source of spread of infection. Prior to the antibiotic era, symptoms of urethritis persisted for about 8 weeks. Epididymitis is now an uncommon complication, and gonococcal prostatitis occurs rarely, if at all. Other unusual local complications of gonococcal urethritis include edema of the penis due to dorsal lymphangitis or thrombophlebitis, submucous inflammatory "soft" infiltration of the urethral wall, periurethral abscess or fistulae, inflammation or abscess of Cowper's gland, and seminal vesiculitis. Balanitis may develop in uncircumcised men. After a decline in gonococcal infections among homosexual men early in the era of AIDS, a disturbing increase in gonorrhea was observed among young homosexual men in the 1990s, probably related to decreased condom use. The clinical features of anorectal and pharyngeal gonorrhea are discussed below.

Gonococcal Infections in Females

Gonococcal cervicitis Mucopurulent cervicitis is the most commonSTDdiagnosis in American women and may be caused by *N. gonorrhoeae*, *C. trachomatis*, and other organisms. Cervicitis may coexist with candidal or trichomonal vaginitis. *N. gonorrhoeae* primarily infects the cervical os but can also infect more peripheral areas of the cervix where columnar epithelium meets stratified squamous epithelium. Except in rare instances, the vaginal mucosa, which is lined by stratified squamous epithelium, does not become infected. Bartholin's glands occasionally become infected.

Women infected with *N. gonorrhoeae* usually develop symptoms. However, the women who either remain asymptomatic or have only minor symptoms may delay in seeking medical attention. Increased vaginal discharge and dysuria (often without urgency or frequency) are the most common symptoms. Although the incubation period of gonorrhea is less well defined in women than in men, symptoms usually develop within 10 days of infection and are more acute and intense than those of chlamydial cervicitis.

The physical examination may reveal a mucopurulent discharge (mucopus) issuing from the cervical os. The examiner may check for mucopurulent discharge by swabbing a sample of mucus from the endocervix and observing its color against the white background of the swab; yellow or green mucus suggests mucopus. However, only 35% of women with gonococcal cervicitis actually have a mucopurulent discharge defined by these criteria. Since Gram's stain is not sensitive for the diagnosis of gonorrhea in women, specimens should be submitted for culture or a nonculture assay (see below). Edematous and friable cervical ectopy as well as endocervical bleeding induced by

gentle swabbing are more often seen in chlamydial infection.

N. gonorrhoeae may be recovered from the urethra and rectum of women with cervicitis, but these are rarely the sole infected sites. Urethritis in women may produce symptoms of internal dysuria, which is often attributed to "cystitis." Pyuria in the absence of bacteriuria seen on Gram's stain of unspun urine, accompanied by urine cultures that fail to yield>10^5colonies of bacteria usually associated with urinary tract infection, signifies the possibility of urethritis due to *C. trachomatis*. Urethral infection with *N. gonorrhoeae* may also occur in this context, but in this instance urethral cultures will usually be positive. Compression of the urethra through the anterior vaginal wall against the symphysis pubis may express urethral exudate.

Complications of gonococcal cervicitis Gonococcal infection may extend deep enough to produce dyspareunia and lower abdominal or back pain. In such cases, it is imperative to consider a diagnosis ofPID and to administer treatment for that disease (Chap. 133). Ascending infection of the genital tract follows ~20% of cases of gonococcal cervicitis and may result in acute endometritis accompanied by abnormal menstrual bleeding, midline lower abdominal pain and tenderness, and dyspareunia. Spread to the fallopian tubes results in acute salpingitis, whose symptoms may be accompanied by signs of cervical motion tenderness and abnormal adnexal mass on pelvic examination. Patients may be febrile, and leukocytosis and an elevated erythrocyte sedimentation rate or C-reactive protein level may be detected. Co-infection with *C. trachomatis* may increase the risk of PID, which is the clinical counterpart of endometritis and salpingitis. Tubal scarring leading to infertility is the most devastating sequela of salpingitis; the increased risk of ectopic pregnancy is also significant. Prompt and appropriate antibiotic therapy for gonococcal salpingitis (prior to the development of an adnexal mass) can prevent tubal infertility in nearly all cases. Bilateral tubal damage occurs in ~20% of women with an adnexal mass. More than half of women with tubal infertility give no history of PID. These women with "silent salpingitis" may report abdominal or pelvic discomfort (such as dysmenorrhea or dyspareunia) that may be attributed to other diagnoses (such as endometriosis). Spread of infection to the pelvis may result in pelvic peritonitis characterized by nausea and vomiting. Spread of gonococci -- or, more commonly, of chlamydiae -- via the peritoneal cavity to the upper abdomen may cause perihepatitis (Fitz-Hugh-Curtis syndrome;Chap. 133).

Gonococcal vaginitis The vaginal mucosa of healthy women is lined by stratified squamous epithelium and is usually not infected by *N. gonorrhoeae*. However, gonococcal vaginitis can occur in anestrogenic women (e.g., prepubertal girls and postmenopausal women), in whom the vaginal stratified squamous epithelial layers are often thinned down to the basilar layer, which can be infected by *N. gonorrhoeae*. The intense inflammation of the vagina makes the physical (speculum and bimanual) examination extremely painful. The vaginal mucosa is red and edematous, and an abundant purulent discharge is present. Infection in the urethra and in Skene's and Bartholin's glands often accompanies gonococcal vaginitis. Inflamed cervical erosion or abscesses in nabothian cysts may also occur. Coexisting cervicitis may result in pus in the cervical os.

Anorectal Gonorrhea Because the female anatomy permits the spread of cervical exudate to the rectum, *N. gonorrhoeae* is sometimes recovered from the rectum of

women with uncomplicated gonococcal cervicitis. The rectum is the sole site of infection in only 5% of women with gonorrhea. Such women are usually asymptomatic but occasionally have acute proctitis manifested by anorectal pain or pruritus, tenesmus, purulent rectal discharge, and rectal bleeding. Among homosexual men, the frequency of gonococcal infection, including rectal infection, fell by³90% throughout the United States in the early 1980s, but a resurgence of gonorrhea among homosexual men was documented in several cities during the 1990s. Gonococcal isolates from the rectum of homosexual men tend to be more resistant than other gonococcal isolates to antimicrobials. Gonococci with multidrug resistance (*mtr*) are more resistant to bile salts and fatty acids in feces and thus are found with increased frequency in homosexual men. The *mtr* mutation involves a DNA-binding protein and results in the derepression of genes encoding an efflux mechanism of resistance. This situation may have been responsible for higher rates of treatment failure for rectal gonorrhea with older regimens consisting of penicillin or tetracyclines.

Pharyngeal Gonorrhea Pharyngeal gonorrhea is usually mild or asymptomatic, although symptomatic pharyngitis does occasionally occur with cervical lymphadenitis. The mode of acquisition is oral-genital sexual exposure, with fellatio being a more efficient means of transmission than cunnilingus. Most cases resolve spontaneously, and transmission from the pharynx to sexual contacts is rare. Pharyngeal infection almost always coexists with genital infection. Swabs from the pharynx should be plated directly onto gonococcal selective media. Because pharyngeal colonization with *N. meningitidis* needs to be differentiated from that with other *Neisseria* species, the diagnosis of pharyngeal gonorrhea is more expensive and difficult than that of anogenital gonorrhea.

Ocular Gonorrhea in Adults Ocular gonorrhea in an adult usually results from autoinoculation from an infected genital site. As in genital infection, the manifestations range from severe to occasionally mild or asymptomatic disease. The variability in clinical manifestations may result from differences in the ability of the infecting strain to elicit an inflammatory response.

Infection may result in a markedly swollen eyelid, severe hyperemia and chemosis, and a profuse purulent discharge (Fig. 147-CD2). The massively inflamed conjunctiva may be draped over the cornea and limbus. Lytic enzymes from the infiltratingPMNsoccasionally cause corneal ulceration and rarely cause perforation.

Prompt recognition and treatment of this condition are of paramount importance. Gram's stain and culture of the purulent discharge establish the diagnosis. Genital cultures should also be performed.

Gonorrhea in Pregnant Women, Neonates, and Children Gonorrhea in pregnancy can have serious consequences for both the mother and the infant. Therefore, early detection and eradication of the disease in the mother are extremely important. Recognition of gonorrhea early in pregnancy also identifies a population at risk for otherSTDs, particularly *Chlamydia* infection and syphilis. These women should be monitored closely for these infections throughout pregnancy. The incidence of gonorrhea in pregnancy ranges from rare to ~10%, depending upon the population surveyed. Salpingitis andPID can occur during the first trimester and are associated with

a high rate of fetal loss. In the second and third trimesters, the relative impermeability of the cervical mucus (under the influence of progesterone) and the obliteration of the intrauterine cavity (resulting from the attachment of the chorion to the endometrial decidua by around the twelfth week of gestation) pose physical barriers that usually prevent ascending infection. Pharyngeal infection, most often asymptomatic, may be more common during pregnancy because of altered sexual practices. Acquisition of gonococcal infection late in pregnancy can adversely affect labor and delivery as well as the well-being of the fetus. Prolonged rupture of the membranes, premature delivery, chorioamnionitis, funisitis (infection of the umbilical cord stump), and sepsis in the infant (with *N. gonorrhoeae* detected in the gastric aspirate of the newborn during delivery) are common complications of maternal gonococcal infection at term. Hazards to the fetus include spontaneous abortion, perinatal death, premature delivery, perinatal distress, and premature rupture of membranes. Other microorganisms and conditions, including *Mycoplasma hominis*, *Ureaplasma urealyticum*, *C. trachomatis*, and bacterial vaginosis, have been associated with similar complications.

The most common form of gonorrhea in neonates is *ophthalmia neonatorum*, which results from exposure to infected cervical secretions during parturition. Ocular neonatal instillation of a prophylactic agent (e.g., 1% silver nitrate eyedrops or ophthalmic preparations containing erythromycin or tetracycline) is a cost-effective measure for the prevention of ophthalmia neonatorum but is not effective for its treatment, which requires systemic antibiotics. The clinical manifestations are acute and begin 2 to 5 days after birth. A small inoculum of organisms, low virulence of the infecting strain, or partial suppression by ophthalmic prophylaxis can result in a more indolent course. Therefore, gonococcal infection must be ruled out by culture in every case of conjunctivitis in infants. An initial nonspecific conjunctivitis with a serosanguineous discharge is followed by tense edema of both eyelids, chemosis, and a profuse, thick, purulent discharge. Corneal ulcerations that result in nebulae or perforation may lead to anterior synechiae, anterior staphyloma, panophthalmitis, and blindness. Infections described at other mucosal sites in infants, including vaginitis, rhinitis, and anorectal infection, are likely to be asymptomatic. Pharyngeal colonization has been demonstrated in 35% of infants with gonococcal ophthalmia, and coughing is the most prominent symptom in these cases. Septic arthritis is the most common manifestation of systemic gonococcal infection in the newborn. The primary focus ofDGI in most of these cases is uncertain. The onset usually comes at 3 to 21 days of age, and polyarticular involvement is common. Sepsis, meningitis, and pneumonia are seen in rare instances.

AnySTD in children beyond the neonatal period raises the possibility of sexual abuse. In most cases of abuse, the perpetrator is a male assailant known to the child. Gonococcal vulvovaginitis is the most common manifestation of gonococcal infection in children beyond infancy. Anorectal and pharyngeal infections are common in these children and are frequently asymptomatic. The urethra, Bartholin's and Skene's glands, and the upper genital tract are rarely involved. All children with gonococcal infection should also be evaluated for *Chlamydia* infection, syphilis, and possibly HIV infection. All cases of suspected and confirmed child abuse should be reported to the appropriate social service agency in the county where the child resides.

Disseminated Gonococcal Infection DGIresults from gonococcal bacteremia. In the 1970s, DGI occurred in ~0.5% to 3% of persons with untreated gonococcal mucosal

infection. The lower incidence at present is probably attributable to a decline in the prevalence of particular strains that are likely to disseminate. DGI strains resist the bactericidal action of human serum and generally do not incite inflammation at genital sites, probably because of limited generation of chemotactic factors. These strains are often of the Por1A serotype, are highly susceptible to penicillin, and have special nutritional requirements (i.e., the AHU auxotype). Menstruation is a risk factor for dissemination, and approximately two-thirds of cases of DGI are in women. In about half of affected women, symptoms of DGI begin within 7 days of onset of menses. Complement deficiencies, especially of the components involved in the assembly of the membrane attack complex (C5 through C9), predispose to neisserial bacteremia. Up to 13% of patients with DGI have complement deficiencies, and persons with more than one episode of DGI should be screened with an assay for total hemolytic complement activity.

The clinical manifestations ofDGI have sometimes been classified into two stages: a bacteremic stage and a joint-localized stage with suppurative arthritis. A clear-cut progression usually is not evident. Patients in the bacteremic stage have higher temperatures, and their fever is more frequently accompanied by chills. Painful joints are common and often occur in conjunction with tenosynovitis and skin lesions.

Polyarthralgias usually include the knees, elbows, and more distal joints; the axial skeleton is generally spared. Skin lesions are seen in ~75% of patients and include papules and pustules, often with a hemorrhagic component (seePlate IID-60;Fig. 147-CD3). These lesions are usually on the extremities and number between 5 and 40. Frank arthritis, when it develops, involves one or two joints, most often (in decreasing order of frequency) the knees, wrists, ankles, and elbows. The occurrence of arthritis in the absence of signs and symptoms of the bacteremic stage has led to the suggestion that these are separate syndromes. Other joints, such as the small joints of the hands and feet and the sternoclavicular and temporomandibular joints, are occasionally involved. Most patients who develop gonococcal septic arthritis do so without prior polyarthralgias or skin lesions; in the absence of symptomatic genital infection, this disease cannot be distinguished from septic arthritis caused by other pathogens. Rarely, osteomyelitis complicates septic arthritis involving small joints.

Although it has been postulated that the initial arthritis and skin lesions are due to direct tissue invasion by *N. gonorrhoeae*, the organism has been recovered from fewer than 5% of skin lesions cultured. This low isolation rate has been attributed to either a small inoculum of infecting organisms or the fastidious growth requirements of *N. gonorrhoeae* strains that disseminate. Gonococcal antigens have been identified in "sterile" skin lesions by immunofluorescent staining techniques. There is also evidence that immune-mediated or hypersensitivity phenomena caused by gonococcal antigens account for skin lesions. Other manifestations of noninfectious dermatitis, such as nodular lesions, urticaria, and erythema multiforme, have been described. Gonococcal endocarditis, although rare today, was relatively common in the preantibiotic era, causing about one-quarter of reported cases of endocarditis. Another unusual complication ofDGI is meningitis.

Gonococcal Infection in HIV-Infected Persons The association between gonorrhea and the acquisition of HIV has been demonstrated in several well-controlled studies,

mainly in Kenya and Zaire. The nonulcerativeSTDsenhance the transmission of HIV by three- to fivefold, possibly because of increased viral shedding in persons with urethritis or cervicitis (Chap. 309). HIV has been detected by polymerase chain reaction (PCR) more commonly in ejaculates from HIV-positive men with gonococcal urethritis than in those from HIV-positive men with nongonococcal urethritis. PCR positivity diminishes by twofold following appropriate therapy for urethritis. Not only does gonorrhea enhance the transmission of HIV; it may also increase the individual's risk for acquisition of HIV. A proposed mechanism is the significantly greater number of CD4+ lymphocytes and dendritic cells that can be infected by HIV in endocervical secretions of women with nonulcerative STDs than in those of women with ulcerative STDs.

DIFFERENTIAL DIAGNOSIS

The clinical features of uncomplicated gonococcal infections closely resemble those of genital infections caused by *C. trachomatis*. Although the symptoms produced by chlamydial infections tend to be milder, the two infections are often indistinguishable on clinical grounds alone. Co-infection with *N. gonorrhoeae* and *C. trachomatis* is seen in up to 40% of cases. The differential diagnosis of urethritis, epididymitis, and proctitis in men, of cervicitis in women, and of vaginitis in prepubertal girls is discussed inChap. 132; that ofPID inChap. 133; and that of acute arthritis in young adults in Chap. 323. The differential diagnosis of the bacteremic stage ofDGIincludes acute rheumatoid arthritis, sarcoidosis, erythema nodosum, drug-induced arthritis, and viral infections (e.g., hepatitis B and acute HIV infection).

LABORATORY DIAGNOSIS

A rapid diagnosis of gonococcal infection in men may be obtained by Gram's staining of urethral exudates (Fig. 147-CD4). The detection of gram-negative intracellular diplococci (GNID) is usually highly specific and sensitive in diagnosing gonococcal urethritis in symptomatic males but is only ~50% sensitive in diagnosing gonococcal cervicitis. Samples should be collected with Dacron or rayon swabs. Part of the sample should be inoculated onto a plate of modified Thayer-Martin or other gonococcal selective medium for culture. It is important to process all samples immediately because gonococci do not tolerate drying. If plates cannot be incubated immediately, they can be held safely for several hours at room temperature in candle extinction jars prior to incubation. If processing is to occur within 6 h, transport of specimens may be facilitated by the use of nonnutritive swab transport systems such as Stuart or Amies medium. For longer holding periods (e.g., when specimens for culture are to be mailed), culture media with self-contained CO_2-generating systems (such as the JEMBEC or Gono-Pak systems) may be used. Specimens should also be obtained for the diagnosis of chlamydial infection.

PMNsare often seen in the endocervix on a Gram's stain, and an abnormally increased number (³30 PMNs per field in five 1000´ oil-immersion fields) establishes the presence of an inflammatory discharge (mucopurulent cervicitis). Unfortunately, the presence or absence ofGNID in cervical smears does not accurately predict which patients have gonorrhea, and the diagnosis in this setting should be made by culture. The sensitivity of a single endocervical culture is ~80 to 90%, with the precise figure depending on the quality of the medium and the adequacy of the clinical specimen. The yield can be

enhanced by culture of a second cervical specimen. If a history of rectal sex is elicited, a rectal wall swab (uncontaminated with feces) should be cultured. A presumptive diagnosis of gonorrhea cannot be made on the basis of gram-negative diplococci in smears from the pharynx, where other *Neisseria* species are components of the normal flora.

Nucleic acid probe tests are now widely used for the direct detection of *N. gonorrhoeae* in urogenital specimens. A common assay employs a nonisotopic chemiluminescent DNA probe that hybridizes specifically with gonococcal 16S ribosomal RNA. Studies assessing the utility of the nucleic acid probe system in high-risk outpatients undergoing screening forSTDshave revealed that it is at least as sensitive as conventional culture techniques and may be a cost-effective alternative to culture, especially in high-risk males. A disadvantage of non-culture-based assays in general is that specimens submitted in probe-transport systems cannot be cultured subsequently. Therefore, a culture-confirmatory test is not possible, and formal antimicrobial susceptibility testing, if needed, cannot be performed. Low-cost point-of-care tests are under development for use in resource-poor settings, where specific diagnosis often gives way to syndromic management. DNA amplification techniques such asPCR may eventually prove to be equivalent to or more sensitive than culture methods.

Because of the legal implications, gonococcal infection in children must be diagnosed only with standard culture systems. Nonculture tests for gonococcal infection should not be used alone and have not been approved by the U.S. Food and Drug Administration for use with specimens obtained from the genital tract, pharynx, and rectum of infected children. Cultures should be obtained from the pharynx and anus of both girls and boys, the vagina of girls, and the urethra of boys. Cervical specimens are not recommended for prepubertal girls. For boys with a urethral discharge, a meatal specimen of the discharge is adequate for culture. Presumptive colonies of *N. gonorrhoeae* should be identified definitively by at least two independent methods (e.g., biochemical, enzyme substrate, or serologic).

Blood should be cultured in suspected cases ofDGI. The use of Isolator blood culture tubes may enhance the yield. The probability of positive blood cultures decreases after 48 h of illness. Synovial fluid should be inoculated into blood culture broth medium and plated onto chocolate agar rather than selective medium because this fluid is not likely to be contaminated with commensal bacteria. Gonococci are infrequently recovered from early joint effusions containing <20,000 leukocytes/uL but may be recovered from effusions containing >80,000 leukocytes/uL. The organisms are seldom recovered from blood and synovial fluid of the same patient.

TREATMENT

It is no surprise that *N. gonorrhoeae*, with its remarkable capacity to alter its antigenic structure and adapt to changes in the microenvironment, has become resistant to numerous antibiotics. The first effective agents against gonorrhea were the sulfonamides, which were introduced in the 1930s. Within a decade, antibiotic resistance emerged, resulting in treatment failures in one-third of patients. Penicillin was then employed as the drug of choice for the treatment of gonorrhea. By 1965, 42% of gonococcal isolates had developed low-level resistance to penicillin G. To prevent

treatment failures, the Centers for Disease Control and Prevention (CDC) at that time recommended doubling the dose of penicillin for the treatment of gonorrhea. Resistance due to the production of penicillinase arose later.

Gonococci become fully resistant to antibiotics either by chromosomal mutations or by acquisition of R factors (plasmids). Two types of chromosomal mutations have been described. The first type, which is drug specific, is a single-step mutation leading to high-level resistance. The second type involves mutations at several chromosomal loci that combine to determine the level as well as the pattern of resistance. Strains with mutations in chromosomal genes were first observed in the late 1950s. As recently as 1997, strains with chromosomal resistance (CMRNG) accounted for resistance to penicillin, tetracycline, or both in ~20% of strains surveyed in the United States.

b-Lactamase (penicillinase)-producing strains of *N. gonorrhoeae* (PPNG) carrying plasmids with the Pc_rdeterminant were seen almost simultaneously in the United States, England, western Africa, and the Philippines in the late 1970s. PPNG strains have since spread worldwide and by the early 1980s accounted for>50% of all gonococcal isolates in some parts of the developing world. The average prevalence of PPNG in the United States dropped by two-thirds after most penicillin use was discontinued and is now on the order of 4%, with higher rates reported from certain areas. *N. gonorrhoeae* strains with plasmid-borne tetracycline resistance (TRNG) can mobilize some b-lactamase plasmids, and PPNG and TRNG occur together, sometimes along with CMRNG. Penicillin, ampicillin, and tetracycline are no longer reliable agents for the treatment of gonorrhea and should not be used. Third-generation cephalosporins have remained highly effective as single-dose therapy for gonorrhea. Even though the minimal inhibitory concentrations (MICs) of ceftriaxone for certain strains may reach 0.015 to 0.125 mg/L [higher than MICs for fully susceptible strains (0.0001 to 0.008 mg/L)], these levels are greatly exceeded in blood, the urethra, and the cervix when the routinely recommended ceftriaxone and cefixime regimens are administered (see below). These regimens almost always result in an effective cure.

Quinolone-containing regimens are also recommended for treatment of gonococcal infections; the fluoroquinolones offer the advantage of antichlamydial activity when administered for 7 days. Serum concentrations following therapeutic dosages of the quinolones exceed theMIC for *N. gonorrhoeae* by ~100-fold. However, quinolone-resistant *N. gonorrhoeae* (QRNG) appeared soon after these agents were first used to treat gonorrhea, particularly in Southeast Asia. QRNG strains have been reported recently in the United States, mostly in the far western states. Alterations in DNA gyrase and topoisomerase IV have been implicated as mechanisms of fluoroquinolone resistance.

Resistance to spectinomycin, which is used as an alternative agent, has been reported, but resistance to this agent is usually not associated with resistance to other antibiotics. Therefore, spectinomycin can be reserved for use against multiresistant strains of *N. gonorrhoeae*. Nevertheless, outbreaks caused by strains resistant to spectinomycin have been documented in Korea and England when the drug was used as a primary agent to treat gonorrhea.

Although clinical isolates of *N. gonorrhoeae* vary in their antimicrobial susceptibility

patterns in different parts of the world, they remain susceptible to a wide variety of agents. Because failure of treatment can lead to continued transmission and the emergence of antibiotic resistance, the importance of adequate treatment with a regimen that the patient will adhere to cannot be overemphasized. Thus highly effective single-dose regimens have been developed for the treatment of uncomplicated gonococcal infections. The 1998CDCtreatment guidelines for gonococcal infections are summarized inTable 147-1; the recommendations for uncomplicated gonorrhea apply to HIV-infected as well as HIV-uninfected patients. The third-generation cephalosporins cefixime and ceftriaxone are the mainstay of therapy for uncomplicated gonococcal infection of the urethra, cervix, rectum, or pharynx. Single doses of ciprofloxacin or ofloxacin are also effective first-line regimens. Because of resistance to fluoroquinolones in several parts of Southeast Asia, these agents can no longer be considered effective in that region. Because co-infection with *C. trachomatis* occurs frequently, initial treatment regimens must incorporate an agent (e.g., azithromycin or doxycycline) effective against chlamydial infection. Pregnant women with gonorrhea should receive concurrent treatment with a macrolide antibiotic for possible *Chlamydia* infection; doxycycline should not be used during pregnancy. A single 1-g dose of azithromycin, which is effective therapy for uncomplicated chlamydial infections, results in an unacceptably low cure rate (93%) for gonococcal infections and should not be used alone. Uncomplicated gonococcal infections in penicillin-allergic persons who cannot tolerate quinolones may be treated with a single dose of spectinomycin. Persons with uncomplicated infections who receive a recommended regimen need not return for a test of cure. Cultures for *N. gonorrhoeae* should be performed if symptoms persist after therapy with an established regimen, and any gonococci isolated should be tested for antimicrobial susceptibility.

Symptomatic gonococcal pharyngitis is more difficult to eradicate than genital infection. Few regimens result in cure rates of >90%. Persons who cannot tolerate cephalosporins or quinolones can be treated with spectinomycin, but this agent results in a cure rate of £52%. Therefore, persons given spectinomycin should have a pharyngeal culture performed 3 to 5 days after treatment as a test of cure.

Treatments for gonococcal epididymitis and PID are discussed in Chaps. 132 and133, respectively. Ocular gonococcal infections in older children and adults should be managed with a single dose of ceftriaxone combined with saline irrigation of the conjunctivae (both undertaken expeditiously), and patients should undergo a careful ophthalmologic evaluation that includes a slit-lamp examination.

DGImay require higher dosages and longer durations of therapy (Table 147-1). Hospitalization is indicated if the diagnosis is uncertain, if the patient has localized joint disease that requires aspiration, or if the patient cannot be relied on to comply with treatment. Open drainage is necessary only occasionally, e.g., for management of hip infections that may be difficult to drain percutaneously. Nonsteroidal anti-inflammatory agents may be indicated to alleviate pain and hasten improvement of affected joints. Gonococcal meningitis and endocarditis should be treated in the hospital with high-dose intravenous ceftriaxone (1 to 2 g every 12 h); therapy should continue for 10 to 14 days for meningitis and for at least 4 weeks for endocarditis. All persons who experience more than one episode of DGI should be evaluated for complement deficiency.

PREVENTION AND CONTROL

Condoms, if properly used, provide effective protection against the transmission and acquisition of gonorrhea as well as other infections that are transmitted to and from genital mucosal surfaces. Spermicidal preparations used with a diaphragm or cervical sponges impregnated with nonoxynol 9 offer some protection against gonorrhea and chlamydial infection. However, the frequent use of preparations that contain nonoxynol 9 is associated with mucosal disruption that paradoxically may enhance the risk of HIV infection in the event of exposure. All patients should be instructed to refer sex partners for evaluation and treatment. All sex partners of persons with gonorrhea should be evaluated and treated for *N. gonorrhoeae* and *C. trachomatis* infections if their last contact with the patient took place within 60 days before the onset of symptoms or the diagnosis of infection in the patient. If the patient's last sexual encounter was >60 days before onset of symptoms or diagnosis, the patient's most recent sex partner should be treated. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms. Greater emphasis must be placed on prevention by public health education, individual patient counseling, and behavior modification. Preventing the spread of gonorrhea may help reduce the transmission of HIV. No effective vaccine for gonorrhea is yet available, but efforts to test a porin vaccine candidate are under way.

ACKNOWLEDGEMENT

The authors acknowledge the contributions of Dr. King K. Holmes and Dr. Stephen A. Morse to the chapter on this subject in the earlier editions.

148. *MORAXELLA CATARRHALIS* AND OTHER *MORAXELLA* SPECIES - *Daniel M. Musher*

MORAXELLA CATARRHALIS

The gram-negative coccus now known as *Moraxella catarrhalis* has undergone three changes of name in as many decades. Originally called *Micrococcus catarrhalis*, it was renamed *Neisseria catarrhalis* in the 1960s because of its morphologic similarity to *Neisseria* spp. Then, in 1970, it was elevated to the status of a distinct genus, *Branhamella*, on the basis of DNA homology. In 1979 this organism was placed into the genus *Moraxella*, of which *Branhamella* may be a subgenus. A component of the normal bacterial flora of the upper airways, *M. catarrhalis* has been increasingly recognized as a cause of otitis media, sinusitis, and bronchopulmonary infection.

BACTERIOLOGY AND IMMUNITY

On Gram's staining, *M. catarrhalis* organisms appear as gram-negative cocci, sometimes occurring in pairs and retaining the side-by-side kidney-bean configuration of *Neisseria* (Plate VI-1). These cocci tend to retain crystal violet during the decolorizing step and may be confused with *Staphylococcus aureus*. *Moraxella* colonies grow well on blood or chocolate agar but may be overlooked because of their resemblance to *Neisseria* spp. (a major component of the normal pharyngeal flora). *Moraxella* is readily distinguishable from *Neisseria* spp. by biochemical tests.

Strains of *M. catarrhalis* show a surprising degree of homogeneity in terms of their outer-membrane proteins. Antibody to some of these proteins is generally present in serum of children over the age of 4 years; however, colonizing or disease-causing isolates may survive in serum despite this naturally present antibody and complement. Bactericidal antibody emerges following natural infection and may be directed against one or more conserved outer-membrane proteins -- a property of potential value in vaccine development. The presence of certain outer-membrane proteins is associated with virulence in mice, and antibody may be protective. These proteins are under investigation for use as vaccines.

EPIDEMIOLOGY

With repeated cultures and the use of selective media, *M. catarrhalis* can be isolated from the upper respiratory tract or saliva of 50% of healthy schoolchildren and of up to 7% of healthy adults. When conventional microbiologic techniques are used, *Moraxella* can be isolated from sputum of about 10% of persons who have chronic bronchitis and 25% of those who have bronchiectasis in the absence of acute infection. Investigators in both the northern and southern hemispheres have reported a striking seasonal variation in the isolation of this organism from clinical specimens, with a peak in late winter/early spring and a nadir in late summer/early fall. Direct contact has not been shown to contribute to community-acquired infection, but nosocomial spread of infection has been documented occasionally.

OTITIS MEDIA AND SINUSITIS

M. catarrhalis has repeatedly been shown to be the third most common bacterial isolate from middle-ear fluid of children who have otitis media, being surpassed only by *Streptococcus pneumoniae* and nontypable *Haemophilus influenzae*. Recent studies have shown that this organism is also a prominent isolate from sinus cavities in acute and chronic sinusitis.

PURULENT TRACHEOBRONCHITIS AND PNEUMONIA

M. catarrhalis causes acute exacerbations of chronic bronchitis (increased production and/or purulence of sputum), purulent tracheobronchitis (the latter also involving fever and leukocytosis), and pneumonia. The great majority of infected persons are>50 years old and have a long history of cigarette smoking and underlying chronic obstructive pulmonary disease (COPD); many have lung cancer as well. In one study, 76% of affected persons had COPD (severe in many cases), and one-third of those with COPD had lung cancer; most patients also had clinical evidence of malnutrition. In one extensive series of cases, *M. catarrhalis* pneumonia did not occur in otherwise-healthy hosts.

Symptoms of *M. catarrhalis* infection have been regarded as modest in severity. Both cough and the amount and purulence of sputum are usually increased above baseline. Chills are reported in one-quarter of patients, pleuritic pain in one-third, and malaise in 40%. Most patients have peak temperatures of<38.3°C (<101°F), and peripheral white blood cell counts are <10,000/uL in nearly one-quarter of cases. Microscopic examination of a good sputum specimen following Gram's staining regularly reveals profuse organisms, and quantitative culture yields ~ 2 ´ 10^8 colony-forming units per milliliter (Plate VI-1). The radiologic appearance is variable; in one study, 43% of subjects had segmental or lobar infiltrates, and the remainder had a mixed pattern of subsegmental, segmental, interstitial, and diffuse involvement. These clinical, laboratory, and radiographic findings do not differ from those of pneumococcal or *Haemophilus* pneumonia in an older patient population. However, a far lesser degree of bloodstream invasion occurs in *M. catarrhalis* infection; in one series, none of 25 patients with *M. catarrhalis* pneumonia had bacteremia. Nevertheless, pneumonia due to *M. catarrhalis* is a marker for severe underlying disease: nearly half of patients die within 3 months of onset.

OTHER SYNDROMES

Local extension causing empyema is very uncommon, and, as might be inferred from the low rate of bacteremia, metastatic complications of *M. catarrhalis* pneumonia, such as septic arthritis, are exceedingly rare. As of 1995, 58 cases of bacteremic infection due to *M. catarrhalis* had been reported, mainly in children<10 years old or adults>60 years old; most of these patients were immunocompromised. The syndromes reported have included bacteremia with no apparent focus, pneumonia, endocarditis, and meningitis. A petechial or purpuric rash, reminiscent of that observed in meningococcal sepsis and associated with disseminated intravascular coagulation, has been described in a few cases.

TREATMENT

Treatment of *M. catarrhalis* infection with a penicillin/clavulanic acid combination seems highly appropriate. Penicillin resistance first appeared in *Branhamella* isolates in the mid-1970s and is now found in 85% of clinical isolates. Resistance is mediated by two closely relatedb-lactamases, BRO-1 and BRO-2, which are present in 90% and 10% of resistant isolates, respectively. These enzymes are active against penicillin, ampicillin, and amoxicillin but less so against cephalosporins, especially third-generation cephalosporins, and they bind avidly to clavulanic acid and sulbactam.

Cephalosporins, especially those of the second and third generations, are effective alternatives. Isolates in the United States are also nearly uniformly susceptible to tetracycline, erythromycin, trimethoprim-sulfamethoxazole, quinolones, and chloramphenicol, although tetracycline resistance -- perhaps due to TetB determinants -- is increasing in Europe and Asia and has been documented in the United States. A 5-day course of therapy has been shown to cure respiratory infection, although a slightly longer course may be required in sinusitis.

During the period between the identification of gram-negative cocci in a Gram-stained specimen and the final identification of the organisms by culture, the severity of the condition and the potential presence of other infecting organisms should guide antibiotic selection. For example, an exacerbation of bronchitis caused by *M. catarrhalis* might be treated with tetracycline or trimethoprim-sulfamethoxazole; however, in a patient with pneumonia, the possibility that pneumococci resistant to these agents also might be present dictates the choice of ampicillin/sulbactam or a third-generation cephalosporin, at least until culture results become available.

OTHER *MORAXELLA* SPECIES

Other *Moraxella* species cause a wide range of infections, including bronchitis, pneumonia, empyema, endocarditis, meningitis, conjunctivitis, urinary tract infection, septic arthritis, and wound infection. In a report on all *Moraxella* isolates submitted to the Centers for Disease Control and Prevention between 1953 and 1980, certain clinical associations were apparent (Table 148-1). *M. osloensis* and *M. nonliquefaciens*, the most commonly isolated species, were cultured from a wide range of normally sterile body sites, including blood, cerebrospinal fluid, and joints. *M. osloensis* was the *Moraxella* species most frequently isolated from blood; *M. nonliquefaciens* tended to be isolated from the ears, nose, or throat (47%) or the sputum (8%) and has since been implicated as a cause of conjunctivitis and keratitis. *M. urethralis* was isolated most often from urine and the genital tract and probably represents the *Moraxella* species implicated previously in urethritis. More than half of isolates of *M. phenylpyruvica* and *M. atlantae* were obtained from normally sterile sites. A recent study found *Moraxella* spp., including *M. catarrhalis*, in 35% of infected wounds following cat bites and in 10% of those following dog bites. The clinical features of infections due to *Moraxella* spp. other than *M. catarrhalis* and the nature of the hosts in which they occur have not been fully characterized.

149. *HAEMOPHILUS* INFECTIONS - *Timothy F. Murphy*

HAEMOPHILUS INFLUENZAE

MICROBIOLOGY

Haemophilus influenzae was first recognized in 1892 by Pfeiffer, who erroneously concluded that the bacterium was the cause of influenza. The bacterium is a small (1- by 0.3-um) gram-negative organism of variable shape; hence, it is often described as a pleomorphic coccobacillus. In clinical specimens such as cerebrospinal fluid (CSF) and sputum, it frequently stains only faintly with phenosafranin and therefore can easily be overlooked.

H. influenzae grows both aerobically and anaerobically. Its aerobic growth requires two factors: hemin (X factor) and nicotinamide adenine dinucleotide (V factor). These requirements are used in the clinical laboratory to identify the bacterium. Six major serotypes of *H. influenzae* have been identified; designated *a* through *f*, they are based on antigenically distinct polysaccharide capsules. In addition, some strains lack a polysaccharide capsule and are referred to as *nontypable* strains. Type b and nontypable strains are the most relevant strains clinically, although encapsulated strains other than type b can cause disease. *H. influenzae* was the first free-living organism to have its entire genome sequenced.

The antigenically distinct type b capsule is a linear polymer composed of ribosyl-ribitol phosphate. Strains of *H. influenzae* type b (Hib) cause disease primarily in infants and children under the age of 6 years. Nontypable strains are primarily mucosal pathogens, although the incidence of invasive disease caused by these strains is increasing.

EPIDEMIOLOGY AND TRANSMISSION

H. influenzae is an exclusively human pathogen. The organism is spread by airborne droplets or by direct contact with secretions or fomites. Nontypable strains colonize the upper respiratory tract of up to three-fourths of healthy adults. Colonization with nontypable *H. influenzae* is a dynamic process; new strains are acquired and other strains are replaced periodically.

Hibstrains colonize the nasopharynx of children at a rate of 3 to 5%; before the introduction of type b vaccine, higher rates were seen in day-care centers. The widespread use of conjugate vaccines has resulted in a striking decrease not only in the rate of nasopharyngeal colonization by Hib but also in the incidence of meningitis due to Hib. Studies in selected populations suggest the reemergence of invasive Hib infections and higher than expected rates of nasopharyngeal colonization by Hib in vaccinated children. Continued surveillance of Hib disease and colonization rates will be important in evaluating the success of current vaccination strategies.

Certain population groups have a higher incidence of invasiveHibdisease than the general population. The incidence of meningitis due to Hib has been three to four times higher among black children than among white children in several studies. In some Native American groups, the incidence of invasive Hib disease is 10 times higher than

that in the general population. Although this increased incidence has not yet been accounted for, several factors may be relevant, including age at exposure to the bacterium, socioeconomic conditions, and genetic differences in the ability to mount an immune response.

PATHOGENESIS

Hibstrains cause systemic disease by invasion and hematogenous spread to distant sites such as the meninges, bones, and joints. The type b polysaccharide capsule is an important virulence factor affecting the bacterium's ability to avoid opsonization and cause systemic disease.

Nontypable strains cause disease by local invasion of mucosal surfaces. Otitis media results when bacteria reach the middle ear by way of the eustachian tube. Adults with chronic bronchitis experience recurrent lower respiratory tract infection due to nontypable strains. The incidence of invasive disease caused by nontypable strains is low but increasing.

IMMUNE RESPONSE

Antibody to capsule is important in protection from infection byHibstrains. The level of (maternally acquired) serum antibody to the capsular polysaccharide, which is a polymer of polyribitol ribose phosphate (PRP), declines from birth to 6 months of age and, in the absence of vaccination, remains low until around 2 or 3 years of age. The age at the antibody nadir correlates with that of the peak incidence of type b disease. Antibody to PRP then appears partly as a result of exposure to Hib or cross-reacting antigens. Systemic Hib disease is unusual after the age of 6 years because of the presence of protective antibody. Vaccines in which PRP is conjugated to protein carrier molecules have been developed and are now used widely. These vaccines generate an antibody response to PRP in infants and are effective in preventing invasive infections in infants and children.

Since nontypable strains lack a capsule, the immune response to infection is directed at noncapsular antigens. These noncapsular antigens of *H. influenzae* have generated considerable interest as targets of the human immune response and as potential vaccine components.

CLINICAL MANIFESTATIONS

Hib The most serious manifestation of infection withHib is meningitis. The age of peak incidence varies somewhat among populations, depending in part on the use of vaccine, but this infection primarily affects infants under 2 years of age. The clinical manifestations of meningitis caused by Hib are similar to those of meningitis caused by other bacterial pathogens. Fever and altered central nervous system function are the most common features at presentation. Nuchal rigidity may or may not be evident. Subdural effusion, the most common complication, is suspected when, despite 2 or 3 days of appropriate antibiotic therapy, the infant has seizures, hemiparesis, or continued obtundation. The overall mortality from meningitis caused by Hib is approximately 5%, and the rate of morbidity is high. Of survivors, 6% have permanent sensorineural

hearing loss, and about one-fourth have a significant handicap of some type. If more subtle handicaps are sought, up to half of survivors are found to have some neurologic sequelae, such as partial hearing loss and delay in language development.

Epiglottitis is a life-threatening infection involving cellulitis of the epiglottis and supraglottic tissues. It can lead to acute upper airway obstruction. Its unique epidemiologic features are its occurrence in an older age group (2 to 7 years old) than otherHibinfections and its absence among Navajo Indians and Alaskan Eskimos. Sore throat and fever rapidly progress to dysphagia, drooling, and airway obstruction.

Cellulitis due toHiboccurs in young children. The most common location is on the head or neck, and the involved area sometimes takes on a characteristic bluish-red color. Most patients have bacteremia, and 10% have an additional focus of infection.

Hibcauses *pneumonia* in infants. The infection is clinically indistinguishable from other types of bacterial pneumonia (e.g., pneumococcal pneumonia) except that Hib is more likely to involve the pleura.

Several less common invasive conditions can be important clinical manifestations ofHibinfection in children. These include osteomyelitis, septic arthritis, pericarditis, orbital cellulitis, endophthalmitis, urinary tract infection, abscesses, and bacteremia without an identifiable focus. As has already been mentioned, infections due to Hib are unusual among patients older than 6 years.

Nontypable *H. influenzae* Nontypable *H. influenzae* is the second most common cause (after *Streptococcus pneumoniae*) of community-acquired bacterial pneumonia in adults. Nontypable *H. influenzae* pneumonia is especially common among patients with chronic obstructive pulmonary disease (COPD) or AIDS. The clinical features of pneumonia due to *H. influenzae* are similar to those of other types of bacterial pneumonia (including pneumococcal pneumonia). Patients present with fever, cough, and purulent sputum, usually of several days' duration. Chest radiography reveals alveolar infiltrates in a patchy or lobar distribution. Gram-stained sputum contains a predominance of small, pleomorphic, coccobacillary gram-negative bacteria.

Exacerbations ofCOPDcaused by nontypable *H. influenzae* are characterized by increased cough, sputum production, and shortness of breath. Fever is low-grade, and no infiltrates are evident on chest x-ray.

Nontypable *H. influenzae* is one of the three most common causes of childhood otitis media (the other two being *S. pneumoniae* and *Moraxella catarrhalis*). Infants are febrile and irritable, while older children report ear pain. Symptoms of viral upper respiratory infection often precede otitis media. The diagnosis is made by pneumatic otoscopy. An etiologic diagnosis, although not routinely sought, can be established by tympanocentesis and culture of middle-ear fluid.

Nontypable *H. influenzae* also causes puerperal sepsis and is an important cause of neonatal bacteremia. These nontypable strains tend to be of biotype IV and cause invasive disease after colonizing the female genital tract.

Nontypable *H. influenzae* causes sinusitis in adults and children. In addition, the bacterium is a less common cause of various invasive infections that are reported primarily as small-series descriptions and case reports. These infections include empyema, adult epiglottitis, pericarditis, cellulitis, septic arthritis, osteomyelitis, endocarditis, cholecystitis, intraabdominal infections, urinary tract infections, mastoiditis, aortic graft infection, and bacteremia without a detectable focus.

DIAGNOSIS

The most reliable method for establishing a diagnosis ofHibinfection is recovery of the organism in culture. TheCSF of a patient in whom meningitis is suspected should be subjected to Gram's staining and culture. The presence of gram-negative coccobacilli in Gram-stained CSF is strong evidence for Hib meningitis. Recovery of the organism from CSF confirms the diagnosis. Cultures of other normally sterile body fluids, such as blood, joint fluid, pleural fluid, pericardial fluid, and subdural effusion, are confirmatory in other infections.

Detection ofPRP is an important adjunct to culture in rapid diagnosis. Immunoelectrophoresis, latex agglutination, coagglutination, and enzyme-linked immunosorbent assay are effective in detecting PRP. These assays are particularly helpful when patients have received prior antimicrobial therapy and thus are especially likely to have negative cultures.

Before the early 1980s, nontypable strains of *H. influenzae* were frequently misidentified asHibbecause of their autoagglutination when serotypes were determined in agglutination assays. Since nontypable *H. influenzae* is primarily a mucosal pathogen, it is a component of a mixed flora; this situation makes etiologic diagnosis challenging. Nontypable *H. influenzae* infection is strongly suggested by the predominance of gram-negative coccobacilli among abundant polymorphonuclear leukocytes in a Gram-stained sputum specimen from a patient in whom pneumonia or tracheobronchitis is suspected. A sputum culture is helpful when interpreted along with the results of Gram's staining. Although bacteremia is detectable in a small proportion of patients with pneumonia due to nontypable *H. influenzae*, most such patients have negative blood cultures.

A diagnosis of otitis media is based on the detection by pneumatic otoscopy of fluid in the middle ear. An etiologic diagnosis requires tympanocentesis but is not routinely sought. An invasive procedure is also required to determine the etiology of sinusitis; thus, treatment is often empirical once the diagnosis is suspected in light of clinical symptoms and sinus radiographs.

TREATMENT

Initial therapy for meningitis due toHibshould consist of a cephalosporin such as ceftriaxone or cefotaxime. For children, the dose of ceftriaxone is 75 to 100 mg/kg daily given in two doses 12 h apart. The pediatric dose of cefotaxime is 200 mg/kg daily given in four doses 6 h apart. Adult doses are 2 g every 12 h for ceftriaxone and 2 g every 4 to 6 h for cefotaxime. An alternative regimen for initial therapy is ampicillin (200 to 300 mg/kg daily in four divided doses) plus chloramphenicol (75 to 100 mg/kg daily in four

divided doses). Therapy should continue for a total of 1 to 2 weeks.

Administration of glucocorticoids to patients withHibmeningitis reduces the incidence of neurologic sequelae. The presumed mechanism is reduction of the inflammation induced by bacterial cell-wall mediators of inflammation when cells are killed by antimicrobial agents. Dexamethasone (0.6 mg/kg per day intravenously in four divided doses for 2 days) is recommended for the treatment of Hib meningitis in children over 2 months of age.

Invasive infections other than meningitis are treated with the same antimicrobial agents. For epiglottitis, the dose of ceftriaxone is 50 mg/kg daily, and the dose of cefotaxime is 150 mg/kg daily, given in three divided doses 8 h apart. Epiglottitis constitutes a medical emergency, and maintenance of an airway is critical. The duration of therapy is determined by the clinical response. A course of 1 to 2 weeks is usually appropriate.

Many infections caused by nontypable strains of *H. influenzae*, such as otitis media, sinusitis, and exacerbations ofCOPD, can be treated with oral antimicrobial agents. Approximately 25% of nontypable strains produce b-lactamase and are resistant to ampicillin. Infections caused by ampicillin-resistant strains can be treated with a variety of agents, including trimethoprim-sulfamethoxazole, amoxicillin/clavulanic acid, various extended-spectrum cephalosporins, and newer macrolides (azithromycin and clarithromycin). Fluoroquinolones are highly active against *H. influenzae* but are not currently recommended for the treatment of children or pregnant women because of possible effects on articular cartilage.

PREVENTION

Vaccination The development of conjugate vaccines that prevent invasive infections withHib in infants and children has been a dramatic success. Four such vaccines are licensed in the United States. In addition to eliciting protective antibody, these vaccines prevent disease by reducing pharyngeal colonization with Hib.

All children should be immunized with anHibconjugate vaccine, receiving the first dose at approximately 2 months of age, the rest of the primary series between 2 and 6 months of age, and a booster dose at 12 to 15 months of age. Specific recommendations vary for the different conjugate vaccines. The reader is referred to the recommendations of the American Academy of Pediatrics. Currently, no vaccines are available for the prevention of disease caused by nontypable *H. influenzae*.

Chemoprophylaxis The risk of secondary disease is greater than normal among household contacts of patients withHibdisease. The attack rate is as high as 4% among susceptible infants. Therefore, all children and adults in households where there are contacts<4 years old should receive prophylaxis with oral rifampin. (This rule does not apply when all household contacts under the age of 4 years have been completely immunized with conjugate vaccine.) Children<12 years old should receive rifampin at a dose of 20 mg/kg once daily for 4 days, and adults should receive 600 mg daily for 4 days. The index case should receive rifampin before or at the time of discharge from the hospital because antimicrobial agents used for the treatment of meningitis do not reliably eradicate Hib from the nasopharynx.

When two or more cases of invasiveHibdisease have occurred within 60 days at a child-care facility attended by incompletely vaccinated children, administration of rifampin to all attendees and personnel is indicated, as is recommended for household contacts. The data on secondary cases among contacts in child-care facilities following a single case are less clear. The administration of rifampin prophylaxis to contacts should be considered, but each decision should be individualized and in part based on the contacts' immunization history, the size of the center, and the extent of contact.

HAEMOPHILUS INFLUENZAE BIOGROUP AEGYPTIUS

H. influenzae biogroup aegyptius was formerly called *Haemophilus aegyptius* because of phenotypic characteristics distinct from those of *H. influenzae*. However, later studies involving DNA hybridization and DNA transformation demonstrated that *H. aegyptius* and *H. influenzae* are members of the same species.

H. influenzae biogroup aegyptius has long been associated with conjunctivitis. Moreover, this strain is now known to be the cause of Brazilian purpuric fever (BPF), which was first recognized in 1984 in the rural Brazilian town of Promissao. The sharing of many phenotypic and genotypic characteristics by the various strains of *H. influenzae* biogroup aegyptius that cause BPF indicates that these strains represent a clone of *H. influenzae*. The age of peak incidence of BPF is 1 to 4 years, with a range of 3 months to 8 years. The illness can occur sporadically or in outbreaks. Typically, after an episode of purulent conjunctivitis, high fever occurs in association with vomiting and abdominal pain. Within 12 to 48 h after onset, the patient develops petechiae, purpura, and peripheral necrosis and experiences vascular collapse. The characteristic laboratory features are thrombocytopenia, prolonged prothrombin time, uniformly unrevealingCSFfindings, and blood cultures positive for *H. influenzae* biogroup aegyptius. Initial reports cited high mortality (70%), but subsequent studies have indicated that milder forms of the illness exist. Most patients have resolved or resolving purulent conjunctivitis, and culture of the conjunctiva is positive in approximately one-third of cases. BPF has been seen in several towns in Brazil and on two occasions in Australia.

HAEMOPHILUS DUCREYI

Haemophilus ducreyi is the etiologic agent of chancroid, a sexually transmitted disease characterized by genital ulceration and inguinal adenitis. *H. ducreyi* poses a significant health problem in developing countries. Although this infection is less common in the United States, its incidence has increased dramatically in the past several years. In addition to being a cause of morbidity in itself, chancroid is associated with infection with HIV because of the role of genital ulceration in the transmission of HIV.

MICROBIOLOGY

H. ducreyi is a highly fastidious coccobacillary gram-negative bacterium whose growth requires X factor (hemin). Although, in light of this requirement, the bacterium has been classified in the genus *Haemophilus*, DNA homology and chemotaxonomic studies have established substantial differences between *H. ducreyi* and other *Haemophilus* species.

Taxonomic reclassification of the organism is likely in the future but awaits further study.

The histology of the genital ulcer of chancroid is characterized by perivascular and interstitial infiltrates of macrophages and of CD4+ and CD8+ lymphocytes. The appearance is consistent with a delayed-type hypersensitivity, cell-mediated immune response. The presence of CD4+ cells and macrophages in the ulcer may explain, in part, the facilitation of transmission of HIV in patients with chancroid.

EPIDEMIOLOGY AND PREVALENCE (See also Chap. 132)

Chancroid is a common cause of genital ulcers in developing countries. In the United States, chancroid is now endemic in some regions, and several large outbreaks have occurred since 1981. Recurring epidemiologic themes have been apparent in these outbreaks: (1) transmission has been predominantly heterosexual; (2) males have outnumbered females by ratios of 3:1 to 25:1; (3) prostitutes have been important in transmission of the infection; and (4) chancroid has been strongly associated with illicit drug use. The incidence of chancroid in the United States will undoubtedly increase in the coming years, and the genital ulcers associated with this infection will continue to play a role in the transmission of HIV.

CLINICAL MANIFESTATIONS

Infection is acquired as the result of a break in the epithelium during sexual contact with an infected individual. After an incubation period of 4 to 7 days, the initial lesion -- a papule with surrounding erythema -- appears (Plate IID-54). In 2 to 3 days, the papule evolves into a pustule, which spontaneously ruptures and forms a sharply circumscribed ulcer (Fig. 132-CD1) that is generally not indurated. The ulcers are painful and bleed easily; little or no inflammation of the surrounding skin is evident. Approximately half of patients develop enlarged, tender inguinal lymph nodes, which frequently become fluctuant and spontaneously rupture.

The presentation of chancroid does not usually include all of the typical clinical features and is sometimes atypical. Multiple ulcers can coalesce to form giant ulcers. Ulcers can appear and then resolve, with inguinal adenitis and suppuration following 1 to 3 weeks later; this clinical picture can be confused with that of lymphogranuloma venereum. Multiple small ulcers can resemble folliculitis. Other differential diagnostic considerations include the various infections causing genital ulceration, such as primary syphilis, condyloma latum of secondary syphilis, genital herpes, and donovanosis. In rare cases chancroid lesions become secondarily infected with bacteria; the result is extensive inflammation.

DIAGNOSIS

Clinical diagnosis of chancroid is often inaccurate, and laboratory confirmation should be attempted in suspected cases. Gram's staining of a swab of the lesion may reveal a predominance of characteristic gram-negative coccobacilli, but the presence of other bacteria often makes it difficult to interpret this result. An accurate diagnosis of chancroid relies on cultures of *H. ducreyi* from the lesion. In addition, aspiration and culture of suppurative lymph nodes should be considered. Since the organism can be

difficult to grow, the use of selective and supplemented media is necessary.

TREATMENT

Clinical isolates of *H. ducreyi* often exhibit plasmid-mediated resistance to ampicillin, chloramphenicol, tetracyclines, and sulfonamides. Nevertheless, chancroid can be treated effectively with several regimens, including (1) ceftriaxone, 250 mg intramuscularly as a single dose; (2) azithromycin, 1 g orally as a single dose; (3) erythromycin, 500 mg orally four times daily for 7 days; and (4) ciprofloxacin, 500 mg orally twice daily for 3 days. Ciprofloxacin should not be administered to pregnant or lactating women or to persons<18 years old. Any therapeutic regimen may fail; single-dose ceftriaxone has a high failure rate in HIV-positive individuals. Isolates from patients who do not respond promptly to treatment should be tested for antimicrobial susceptibility. In patients with HIV infection, healing may be slow and longer courses of treatment may be necessary. Contacts of patients with chancroid should be identified and treated whenever possible.

OTHER *HAEMOPHILUS* SPECIES

Haemophilus species are often recovered as components of the flora of the normal human upper respiratory tract. However, these bacteria are infrequent causes of infection because of their low pathogenic potential. *Haemophilus* species have fastidious growth requirements and are generally rather slow-growing. The species implicated in human infections include *H. parainfluenzae*, *H. aphrophilus*, and *H. paraphrophilus* (Chap. 150); *H. parahaemolyticus*; *H. haemolyticus*; and *H. segnis*. *Haemophilus* species are differentiated from one another by several characteristics, primarily their requirements for X and V factors. Species designated *para*- require V factor but not X factor for growth, whereas the others require either X and V or X only.

A variety of infections involving almost all organ systems can be caused by *Haemophilus* species. Most of these unusual manifestations have been reported as single cases and small series.

The antimicrobial susceptibility characteristics of other *Haemophilus* species are similar to those of *H. influenzae*. Some strains produce b-lactamase and are thereby resistant to ampicillin. Other strains are sensitive to ampicillin, and this agent has been used successfully to treat many infections. Alternative agents with good activity against most *Haemophilus* species include trimethoprim-sulfamethoxazole, third-generation cephalosporins, tetracycline, chloramphenicol, and aminoglycosides. Endocarditis caused by ampicillin-sensitive strains should be treated with ampicillin plus an aminoglycoside.

(Bibliography omitted in Palm version)

150. INFECTIONS DUE TO THE HACEK GROUP AND MISCELLANEOUS GRAM-NEGATIVE BACTERIA - *Dennis L. Kasper*, *Tamar F. Barlam*

HACEK GROUP ORGANISMS

HACEK organisms are a group of fastidious, slow-growing, gram-negative bacteria whose growth requires an atmosphere of carbon dioxide. Species belonging to this group include several ***H***aemophilus species, ***A***ctinobacillus *actinomycetemcomitans*, ***C***ardiobacterium *hominis*, ***E***ikenella *corrodens*, and ***K***ingella *kingae*. HACEK bacteria normally reside in the oral cavity and have been associated with local infections in the mouth. They are also known to cause severe systemic infections, most often bacterial endocarditis (Chap. 126).

Of the HACEK group, the *Haemophilus* species, *A. actinomycetemcomitans*, and *C. hominis* are most frequently associated with endocarditis, which can develop on either native or prosthetic valves. In large series, up to 3% of cases of infective endocarditis are attributable to HACEK organisms. The clinical course of HACEK endocarditis tends to be subacute; however, embolization is common. The overall prevalence of major emboli associated with HACEK endocarditis ranges from 28 to 60% in different series. Cultures of blood from patients with suspected HACEK endocarditis may require up to 30 days to become positive, although most are positive within the first week. Because of this slow growth, antimicrobial testing may be difficult, and strains producingb-lactamase may not be identified accurately. This factor should be considered when choosing a therapeutic regimen.

The cure rates for HACEK prosthetic valve endocarditis appear to be high. Unlike prosthetic valve endocarditis caused by other gram-negative organisms, HACEK endocarditis is often cured with antibiotic treatment alone -- i.e., without surgical intervention.

***Haemophilus* Species** *Haemophilus* species cause over half of all cases of HACEK endocarditis. *H. parainfluenzae* is most common, with *H. aphrophilus* and *H. paraphrophilus* less common. Up to 50% of patients with native valve endocarditis due to *Haemophilus* species report a history of cardiac valvular disease, 60% have been ill for <2 months before presentation, and 50% are anemic at presentation. Some 19% of these patients develop congestive heart failure. Mortality rates of up to 30% have been reported, with most deaths attributed to cerebral embolism; however, recent studies have documented mortality rates of <5%. In rare cases, *H. parainfluenzae* has been isolated from other infections, such as meningitis; brain, dental, and liver abscess; pneumonia; and septicemia.

TREATMENT

Therapy for endocarditis due to *Haemophilus* species should be based on antibiotic sensitivity testing. Empirical combination therapy with ampicillin and gentamicin, successful in prior studies, is no longer recommended because of increasing b-lactamase production by these strains. Treatment with ceftriaxone (2 g/d) is a reasonable initial approach.

Actinobacillus actinomycetemcomitans *A. actinomycetemcomitans*, another slow-growing inhabitant of the oral cavity, can be isolated from soft tissue infections and abscesses in association with *Actinomyces israelii.* About 30% of actinomycotic lesions also yield *A. actinomycetemcomitans* on culture. *A. actinomycetemcomitans* has been associated with severe destructive periodontal disease, characterized by loss of alveolar bone of the molars and incisors, in both children and adults. Patients who develop endocarditis with this organism typically have severe periodontal disease and underlying cardiac valvular damage as well as high rates of embolic phenomena. *A. actinomycetemcomitans* has been isolated from patients with brain abscess, meningitis, parotitis, osteomyelitis, urinary tract infection, pneumonia, and empyema, among other infections.

TREATMENT

Most isolates are susceptible to third-generation cephalosporins such as ceftriaxone (2 g/d), semisynthetic penicillins such as mezlocillin, trimethoprim-sulfamethoxazole, quinolones, and azithromycin. However, because of the variability among strains, susceptibility testing should be undertaken. Endocarditis should normally be treated for 4 weeks; however, prosthetic valve infections or infections in patients with complications such as embolization justify 6 weeks of therapy.

Cardiobacterium hominis *C. hominis* primarily causes endocarditis in patients with underlying valvular heart disease or with prosthetic valves. Many patients have signs and symptoms of long-standing infection before diagnosis and have evidence of arterial embolization, vasculitis, cerebrovascular accidents, immune complex glomerulonephritis, or arthritis at presentation. As in endocarditis due to other HACEK organisms, embolization, mycotic aneurysms, and congestive heart failure are frequent.

TREATMENT

Antibiotic sensitivity testing of *C. hominis* is difficult. Most cases of infection due to *C. hominis* are treated with penicillin (16 to 18 million units per day in 6 divided doses), either alone or in combination with an aminoglycoside (e.g., gentamicin, 5 to 6 mg/kg per day in 3 divided doses). The value of the aminoglycoside in this situation has not been established.

Eikenella corrodens *E. corrodens*, a fastidious, facultative gram-negative organism, is part of the endogenous flora of the mouth and nasopharynx. It is most frequently recovered from sites of infection in conjunction with other bacterial species. Clinical sources of *E. corrodens* include sites of human bite wounds (clenched-fist injuries), endocarditis, soft tissue infections of the head and neck, soft tissue infections in injection drug users, osteomyelitis, respiratory infections, chorioamnionitis, gynecologic infections associated with intrauterine devices, meningitis and brain abscesses, and visceral abscesses.

TREATMENT

E. corrodens-associated infections can be treated with ampicillin (2 g every 4 h) or with second- or third-generation cephalosporins. The organism is susceptible to the

fluoroquinolones in vitro but is resistant to metronidazole and clindamycin.

Kingella kingae *K. kingae* is a b-hemolytic, fastidious, nonmotile gram-negative rod. Because of improved microbiologic methodology, isolation of this organism is increasingly common. In young children, *K. kingae* causes septic arthritis and osteomyelitis. In several series, *K. kingae* has been the third most common cause of septic arthritis in children<24 months of age; staphylococcal and streptococcal species remain most prevalent. In children <4 years of age, there is evidence for prolonged nasopharyngeal colonization, with carriage rates of 10%. Invasive *K. kingae* infections with bacteremia are associated with stomatitis. Both *K. kingae* colonization and primary herpes -- a major cause of stomatitis -- peak in children 6 to 48 months of age. *K. kingae* bacteremia can present with a petechial rash similar to that seen with *Neisseria meningitidis* sepsis.

Infective endocarditis, unlike other infections with *K. kingae*, occurs in older children and adults. The majority of patients have preexisting valvular disease. As in endocarditis caused by the other HACEK organisms, there is a high incidence of complications, including arterial emboli, cerebrovascular accidents, tricuspid insufficiency, and congestive heart failure with cardiovascular collapse.

TREATMENT

K. kingae can be susceptible to ampicillin, second- and third-generation cephalosporins, fluoroquinolones, vancomycin, clindamycin, macrolides, and trimethoprim-sulfamethoxazole. Because of increasingb-lactamase production in *K. kingae* strains, susceptibility testing should be performed to guide therapy. Ceftriaxone (2 g/d) or ampicillin-sulbactam (3 g of ampicillin every 6 h) are both appropriate choices for initial therapy.

OTHER GRAM-NEGATIVE BACTERIA

Acinetobacter **Species** See Chap. 153.

Achromobacter xylosoxidans Previously known as *Alcaligenes xylosoxidans*, the gram-negative bacillus *Achromobacter xylosoxidans* is probably part of the endogenous intestinal flora and has been isolated from water sources. Immunocompromised hosts appear to be at increased risk for infection with this organism. Nosocomial sources to which outbreaks of infection with *A. xylosoxidans* have been attributed include contaminated intravenous fluids, pressure transducers, and disinfectants. Clinical illness has been associated with isolates from many sites, including blood (often in the setting of infected intravascular devices), urine, respiratory secretions, cerebrospinal fluid, peritoneal and pleural fluids, and endocarditic prosthetic valves. Community-acquired bacteremia with *A. xylosoxidans* usually occurs in the setting of pneumonia. Metastatic skin lesions are present in one-fifth of cases. The reported mortality rate is 67%, similar to rates for other bacteremic gram-negative pneumonias.

TREATMENT

In vitro susceptibility testing of all clinically relevant isolates is essential to the selection

of appropriate therapy.

Agrobacterium radiobacter (tumefaciens) This organism has been associated with intravascular catheter-related infections in immunocompromised hosts, especially individuals infected with HIV. Clinically important infections associated with *A. radiobacter* include prosthetic joint and prosthetic valve infections, bacteremia, peritonitis, and urinary tract infections.

TREATMENT

Antibiotic sensitivity testing is essential in the choice of therapy.

***Capnocytophaga* Species** This genus of fusiform, long, thin, gram-negative coccobacilli is facultatively anaerobic and requires an atmosphere enriched in carbon dioxide for optimal growth. *C. ochracea*, *C. gingivalis*, and *C. sputigena* are inhabitants of the healthy human oral cavity and have been isolated from the female genital tract. Their isolation has also been reported from blood, cerebrospinal fluid, and respiratory fluids (including pleural collections). These organisms have been associated with sepsis in immunocompromised hosts; particularly at risk are patients with acute myelogenous leukemia or acute lymphocytic leukemia. In the immunocompetent host, these three species probably play a role in localized juvenile periodontitis; however, they have been isolated from many other sites as well, usually as part of a polymicrobial infection. In vitro sensitivity testing of these organisms is difficult because they are slow-growing and fastidious.

C. canimorsus and *C. cynodegmi* are endogenous to the canine mouth. Patients infected with these species frequently have a history of dog bites or of exposure to dogs without scratches or bites. Asplenia, glucocorticoid therapy, and alcohol abuse are predisposing conditions and are associated with relatively fulminant infections. The interval from dog bite to presentation averages 5 days but ranges from 1 day to 1 month. *C. canimorsus* causes a wide range of infections, including severe sepsis with shock and disseminated intravascular coagulation, meningitis, endocarditis, cellulitis, and septic arthritis. In the asplenic individual who has recently sustained a dog bite, infection with this organism must be considered early because of a potentially rapid progression to death.

TREATMENT

Although penicillin has been considered first-line therapy for infections due to *C. ochracea*, *C. gingivalis*, and *C. sputigena*, an increasing number of isolates reportedly produce b-lactamase. Clindamycin (600 to 900 mg every 6 to 8 h) or drug combinations including a penicillin derivative plus a b-lactamase inhibitor -- such as ampicillin/sulbactam (1.5 to 3.0 g of ampicillin every 6 h) -- are currently recommended for empirical therapy. Penicillin (12 to 18 million units daily in 6 divided doses) is the drug of choice for infections with *C. canimorsus*. This regimen should also be given prophylactically to asplenic patients sustaining dog-bite injuries. Patients with suspected infection due to *C. canimorsus* should be treated empirically, because identification of this organism and determination of its antibiotic sensitivity can take many days. Other drugs to which *C. canimorsus* is reportedly susceptible include clindamycin, imipenem,

quinolones, and third-generation cephalosporins.

Chromobacterium violaceum This organism is rarely a human pathogen but reportedly has been responsible for life-threatening infections with severe sepsis and metastatic abscesses. A slender, slightly curved, gram-negative rod that is facultatively anaerobic, *C. violaceum* inhabits tropical water and soil and causes infection after contamination of skin wounds. Patients with defective neutrophil function (e.g., those with chronic granulomatous disease) are infected by this organism with unusual frequency. The mortality rate in the United States from infection with *C. violaceum* has been reported at>60%.

TREATMENT

C. violaceum is generally susceptible to ciprofloxacin (500 mg every 12 h orally or 400 mg every 12 h intravenously), trimethoprim-sulfamethoxazole, gentamicin, and chloramphenicol.

***Chryseobacterium* Species** *C. meningosepticum* and *C. indologenes* were previously classified as *Flavobacterium* species. *C. meningosepticum* is a ubiquitous organism and an important cause of nosocomial infections. It has been associated with outbreaks due to contaminated fluids, such as disinfectants, arterial catheter flush solutions, and aerosolized antibiotics, and with sporadic infections due to indwelling devices, vials, sink traps, feeding tubes, and other fluid-associated apparatus. Patients with nosocomial *C. meningosepticum* infection usually have underlying immunosuppression (e.g., related to malignancy). *C. meningosepticum* has been reported to cause meningitis (primarily in neonates), sepsis, endocarditis, bacteremia, soft tissue infections, and pneumonia. *C. indologenes* has caused bacteremia, sepsis, and pneumonia, typically in immunocompromised patients with indwelling devices.

TREATMENT

Antibiotic treatment should be based on susceptibility results because of the high likelihood that *C. meningosepticum* will produceb-lactamase. Early reports suggested that vancomycin might be efficacious, but more recent data refute this conclusion.

Plesiomonas shigelloides This freshwater organism is a cause of acute diarrhea (Chap. 131) and occasionally of serious extraintestinal disease. *P. shigelloides* is transmitted to humans via contaminated water or food. This motile, facultatively anaerobic gram-negative rod most often produces mild diarrhea with mucoid, bloody feces containing leukocytes. Severe extraintestinal infections have been reported, most commonly in immunocompromised hosts, and include bacteremia, cellulitis, neonatal sepsis and meningitis, and septic arthritis.

TREATMENT

There is great variability among strains in terms of antibiotic sensitivity patterns, and isolates must be tested before appropriate therapy can be selected.

***Aeromonas* Species** Five species of *Aeromonas* are known to be associated with

disease in humans, but >85% of these infections are caused by *A. hydrophila*, *A. caviae*, and *A. veronii* biovar. *sobria*. *Aeromonas* proliferates in potable and fresh water and in soil. It remains controversial whether *Aeromonas* is a cause of bacterial gastroenteritis. Although many case reports have associated *Aeromonas* with gastroenteritis, no clear outbreaks with a single isolate have been documented, no conclusive animal model exists, and asymptomatic colonization of the intestinal tract with *Aeromonas* occurs frequently. However, rare cases of hemolytic-uremic syndrome occurring after bloody diarrhea have been shown to be secondary to the presence of *Aeromonas*. In addition, identification of an enterotoxin (different from the Shiga-like toxin produced by *Escherichia coli* O157:H7) in these cases supports the hypothesis that *Aeromonas* causes gastroenteritis.

Aeromonas causes sepsis and bacteremia in infants with multiple medical problems and in immunocompromised hosts, particularly those with cancer or hepatobiliary disease. *Aeromonas* infection and sepsis can occur in trauma patients with myonecrosis or in burn patients exposed to *Aeromonas* by environmental contamination of their wounds from fresh water or soil sources. Mortality ranges from 25% for sepsis in immunocompromised adults to>90% in patients with myonecrosis. *Aeromonas* can produce skin lesions resembling the ecthyma gangrenosum lesions seen in *Pseudomonas aeruginosa* infection. These lesions are hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration.

Aeromonas wound infections can occur in healthy adults who sustain minor trauma with environmental contamination, usually water-related; after severe trauma and crush injuries with sepsis and environmental exposure, usually to soil; and in nosocomial infections related to catheters, surgical incisions, or use of leeches. Other clinical manifestations include meningitis, peritonitis, pneumonia, and ocular infections.

TREATMENT

Treatment should be guided by antimicrobial susceptibility testing. *Aeromonas* species are generally susceptible to fluoroquinolones (e.g., ciprofloxacin at a dosage of 500 mg every 12 h orally or 400 mg every 12 h intravenously), trimethoprim-sulfamethoxazole at a trimethoprim dosage of 10 mg/kg per day in 3 or 4 divided doses, third-generation cephalosporins, and aminoglycosides. However, resistance is increasing.
